What Hilbert did in the case of axiomatic euclidean geometry was to construct a model of the geometrical system within the domain of arithmetic. He could then argue that, if a contradiction were deducible from the geometrical axioms, a contradiction could also be reached by purely arithmetical reasoning. It follows that, when once the consistency of arithmetic is granted, the consistency of the system of euclidean geometry is assured. Thus, although the method of models does not establish the consistency of geometry in an absolute sense, it does nevertheless furnish a proof of the consistency of geometry relative to that of arithmetic—and even this is a substantial achievement.

Hilbert obtained two main results concerning freedom from contradiction. He began by taking a certain number field Ω, consisting of all the algebraic numbers that can be obtained by 'beginning with the number 1 and applying a finite number of times the four rational operations: addition, subtraction, multiplication, division, and the fifth operation $|\sqrt{(1 + \omega^2)}|$, where ω denotes any number already obtained by means of the five operations'. By defining a point as an ordered pair (x,y) of numbers in Ω, a line as a set of ratios $u:v:w$ with not both of u and v zero, the relation of incidence by the equation $ux + vy + w = 0$, the order of points on a line in terms of the order of magnitude of their coordinates, and so forth—prompted always by the familiar usages of coordinate geometry—he was able to construct a model that satisfied all those of his axioms that apply to plane geometry, with the single exception of V, 2 (the axiom of linear completeness); and the same method could readily be extended to the axioms for three-dimensional space. And if the restricted field Ω was replaced simply by the field of all real numbers, so that the model became identical with ordinary cartesian geometry, all the axioms were then satisfied, V, 2 included. The reason why Hilbert thought it worth while to give a separate proof of the less comprehensive consistency theorem was that the 'arithmetic' to which the consistency of geometry was made relative was logically much simpler in that case, and therefore even less open to philosophical doubt than the full arithmetic of the real continuum.

Having demonstrated the consistency of his axioms, Hilbert went on to show also that these were, in all essential respects, independent. This he did, in Weyl's phrase, 'by means of quite a few peculiar geometries, constructed *ad hoc*'; for a possible way of showing that some given axiom in a set is independent of the other axioms is by constructing a model for which all the axioms are satisfied, with the single exception of this particular one. Hilbert first of all inferred the independence of the axiom of parallels by appealing to the known model of non-euclidean geometry that can be set up by taking as the 'space' of the model the interior of a sphere in cartesian space, and defining 'congruence' in it by means of the collineations of the cartesian space that transform the sphere into itself.[1]

Besides the axiom of parallels, there are two more of the twenty axioms whose independence is of especial interest, namely the last of the axioms of congruence, III, 5, and the axiom of Archimedes, V, 1; and Hilbert dealt with these in the following way. He first of all modified three-dimensional cartesian geometry by defining 'distance' by means of the formula

$$\sqrt{[(x_1 - x_2 + y_1 - y_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2]},$$

instead of by the usual formula derived from the theorem of Pythagoras. This gave him a 'geometry' which satisfies all of the axioms except III, 5. And finally, in order to demonstrate the independence of axiom V, 1, he constructed a field $\Omega(t)$ of algebraic functions of t by proceeding exactly as in the construction of the earlier field Ω of algebraic numbers, but beginning now with the real variable t instead of with the number 1. Since every element of $\Omega(t)$ has a constant sign for all sufficiently large t, an ordering relation for this field may be defined by taking '$a(t) < b(t)$' to mean '$a(t) - b(t) < 0$, in the ordinary sense, for all sufficiently large t'. But, with this definition of order, no finite multiple $n.1$ of 1 can exceed t, and the field $\Omega(t)$ is therefore non-archimedean. The 'cartesian' geometry based on this field then satisfies all the twenty axioms except V, 1.

Two further metamathematical results, established in the *Grundlagen*, that have become part of common geometrical knowledge are concerned with the theorems of Pappus (or Pascal) and Desargues. The first of these theorems asserts that, if A, B, C and A', B', C' are triads of points on two intersecting lines, then the three points $BC'.B'C$, $CA'.C'A$, $AB'.A'B$ are collinear; and the second asserts that, if ABC and $A'B'C'$ are coplanar triangles such that the lines AA', BB', CC' are concurrent, then the three points $BC.B'C'$, $CA.C'A'$, $AB.A'B'$ are collinear. These theorems, which involve no relations but those of incidence, belong more properly to projective geometry than to euclidean geometry; and the well-known facts about them are that Desargues's theorem can be proved from axioms of incidence for space but not from axioms of incidence for the plane only, while Pappus's theorem cannot be proved at all from axioms of incidence alone, since it demands a commutative ground-field.[2]

---

[1] This model is due to Klein. Its existence establishes the consistency of non-euclidean geometry in much the same way as the existence of the cartesian model establishes the consistency of euclidean geometry. An alternative model for the same type of non-euclidean geometry was devised by Poincaré. On the subject of these models see Note 2, p. 227.

[2] H. F. Baker discusses the theorems of Pappus and Desargues in relation to the axioms of geometry in his *Principles of Geometry*, I, Foundations (1922).

Hilbert confined his discussion of the two theorems to the special cases in which the lines of collinearity that are asserted to exist are at infinity. For Desargues's theorem he proved the following result:

'There exists a plane geometry in which all the axioms I, 1–3, II, III, 1–4, IV*, V hold, i.e. all the linear and plane axioms except for the axiom of congruence III, 5, and for which Desargues's theorem is not true. Desargues's theorem is therefore not a consequence of the specified axioms; it requires for its proof either the space axioms or axiom III, 5 on the congruence of triangles.' The axiom IV* referred to is a strengthened form of the axiom of parallels IV, with the words 'at most one line' replaced by 'one and only one line'.

The treatment of Pappus's theorem depended on a purely algebraic result, to the effect that an ordered skew-field (i.e. an algebraic system for which all the axioms for an ordered field are postulated, with the single exception of the commutative law of multiplication $ab = ba$) is necessarily commutative if it is archimedean. The main conclusion that Hilbert was able to draw from this result was that Pappus's theorem can be proved without the axioms of congruence provided that a form of the Archimedean axiom V, 1 is taken, but not otherwise.

3 Axiomatic theories and their significance

With the publication in 1899 of his *Grundlagen der Geometrie*, Hilbert improved substantially upon the best that had previously been done by way of logical justification of euclidean geometry; and having achieved this initial success, he devoted the major part of his working life from that time on to the much greater task of applying his new metamathematical method to pure mathematics as a whole (though continuing at the same time to pursue more orthodox mathematical research as well). His conception of metamathematics became more precise as the work progressed, and his standard of rigour became correspondingly more stringent—so much so, indeed, that in the end even so modest an objective as the attainment of perfect rigour in the arithmetic of the natural numbers proved to be for ever out of reach. But in spite of the ultimate breakdown of the undertaking, the work done and the results obtained have greatly enhanced our knowledge and understanding of the formal articulation of both mathematics and logic; and through this work, no less than by his more strictly mathematical innovations, Hilbert has done much to shape the mathematical tradition inherited by the mid-twentieth century.

Hilbert evolved a distinctive personal philosophy of mathematics, which had very different presuppositions from the philosophy of Russell that we considered in Chapter 6; and his system is often referred to by the name of *formalism* in order to distinguish it from Russell's logistic system. The results of the researches that have centred round formalism are set forth with admirable lucidity in the two volumes of *Grundlagen der Mathematik*, which Hilbert published in 1934 and 1939 in collaboration with Paul Bernays, whose own further contribution to the foundations of mathematics we shall consider in Chapter 11 below. The account of formalism that now follows is directly based on this standard work, and the details that we are often obliged to omit are all to be found in its pages.

Whereas Russell has consistently maintained that the whole of pure mathematics is reducible to logic, Hilbert firmly believed mathematics to be an autonomous activity of the mathematician; and so formalism is more mathematical than philosophical in spirit, and it reflects very clearly the tendency towards total abstraction that was becoming dominant in mathematics at the time when the formalist outlook was being developed. The general tendency in mathematics in the latter part of the nineteenth century had been in the direction of more and more extensive use of the axiomatic method, and Hilbert characteristically thought of mathematics in axiomatic terms. The entire formalist programme was in fact based on a further development of the axiomatic principle; and in order to appreciate its aims we accordingly need to begin by clarifying the notion of an axiomatic theory.

At the beginning of the *Grundlagen der Mathematik* an important distinction is drawn between two accepted senses of the word 'axiomatic', there distinguished as 'concrete' (*inhaltlich*) and 'formal'. In applying the *concrete* axiomatic method we take some body of empirical knowledge with which we are already tolerably familiar, and we try to make this knowledge systematic by idealizing the concepts which it involves and picking out from among the known facts a small number of basic principles from which all else can be derived by deduction. This is the method that was applied by Euclid to geometry and by Newton to mechanics; and it has been used more recently, though not yet with complete success, in the theory of probability. The *formal* axiomatic method on the other hand, which is the method of pure mathematics *par excellence*, is not tied to any existing factual knowledge, since it is a method of constructing an abstract theory by beginning with arbitrary primitive ideas and primitive propositions, and then developing formal consequences without reference to any sort of meaning.

The concrete axiomatic method is a most powerful intellectual instrument, which can be used whenever a new science is taking shape—that is to say when familiarity with and understanding of some range of phenomena have reached a point at which general laws that govern it begin to be discernible. Use of this method raises mere factual knowledge to the level of scientific theory; and in natural science the method is fully adequate to what is required of it. But in mathematics, where empirical fact provides only the initial prompting for a mathematical investigation (and perhaps the material for subsequent application of the resulting theory), and where both logistic and formalist philosophers are agreed in recognizing only logic as final arbiter in questions of mathematical correctness, it is the *formal* axiomatic method that is needed. Nevertheless, most mathematicians would admit that this formal method is not sufficient by itself. We cannot be content with a mathematics that is imprisoned within a world of total abstraction,[1] a mathematics in which any axiomatic theory that may be arbitrarily set up is as good as any other. Mathematics may indeed recognize no criteria of *correctness* but those of logic, but the *significance* of mathematical theories can hardly be altogether separated from the possibility of their application in wider realms of knowledge. Mathematics is, in fact, indissolubly linked with scientific as well as with everyday thinking, and this connexion forms part of its significance as knowledge. It is for this reason that the literature of foundations of mathematics contains important discussions relating to the *Anwendungsproblem* or problem of application; and this problem obviously calls for use of the concrete axiomatic method. Pure mathematics provides logical analyses of various abstract structural patterns, and a particular mathematical theory can find an application in a particular range of experience if the pattern with which it deals is in fact present in that experience. To reveal the possibility of the application, therefore, and to assess its precision, we need to isolate the pattern of the experience itself, by treating this axiomatically in the concrete manner. That is a topic to which we shall return in Part III (cf. Chapter 13).

Quite apart from the question of whether a given abstract theory applies to a particular body of experience, we may also want to ask whether such a theory is significant *in itself*, that is to say as an abstract theory. A formal axiomatic theory—which is nothing but an edifice of propositions that exists as an organic whole for no other reason than that the propositions are all deducible from certain propositions which have been adopted, by arbitrary fiat, as the axioms of the theory—is not 'significant' in the same sense as a concrete theory, rooted in already familiar knowledge; and for it some special sort of vindication is plainly needed. The most obvious suggestion as to how a formal theory should be exhibited as non-trivial is that we ought to show that the structure which it analyses actually exists in some concrete domain —in other words, that we ought to point to some realization of the theory. But although to do this would be quite sufficient to satisfy mathematicians and scientists that a particular branch of abstract mathematics is significant, no philosophically acceptable demonstration of significance is in fact possible by such means; for almost every body of knowledge bristles with philosophical difficulties, and to try to justify abstract euclidean geometry, say, by pointing to empirically known facts concerning drawing and measuring would be to make the stronger partner lean upon the weaker. It is only in a few cases, moreover, that the theories which make up abstract mathematics have grown directly out of more intuitive knowledge at all, and there are now many branches of pure mathematics that have no immediate intuitive counterpart. Looking at the question of significance from the point of view of philosophy of mathematics, therefore, we must ask with reference to any given abstract mathematical theory not 'Has this theory a realization in some more concrete domain of knowledge?' but rather 'Does this theory in principle admit of realization?'. In other words, we shall ask if it is theoretically possible to replace the primitive concepts of the theory by well-defined specific concepts in such a way that the primitive propositions all become true assertions. Any such interpretation of the undetermined concepts will be said to yield a *realization* of the abstract theory (i.e. a model, in the sense of p. 197 above).

---

[1] It is of some interest to recall that Hilbert himself was an author of a book on intuitive geometry—D. Hilbert and S. Cohn-Vossen: *Anschauliche Geometrie* (Berlin, 1932); English translation *Geometry and the Imagination* (New York, 1956).

The idea of realizability that we have here is obviously related to the idea of satisfiability introduced in Chapter 3, but it applies to entire formal theories instead of to isolated formulae. We said earlier (p. 71) that a formula of the calculus of predicates is *satisfiable* for a given domain of individuals if predicates defined for this domain can be substituted for the predicate variables in it, and particular individuals and propositions for any individual and propositional variables that may be present, in such a way that the formula yields a true proposition. We now say that a formal theory is *realizable* if a domain of individuals can be chosen, and constant individuals and predicates taken, in such a way that, with this particular specification of the primitive elements of the theory, all the axioms are true propositions.

The most direct way of showing that an abstract theory is realizable, and ultimately the only one, is by actually producing a realization, though not necessarily in any concrete domain; but here we already find ourselves confronted with a fundamental difficulty. Only in a very few cases, in fact, can we claim actually to *produce* a realization, namely in those cases in which we can do this with a finite domain of individuals. For, unless the domain of individuals is finite, its very existence raises philosophical problems of the same order as those relating to the abstract system which our construction of the realization is designed to justify. If we are seeking a realization of the abstract theory of groups, say, we need only take some finite group, specified by a multiplication table which we can write out in full, and there, beyond all possibility of doubt, is a demonstration that the theory of groups is realizable. Or again, we have a completely satisfactory realization of abstract projective geometry of two dimensions in the well-known 7-point geometry (see Note 1, p. 224), and this model of the abstract theory can be defined combinatorially by a finite table of incidence relations. To produce in such a way a finite model is to give a perfect proof of realizability, but unfortunately there are quite simple systems of axioms for which no finite model can exist (cf. the example given on p. 72). This means that we are forced to deal with infinite domains of individuals; and so we must consider how these are to be handled.

4 The domain of numerals, treated by finitary means

The simplest infinite totality is that of the natural numbers, a progression which is usually defined implicitly by means of the Peano axioms. But if we adopt such a definition we make the domain of numbers itself dependent on an abstract axiomatic theory, which in turn gives rise to its own question of realizability; and so our whole method is vitiated by circularity. If we are to use the set of natural numbers, or some equivalent totality, as a domain of individuals for the construction of realizations, we must find a way of actually exhibiting this set directly, as an object of immediate perception or intuition, instead of characterizing it implicitly by means of axioms. Admittedly we cannot have the whole infinite collection before us, but we must at least be able to survey as much of it as is needed at any particular moment.

We can make a start by taking as the individuals of our progression the symbols |, ||, |||, . . . , which we obtain one after another by starting with a single vertical stroke and then appending a further stroke at each stage of the construction. For the sake of clarity in the following discussion we shall call these stroke-symbols *numerals*, and we shall use small German letters (in metastatements, or statements about the primary theory) to stand for unspecified numerals. Given any two numerals, we can compare them with regard to length. By crossing off one stroke from each of them again and again we can decide in a finite number of steps whether or not they are of the same length; and if they are not, we find out in this way which is the shorter. We are thus able to define an order among the distinct numerals, by putting $\mathfrak{a} < \mathfrak{b}$ whenever the symbol $\mathfrak{a}$ is shorter than the symbol $\mathfrak{b}$. If $\mathfrak{a}$ and $\mathfrak{b}$ are any two numerals, we define their sum $\mathfrak{a} + \mathfrak{b}$ as the numeral obtained when $\mathfrak{b}$ is written immediately to the right of $\mathfrak{a}$, and we define their product $\mathfrak{a} . \mathfrak{b}$ as the numeral that is obtained when $\mathfrak{a}$ is substituted for each of the strokes in the symbol denoted by $\mathfrak{b}$.

In order that the numerals may provide a non-hypothetical domain of individuals for realizations of axiomatic theories, we must be able to prove, by reasoning that never goes beyond the immediately given, all the arithmetical properties that we shall need in the construction of such realizations. Such non-hypothetical reasoning is referred to by Hilbert and Bernays as 'finitary inference' (*das finite Schließen*). To quote their words:

> 'We shall always use the word "finitary" to indicate that the discussion, assertion, or definition in question is kept within the bounds of thorough-going producibility of objects and thorough-going practicability of processes, and may accordingly be carried out within the domain of concrete inspection.'[1]

What is essential to finitary reasoning is thus that (a) the entities talked about are produced and not merely postulated, and (b) no process of definition or calculation is admitted unless it can be guaranteed to terminate in a finite number of steps, and a definite bound can be set to this number in advance.

All the definitions that we have so far laid down in relation to numerals are finitary; and we can also give finitary interpretations to the two fundamental arithmetical procedures of proof by mathematical induction and definition by recursion. A proof by induction of a theorem $\mathfrak{A}(n)$ gives us a means of verifying $\mathfrak{A}(\mathfrak{n})$, for any assigned numeral $\mathfrak{n}$, in a number of steps to which a bound can be assigned in advance; and a recursive definition of a function $\mathfrak{f}(n)$ similarly enables us actually to evaluate $\mathfrak{f}(\mathfrak{n})$, for any particular $\mathfrak{n}$, also in a previously bounded number of steps. With these basic procedures at our disposal, we can now reformulate in finitary terms the usual arguments by which it is customary to establish the associative, commutative, and distributive laws for addition and multiplication, we can introduce the concept of prime number, and we can prove the 'fundamental theorem of arithmetic', the theorem which asserts that every integer is representable, in one and essentially only one way, as a product of prime factors.

Adoption of the finitary point of view first reveals itself as an irksome limitation on arithmetical thinking when we have occasion to work with propositions that involve quantifiers. An assertion $(x)\mathfrak{A}(x)$ can only be understood as meaning that, for any choice of a numeral $\mathfrak{n}$, the proposition $\mathfrak{A}(n)$ can be shown finitarily to be true; and an assertion $(Ex)\mathfrak{A}(x)$ has to be interpreted in such a way that it can only be made when we actually know some particular numeral $\mathfrak{n}$ for which $\mathfrak{A}(\mathfrak{n})$ is true, or at the very least when we have a process of calculation that can be guaranteed to lead to the determination of such a numeral in a previously bounded number of steps.

---

[1] 'Wir [wollen] allemal mit dem Worte „finit" zum Ausdruck bringen, daß die betreffende Überlegung, Behauptung oder Definition sich an die Grenzen der grundsatzlichen Ausführbarkeit von Prozessen hält und sich somit im Rahmen konkreter Betrachtung vollzieht.' (*Grundlagen der Mathematik*, I, p. 32.)

Finitary interpretation of non-elementary assertions presents even greater difficulty when the propositions that we wish to assert involve negation. The negation of an elementary proposition, that is to say one without quantifiers, is entirely unproblematic, but the situation is altogether changed when quantifiers are admitted. Let us consider first a proposition of the form $\overline{(Ex)\mathfrak{A}(x)}$. The most natural finitary interpretation of the assertion of this proposition is that, for any $\mathfrak{n}$ whatever, $\mathfrak{A}(\mathfrak{n})$ is false. With this interpretation, however, the alternatives $(Ex)\mathfrak{A}(x)$ and $\overline{(Ex)\mathfrak{A}(x)}$ are not exhaustive, for it may well happen that we have no means of determining an $\mathfrak{n}$ for which $\mathfrak{A}(\mathfrak{n})$ is true, and yet are unable to prove the falsity of $\mathfrak{A}(\mathfrak{n})$ for arbitrary choice of $\mathfrak{n}$. The two decisions, in fact, do not involve the same situation. Thus we find that, in the finitary logic of non-elementary propositions, the law of excluded middle 'A or not-A' (*tertium non datur*) fails to hold. Much the same considerations apply also to propositions of the form $\overline{(x)\mathfrak{A}(x)}$. There is more than one possible finitary interpretation of such an assertion—for instance availability of a counter-example, or derivability of a contradiction from the assumption that $\mathfrak{A}(\mathfrak{n})$ holds for arbitrary choice of $\mathfrak{n}$—but in any case the law of excluded middle is invalid.

It will be clear from what we have just seen that the virtual infallibility of finitary reasoning is only achieved at the cost of a heavy sacrifice of deductive power; and it turns out that this type of argument is too weak to enable us to develop a theory of numerals comparable, either in range or in logical simplicity, with ordinary arithmetic.

We see, then, that the arithmetic of the numerals I, II, III, . . . can never be a complete substitute for arithmetic as ordinarily understood by mathematicians, and it cannot even provide a realization of any formal theory that adequately represents ordinary arithmetic. In spite of this, however, the numerals themselves are of great value in metamathematics, for they do at least provide a potentially infinite system of entities, many properties of which can be treated by purely finitary means. The sequence of numerals I, II, III, . . ., in fact, is now available as a finitary counterpart of the sequence of natural numbers 1, 2, 3, ... If, moreover, as is often the case, we wish the progression of numbers to begin with 0 instead of 1, we can easily modify the numerals so that they behave in the corresponding way. All that we need to do is to replace the sequence of expressions I, II, III, . . . by the sequence 0, 0I, 0II, . . ., and to adapt the definitions of addition and multiplication suitably. The sum $\mathfrak{a} + \mathfrak{b}$ of two numerals in the extended sense is obtained by removing the initial '0' from $\mathfrak{b}$ and appending what remains to the right of $\mathfrak{a}$; and the product $\mathfrak{a} . \mathfrak{b}$ is obtained by removing the '0' from $\mathfrak{a}$ and substituting what is left (which may be nothing at all) for each stroke in the constitution of $\mathfrak{b}$.

5 The metamathematics of formalized theories

We now return to the fundamental question of mathematical significance. Pure mathematics, as it is understood nowadays, belongs to what Kant called the realm of ideas—a domain of pure thought, where the mind is no longer bound in any way by the conditions of sensory intuition or the exigencies of contingent fact—and mathematical theories can therefore only be conceived as abstract axiomatic theories. Such a theory must certainly be accepted as significant if a realization of it can be exhibited. When a finite realization is available, significance is guaranteed in the strongest possible way; but we shall also be satisfied if an infinite realization, based on the system of numerals discussed in §4, can be constructed by finitary means. In view of the fact, however, that only so limited a part of the arithmetic of the numerals is finitary, we can scarcely hope to produce even this kind of realization in any but a few favourable cases. The direct method of establishing significance thus soon fails, and we are obliged to have recourse to some weaker form of guarantee. The weakest criterion that can be held to meet the need at all is the one on which Hilbert based his philosophy of formalism, namely demonstrable consistency. Hilbert was prepared to accept any axiomatic theory as significant—that is to say as characterizing a possible structural pattern—if a proof could be given that no contradiction is deducible from its axioms.

Here, then, we have the essential problem of foundations of mathematics as Hilbert understood it in his later work. *A proof must be given, for each branch of mathematics, that the permitted procedures of demonstration can never yield two theorems $\mathfrak{A}$ and not-$\mathfrak{A}$.* This proof of consistency, furthermore, must be logically unassailable; and the metamathematical argument is accordingly required to be strictly finitary.

Now here there is a difficulty; for an ordinary axiomatic mathematical theory is a relatively ill-defined object of thought, whereas it is of the essence of finitary reasoning that it can only be applied to definite and constructively given entities. It was this consideration that produced a clear break in Hilbert's work on foundations of mathematics, which separates the earlier metamathematical discussion of euclidean geometry in the *Grundlagen der Geometrie* from the mature development of the philosophy of formalism, as presented in Hilbert's later papers and in the *Grundlagen der Mathematik*. In his earlier book, Hilbert first of all expounded an axiomatic treatment of geometry which was to be taken as presenting euclidean geometry in its most modern form—the abstract science that had grown out of pre-Euclidean empirical study of space—and the metamathematics that followed was intended simply to demonstrate by ordinary mathematical argument that this theory had certain important characteristics, especially that of consistency. In the *Grundlagen der Mathematik*, on the contrary, the essential task was to *justify* mathematics in its final abstract form, by exclusively finitary means. Here Hilbert was obliged to apply his metamathematical argument not to the mathematical theory itself, which would be built up merely in conformity with the ordinary canons of mathematical rigour, but to a much stricter formalized theory or *formalism*, of the type that we have described in Chapter 4, §3, chosen in such a way that it would faithfully represent the mathematical theory as far as its totality of theorems was concerned.

Formal theories, as set up by Hilbert, are required to be strictly syntactic in their construction. This means that any such theory must be based on a postulated domain of individuals, a finite set of initial formulae, and certain explicitly formulated rules of derivation (say those belonging to the syntactic treatment of the restricted calculus of predicates, as given on p. 66). Its derivable formulae will then be all those formulae that can be obtained from the initial formulae by a finite number of applications of the rules of derivation. The formal theory is to be set up in such a way that every provable theorem of the original mathematical theory has its counterpart in a derivable formula of the formal theory; and if this can be done, then we shall only need to demonstrate the consistency of the formal theory in order to justify (in the sense explained) the mathematical theory that it represents.

Throughout mathematics, frequent and essential use is made of non-finitary arguments, and the formal systems which are constructed to represent mathematical theories will consequently have to provide rules of derivation which correspond to non-finitary inferences. Hilbert considered, when he devised his metamathematical method, that this did not matter, because even if the intuitive interpretation of a formal system is not finitary, the system itself, treated as a totality of derivations (i.e. finite sequences of formulae, put together in accordance with stated rules) is constructively defined, and is therefore a possible object of finitary discussion. The formalist programme thus offered a reasonable hope that a finitary metamathematics would be able to justify a non-finitary mathematics. We must now examine in detail how the programme was put into effect.

6 Consistency of the restricted calculus of predicates

As a preliminary to Hilbert's main undertaking, it was necessary first of all to apply the new method to symbolic logic, by making the logical calculus that was to be used into a strictly formal system, and then establishing its freedom from contradiction by finitary means. The system of logic that was chosen was, in fact, the restricted calculus of predicates, treated syntactically in the manner that we have already specified in Chapter 3. In order to complete our account of this initial phase in the working out of the formalist philosophy of mathematics, therefore, we have only to show how the consistency of the restricted calculus of predicates can be demonstrated. This is a simple matter.

THEOREM 1. *The restricted calculus of predicates is free from contradiction, in the sense that two formulae* $\mathfrak{A}$ *and* $\overline{\mathfrak{A}}$ *cannot both be derived in the system.*

Proof. (i) We consider first of all the propositional calculus, as presented syntactically in Chapter 2, §6, which forms the most elementary part of the restricted calculus of predicates. The only undefined symbols that occur in it are propositional variables (capital Latin letters) and the logical symbols '$\overline{\ }$' and '$\vee$'. Taking two metalogical symbols 'T' and 'F', we can draw up a truth-table for any formula of the calculus, and in this way we can determine finitarily whether or not the formula is an identical one, i.e. one that has 'T' for every entry in its truth-table. It can now readily be shown (again by finitary argument) that (1) the axioms (a)–(d) are identical formulae, and (2) the property of being identical is left invariant by all applications of the rules of procedure (α) and (β). It follows from this that every derivable formula is identical, and hence that two formulae $\mathfrak{A}$ and $\overline{\mathfrak{A}}$ are never both derivable.

(ii) Turning now from the propositional calculus to the full calculus to which the theorem refers, we find that the same proof continues to apply if we simply strike out from every formula of the calculus of predicates any arguments and quantifiers that may be present in it, retaining only the bare capital letters and treating these as if they were propositional variables. The axiom (e) for example, which reads $(x)F(x) \rightarrow F(y)$, is then changed into the identical formula $F \rightarrow F$, i.e. $\overline{F} \vee F$; and the rules of procedure become trivial in a similar way.

Remark. The proof just given is plainly finitary. The idea behind it may be expressed in general terms in the following way. In order to show that two formulae $\mathfrak{A}$ and $\overline{\mathfrak{A}}$ are not both derivable, we introduce constructively a property of symbolic expressions which (i) belongs to all the axioms, (ii) is invariant with respect to the rules of procedure, and is therefore inherited by every derived formula, and (iii) cannot belong to both $\mathfrak{A}$ and $\overline{\mathfrak{A}}$. It is an extension of this same idea that makes possible the proofs of consistency, shortly to be discussed, that Hilbert devised for various arithmetical formalisms.

7 Consistency of arithmetic

After carrying out his programme in the simple case of logic, Hilbert turned his attention to arithmetic, first of all taking a very small part of arithmetic and justifying it, and then by degrees strengthening the axioms so that more and more of ordinary arithmetic was represented in the formal system. The successive phases of this inquiry are discussed in the first volume of *Grundlagen der Mathematik*.

The systems that are considered are all based on Peano's formalization of arithmetic in terms of the three primitive concepts of number, zero, and successor. A domain of individuals is postulated, corresponding to Peano's class N_0 of numbers; a particular individual of this domain is designated by the (constant) symbol '0'; and a mathematical function a', which associates with every term $\mathfrak{a}$ a uniquely defined term $\mathfrak{a}'$, serves to represent the successor function in the formalism.

In the first and weakest of the successive arithmetical formalisms—which we shall call the system (A_0), although it is unnamed in the *Grundlagen*—there are two constant predicates, each with two arguments, namely the logical predicate of identity, $a = b$, and the arithmetical predicate of inequality, $a < b$. Seven axioms are taken in addition to the axioms (a)–(f) of the restricted calculus of predicates. These are the two axioms (J_1) and (J_2) for identity, three axioms $(<_1)$, $(<_2)$, $(<_3)$ for order of magnitude, and two of the Peano axioms, (P_1) and (P_2), for the successor function. We thus have the following set of axioms:

$$\left.\begin{array}{ll}
(\mathrm{J}_1) & a = a, \\
(\mathrm{J}_2) & a = b \rightarrow (A(a) \rightarrow A(b)), \\
(<_1) & \overline{a < a}, \\
(<_2) & (a < b \;\&\; b < c) \rightarrow a < c, \\
(<_3) & a < a', \\
(\mathrm{P}_1) & a' \neq 0, \\
(\mathrm{P}_2) & a' = b' \rightarrow a = b.
\end{array}\right\} \quad (\mathrm{A}_0)$$

As we can easily see (cf. p. 72), the three axioms for order of magnitude are not satisfiable with a finite number of individuals, and the domain of individuals now postulated must accordingly be infinite.

The rules of derivation for the arithmetical formalism are those of the restricted calculus of predicates, trivially modified where necessary to take account of the fact that we now have certain constant symbols '0', '′', '=', '<' in addition to the symbols of the logical calculus itself. As usual, we allow all identical formulae of the propositional calculus to be used as initial formulae in derivations (cf. p. 68).

In order to prove that a formal system is consistent, we have to show that no two contradictory formulae $\mathfrak{A}$ and $\overline{\mathfrak{A}}$ can both be derived. This is something that is often best done indirectly, by showing that some particular formula is underivable in the system. In view of the usefulness of the principle that allows us to transform the problem in this manner, we shall begin our discussion of consistency by expressing this principle formally in a metamathematical theorem:

THEOREM 2. *A formal system* F *is consistent if and only if there is some formula of the system that is not derivable.*

Proof. (i) If F is consistent then, for any arbitrary choice of a formula $\mathfrak{A}$, it is impossible that both $\mathfrak{A}$ and $\overline{\mathfrak{A}}$ should be derivable, and it follows from this that $\mathfrak{A} \;\&\; \overline{\mathfrak{A}}$ is an underivable formula of the system.

(ii) If F is inconsistent, there are some two formulae $\mathfrak{A}$ and $\overline{\mathfrak{A}}$ that are both derivable. But then, if $\mathfrak{B}$ is any formula whatever, $\mathfrak{B}$ can be derived with the aid of the identical formula $X \rightarrow (\overline{X} \rightarrow Y)$ of the propositional calculus.

To establish the consistency of the arithmetical system (A_0), then, we require to show that there is some formula that cannot be derived. The formula chosen for this role by Hilbert was $0 \neq 0$, and we shall now give an outline of Hilbert's metamathematical proof that no derivation in the system (A_0) can have $0 \neq 0$ for its end-formula.

The proof hinges on the discovery of a property of formulae of the system that can be shown to belong to every derivable formula but not to $0 \neq 0$. When proving the consistency of the propositional calculus, we were able to obtain a property of the required kind by turning to the semantic interpretation of propositional formulae as truth-functions of their arguments; and we could do this because the use of truth-tables is an essentially finitary procedure. In the present situation we again find ready to hand an intuitive interpretation of the symbolic expressions—namely their interpretation as statements in elementary arithmetic—and this suggests that we might try to use the elementary interpretation in order to define a suitable formal property. But this interpretation, as we have already seen in §4, is not wholly finitary. Indeed, if it were finitary we would hardly need to apply the indirect procedures of formalist metamathematics to this part of mathematics. Some means has therefore to be found of extracting an appropriate finitary property of formal expressions from their intuitive arithmetical meaning. This has in fact been done by Hilbert, with the aid of an ingenious process of *reduction*, which plays a most important part in the whole metamathematical treatment of arithmetic.

What reduction achieves is the transformation of formulae that contain bound variables, without essential change of their intuitive truth-content, into formulae that are free from such variables. This is just what is needed, as it is precisely the presence of bound variables that makes arithmetic non-finitary. We shall see, moreover, that a process of reduction is only needed for formulae that do not contain propositional or predicate variables.

To illustrate the nature of the process of reduction, let us take the simple formula

$$(Ex)(\mathfrak{a} < x'' \ \& \ x'' < \mathfrak{b}),$$

in which $\mathfrak{a}$ and $\mathfrak{b}$ are supposed to be given terms. To say that there is an x such that $\mathfrak{a} < x'' < \mathfrak{b}$ is to say that there is a $y \geqslant 0''$ such that $\mathfrak{a} < y < \mathfrak{b}$; and this is the case if and only if $\mathfrak{b}$ exceeds $0''$ and there is at least one number between $\mathfrak{a}$ and $\mathfrak{b}$. We can accordingly replace the original existential statement by the simpler statement

$$0'' < \mathfrak{b} \ \& \ \mathfrak{a}' < \mathfrak{b}.$$

This is, in fact, the formula that would be obtained if the process of reduction, now to be defined, were applied to the original formula. It will be found that the fact that the natural numbers form a progression makes it always possible for us to eliminate existential quantifiers from formulae of the system (A_0) without altering their import as arithmetical statements.

Suppose, then, that $\mathfrak{F}$ is some formula of (A_0) which does not contain any propositional or predicate variable. If $\mathfrak{F}$ has no bound variables it requires no reduction, but if bound variables are present in it we proceed in the following manner: We first of all replace every universal quantifier by an existential quantifier, by the device of substituting $\overline{(E\mathfrak{x})\overline{B(\mathfrak{x})}}$ for $(\mathfrak{x})B(\mathfrak{x})$. Then we select an 'innermost' component of $\mathfrak{F}$ of the form $(E\mathfrak{x})\mathfrak{A}(\mathfrak{x})$, that is to say a component of this form which is such that $\mathfrak{A}(\mathfrak{x})$ does not involve any further existential quantifier. $\mathfrak{A}(\mathfrak{x})$ is therefore a combination, by means of the logical operators of the propositional calculus, of equalities $\mathfrak{a} = \mathfrak{b}$ and inequalities $\mathfrak{a} < \mathfrak{b}$, where $\mathfrak{a}$ and $\mathfrak{b}$ denote numbers (i.e. symbols of the form 0, $0'$, $0''$, etc.) or individual variables, free or bound, possibly with appended dashes. In th metamathematical discussion which follows, we shall find it convenien to write a term $\mathfrak{a}''^{\cdots\prime}$, in which $\mathfrak{t}$ dashes are appended to $\mathfrak{a}$, as $\mathfrak{a}^{(\mathfrak{t})}$.

Having selected a suitable component $(E\mathfrak{x})\mathfrak{A}(\mathfrak{x})$ of $\mathfrak{F}$, we apply certain transformations to $\mathfrak{A}(\mathfrak{x})$, as follows:

(i) We first put $\mathfrak{A}(\mathfrak{x})$ into disjunctive normal form, so that it becomes a disjunction $\mathfrak{C}_1 \vee \ldots \vee \mathfrak{C}_r$, in which each component $\mathfrak{C}_i$ is a conjunction of equalities and inequalities and negations of equalities and inequalities.

(ii) We next eliminate all the negations, by replacing $\mathfrak{a} \neq \mathfrak{b}$ by $\mathfrak{a} < \mathfrak{b} \vee \mathfrak{b} < \mathfrak{a}$ and $\overline{\mathfrak{a} < \mathfrak{b}}$ by $\mathfrak{a} = \mathfrak{b} \vee \mathfrak{b} < \mathfrak{a}$; and then we put the expression once again into disjunctive normal form $\mathfrak{F}_1 \vee \ldots \vee \mathfrak{F}_n$.

(iii) In every equality or inequality of the form $\mathfrak{x}^{(\mathfrak{t})} = \mathfrak{x}^{(\mathfrak{l})}$ or $\mathfrak{x}^{(\mathfrak{t})} < \mathfrak{x}^{(\mathfrak{l})}$, with $\mathfrak{x}$ occurring on both sides, we substitute 0 for $\mathfrak{x}$, thus obtaining $0^{(\mathfrak{t})} = 0^{(\mathfrak{l})}$ or $0^{(\mathfrak{t})} < 0^{(\mathfrak{l})}$.

(iv) We now determine the maximum number of dashes, $\mathfrak{t}$ say, appended to $\mathfrak{x}$ anywhere in the formula $\mathfrak{F}_1 \vee \ldots \vee \mathfrak{F}_n$, as modified in (iii), and we then make up the number of dashes on every $\mathfrak{x}$ in the formula to $\mathfrak{t}$ by adding dashes to both sides of an equality or inequality wherever necessary. For example, the formula

$$(0 < \mathfrak{x}' \mathbin{\&} \mathfrak{x} < a) \lor (\mathfrak{x}''' = a'')$$

would have to be changed into

$$(0'' < \mathfrak{x}''' \mathbin{\&} \mathfrak{x}''' < a''') \lor (\mathfrak{x}''' = a'').$$

The formula $\mathfrak{A}(\mathfrak{x})$ will now have been transformed into a formula which we may write as

$$\mathfrak{C}_1(\mathfrak{x}^{(\mathfrak{t})}) \lor \ldots \lor \mathfrak{C}_m(\mathfrak{x}^{(\mathfrak{t})}) \lor \mathfrak{C}_{m+1} \lor \ldots \lor \mathfrak{C}_n,$$

each disjunctive component $\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$, $i = 1, \ldots, m$, being a conjunction of expressions of the possible forms $\mathfrak{x}^{(\mathfrak{t})} = \mathfrak{a}$, $\mathfrak{x}^{(\mathfrak{t})} < \mathfrak{a}$, $\mathfrak{a} < \mathfrak{x}^{(\mathfrak{t})}$, $\mathfrak{a} = \mathfrak{b}$, $\mathfrak{a} < \mathfrak{b}$; and we accordingly replace $(E\mathfrak{x})\mathfrak{A}(\mathfrak{x})$ by the disjunction

$$(E\mathfrak{x})\mathfrak{C}_1(\mathfrak{x}^{(\mathfrak{t})}) \lor \ldots \lor (E\mathfrak{x})\mathfrak{C}_m(\mathfrak{x}^{(\mathfrak{t})}) \lor \mathfrak{C}_{m+1} \lor \ldots \lor \mathfrak{C}_n.$$

Then, for each of the m formulae $(E\mathfrak{x})\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$, there are two possibilities to be considered.

(1) At least one equality $\mathfrak{x}^{(\mathfrak{t})} = \mathfrak{a}$ occurs in the conjunction $\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$, so that $(E\mathfrak{x})\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$ has the form

$$(E\mathfrak{x})(\mathfrak{x}^{(\mathfrak{t})} = \mathfrak{a} \mathbin{\&} \mathfrak{C}_i^*(\mathfrak{x}^{(\mathfrak{t})})).$$

It is understood, of course, that the residual part $\mathfrak{C}_i^*(\mathfrak{x}^{(\mathfrak{t})})$ of the quantified expression need not be present at all, and if it is present it need not actually involve $\mathfrak{x}$. When $(E\mathfrak{x})\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$ is of the form just given, we replace it by the formula

$$(0^{(\mathfrak{t})} = \mathfrak{a} \lor 0^{(\mathfrak{t})} < \mathfrak{a}) \mathbin{\&} \mathfrak{C}_i^*(\mathfrak{a}),$$

in which there no longer appears either the variable $\mathfrak{x}$ or the quantifier $(E\mathfrak{x})$.

(2) The conjunction $\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$ involves $\mathfrak{x}^{(\mathfrak{t})}$ in inequalities only. In this case we may write $(E\mathfrak{x})\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$ in the form

$$\mathfrak{H} \mathbin{\&} (E\mathfrak{x})(\mathfrak{a}_1 < \mathfrak{x}^{(\mathfrak{t})} \mathbin{\&} \ldots \mathbin{\&} \mathfrak{a}_k < \mathfrak{x}^{(\mathfrak{t})} \mathbin{\&} \mathfrak{x}^{(\mathfrak{t})} < \mathfrak{b}_1 \mathbin{\&} \ldots \mathbin{\&} \mathfrak{x}^{(\mathfrak{t})} < \mathfrak{b}_p),$$

where $\mathfrak{H}$ is the conjunction of all the components of $\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$ that do not involve $\mathfrak{x}^{(\mathfrak{t})}$. We then replace $(E\mathfrak{x})\mathfrak{C}_i(\mathfrak{x}^{(\mathfrak{t})})$ by the conjunction

$$\begin{aligned}
\mathfrak{H} \mathbin{\&} 0^{(\mathfrak{t})} &< \mathfrak{b}_1 \mathbin{\&} \ldots \mathbin{\&} 0^{(\mathfrak{t})} < \mathfrak{b}_p \mathbin{\&} \\
\mathbin{\&} \mathfrak{a}_1' &< \mathfrak{b}_1 \mathbin{\&} \ldots \mathbin{\&} \mathfrak{a}_1' < \mathfrak{b}_p \mathbin{\&} \\
\mathbin{\&} \mathfrak{a}_2' &< \mathfrak{b}_1 \mathbin{\&} \ldots \mathbin{\&} \mathfrak{a}_2' < \mathfrak{b}_p \mathbin{\&} \\
&\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \\
\mathbin{\&} \mathfrak{a}_k' &< \mathfrak{b}_1 \mathbin{\&} \ldots \mathbin{\&} \mathfrak{a}_k' < \mathfrak{b}_p.
\end{aligned}$$

If there is no component of the form $\mathfrak{a} < \mathfrak{x}^{(\mathfrak{t})}$, then only the first line is required; and if there is no component of the form $\mathfrak{x}^{(t)} < \mathfrak{b}$, then $(E\mathfrak{x})\mathfrak{E}_i(\mathfrak{x}^{(t)})$ may be replaced simply by $\mathfrak{H}$ if this expression is non-null and by $0 = 0$ otherwise.

When the process just described has been completed, one quantifier will have been eliminated from the original formula $\mathfrak{F}$ without change of the *intuitive* truth or falsity of the arithmetical statement to which $\mathfrak{F}$ corresponds if it contains no free variables, and without alteration in $\mathfrak{F}$ as a 'truth-function' otherwise; and a finite number of applications of the process therefore suffices to remove all the quantifiers from $\mathfrak{F}$. The formula which finally results is then free from bound variables; it contains exactly the same free variables as the original formula $\mathfrak{F}$; and its 'truth content' is the same as that of $\mathfrak{F}$.

Exercise. Apply the process of reduction to the formula

$$(x)(x < a \rightarrow b < x) \rightarrow a = 0,$$

in which a and b are free variables.

We can now use the procedure of reduction in order to define the metamathematical concept of verifiability for formulae of the arithmetical system (A_0) which do not contain propositional or predicate variables.

DEFINITION. (a) A numerical formula (i.e. one without variables) is *verifiable* if it is true when interpreted in terms of the finitary arithmetic of numerals.

(b) A formula with free individual variables only is *verifiable* if a finitary proof can be given that it becomes a true statement whenever definite numerals are substituted for the variables in it.

(c) A formula with bound variables is *verifiable* if it can be transformed by the process of reduction into a formula that is verifiable in the sense of (a) or (b).

It should be observed that part (c) of the definition requires justification. The process of reduction is not unique (because of the ambiguity of the disjunctive normal form) and we need to show that all possible reductions of a formula lead to the same decision as to its verifiability. The proof of this is long and rather tedious but full details are given by Hilbert and Bernays.

The property of verifiability, as just defined, does not take us outside the sphere of finitary argument, and we are therefore at liberty to use it for metamathematical purposes. By its aid we are able, in fact, to adapt to the formal system (A_0) the general method for proving consistency that we have already described (p. 211). We require to show that the formula $0 \neq 0$ is not derivable; and this will be accomplished if we can demonstrate by finitary means that, if a formula is derivable, then it is also verifiable.

THEOREM 3. *The formalized system of arithmetic* (A_0) *is free from contradiction.*

Proof. Let ($\mathfrak{F}_i$) be any derivation in the system (A_0). We prove that the end-formula of this derivation cannot be $0 \neq 0$; and to do so we divide the proof into two parts.

(i) In the first part of the proof we assume that no bound variables occur in the given derivation ($\mathfrak{F}_i$). Thus the available initial formulae are the identical formulae of the propositional calculus and the seven special axioms (J_1), (J_2), ($<_1$), ($<_2$), ($<_3$), (P_1), (P_2); and the only schema that can be used is the rule of inference (β), as given on p. 67. The derivation ($\mathfrak{F}_i$) is therefore a finite sequence of formulae, each of which is either (i) an identical formula of the propositional calculus or one of the seven special axioms, (ii) a repetition of an earlier formula of the sequence ($\mathfrak{F}_i$) or else a formula obtained by making a substitution in an earlier formula, or (iii) a formula obtained by use of the schema (β).

Our first step is one of unravelling the given derivation ($\mathfrak{F}_i$) into its separate strands (*Auflösung in Beweisfäden*), and this is achieved by starting with the end-formula and working back systematically to the initial formulae of the derivation. We set out the result of the process schematically in the following manner. First of all we put down the end-formula in the middle of the page. Then above it we place the formula or pair of formulae from which it is immediately derived; above each such formula we place in the same way the formula or formulae from which it is immediately derived; and so on, until we have worked back in every instance to an initial formula. If a formula $\mathfrak{W}$ in the resolved derivation is derived from two formulae $\mathfrak{U}$ and $\mathfrak{B}$ by use of the schema (β) we put

$$\begin{tikzcd}
\mathfrak{U} \arrow[dr, dash] & & \mathfrak{B} \arrow[dl, dash] \\
& \mathfrak{W},
\end{tikzcd}$$

while if a formula $\mathfrak{W}$ is derived from a formula $\mathfrak{B}$ by repetition or substitution we put

$$\begin{tikzcd}
\mathfrak{B} \arrow[d, dash] \\
\mathfrak{W}.
\end{tikzcd}$$

In order to avoid confusion in the diagram it is desirable to begin by numbering off the successive formulae of the sequence ($\mathfrak{F}_i$), so that these can be represented by their numbers in the resolved derivation ($\mathfrak{F}_i'$) when this is displayed schematically.

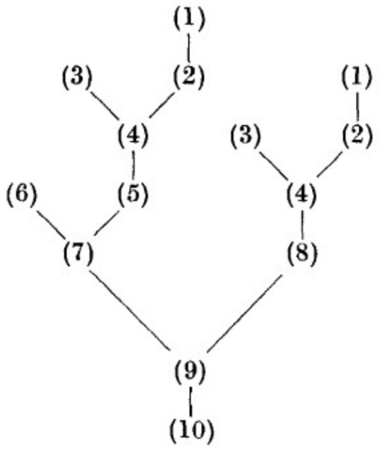
As an illustration of the process of resolution into strands, we give here an example which Hilbert and Bernays discuss on p. 226 of their first volume. The formula $0'''' \neq 0''$ may be derived as follows:

$$\begin{array}{rc}
(1) & (A \rightarrow B) \rightarrow (\bar{B} \rightarrow \bar{A}) \\
(2) & (a' = b' \rightarrow a = b) \rightarrow (a \neq b \rightarrow a' \neq b') \\
(3) & a' = b' \rightarrow a = b \\
\cline{2-2}
(4) & a \neq b \rightarrow a' \neq b' \\
(5) & a' \neq 0 \rightarrow a'' \neq 0' \\
(6) & a' \neq 0 \\
\cline{2-2}
(7) & a'' \neq 0' \\
(8) & a'' \neq 0' \rightarrow a''' \neq 0'' \\
\cline{2-2}
(9) & a''' \neq 0'' \\
(10) & 0'''' \neq 0''.
\end{array}$$

Key:

(1): [identical formula]
(2): [(1) $a' = b'/A$, $a = b/B$]
(3): [(P_2)]
(4): [(3), (2): (β)]
(5): [(4) a'/a, $0/b$]
(6): [(P_1)]
(7): [(6), (5): (β)]
(8): [(4) a''/a, $0'/b$]
(9): [(7), (8): (β)]
(10): [(9) $0'/a$].

The derivation ($\mathfrak{F}_i$) that we have here, when written schematically as a resolved derivation ($\mathfrak{F}_i'$), takes the form:



The formula (10) is the end-formula, and (1), (3), (6) are the initial formulae that are used.

Having unravelled the strands of ($\mathfrak{F}_i$), we now work backwards through $(\mathfrak{F}_i')$, taking each strand in turn and going always from the end-formula of the derivation right back to the initial formula in which the strand originates. In the example given, we would have to follow five different strands: (i) (10) → (9) → (7) → (6); (ii) (10) → (9) → (7) → → (5) → (4) → (3); (iii) (10) → (9) → (7) → (5) → (4) → (2) → (1); (iv) (10) → (9) → (8) → (4) → (3); (v) (10) → (9) → (8) → (4) → (2) → → (1). As we work along the strands, we carry all substitutions back to the initial formulae. In other words, whenever we come to a link

$$\begin{tikzcd}
\mathfrak{B} \arrow[d, dash] \\
\mathfrak{W}
\end{tikzcd}$$

which is such that $\mathfrak{W}$ is obtained from $\mathfrak{B}$ by one or more substitutions, we make the inverse substitutions in $\mathfrak{B}$ and in all the formulae that stand higher than $\mathfrak{B}$ in the strands which pass through $\mathfrak{B}$. Let the derivation $(\mathfrak{F}_i')$, as thus modified, be denoted by $(\mathfrak{F}_i'')$. Then, whenever we have a pair of formulae

$$\begin{tikzcd}
\mathfrak{B} \arrow[d, dash] \\
\mathfrak{W}
\end{tikzcd}$$

in $(\mathfrak{F}_i'')$, $\mathfrak{W}$ is simply a repetition of $\mathfrak{B}$; and whenever we have a triad of formulae

$$\begin{tikzcd}
\mathfrak{U} \arrow[dr, dash] & & \mathfrak{B} \arrow[dl, dash] \\
& \mathfrak{W} &
\end{tikzcd}$$

in $(\mathfrak{F}_i'')$, the passage from $\mathfrak{U}$ and $\mathfrak{B}$ to $\mathfrak{W}$ is a valid application of the rule (β). Thus $(\mathfrak{F}_i'')$ only differs from a proper derivation in that its initial formulae are not restricted to the identical formulae of the propositional calculus and the seven special axioms, but may be any formulae derived from these by substitution.

It is possible that some free variables may still be left in $(\mathfrak{F}_i'')$. This would be the case, for example, if $(\mathfrak{F}_i')$ contained some such sub-derivation as

$$\begin{tikzcd}
A \vee \overline{A} \arrow[d, dash] & & \\
A(a) \vee \overline{A(a)} \arrow[dr, dash] & & (A(a) \vee \overline{A(a)}) \rightarrow B \arrow[dl, dash] \\
& B \arrow[d, dash] & \\
& {}. &
\end{tikzcd}$$

We accordingly eliminate all remaining free variables from $(\mathfrak{F}_i)$ by making the following substitutions: $0 = 0$ for every propositional variable; $\mathfrak{a} = \mathfrak{a}$ for every predicate variable with a single argument $\mathfrak{a}$; $(\mathfrak{a} = \mathfrak{a} \,\&\ldots\&\, \mathfrak{t} = \mathfrak{t})$ for every predicate variable with the arguments

$\mathfrak{a}, \ldots, \mathfrak{t}$; and 0 for every individual variable. Then the array of formulae that we are left with is still a derivation in the same extended sense as $(\mathfrak{F}_i'')$; and every formula in the array is a numerical formula, that is to say a combination by means of the operators of the propositional calculus of equalities $\mathfrak{s} = \mathfrak{t}$ and inequalities $\mathfrak{s} < \mathfrak{t}$ between definite 'numbers' 0, $0'$, $0''$, etc. If, moreover, the original derivation $(\mathfrak{F}_i)$ had $0 \neq 0$ as its end-formula, the derivation yielded by the process that we have just described would also end with $0 \neq 0$.

Now it can be verified, by finitary argument, that (1) the initial formulae of the modified derivation are all true statements when they are given an interpretation based on the finitary arithmetic of the numerals 0, 0|, 0||, ...; (2) both the operation of repeating a formula and the operation of applying the rule (β) leave truth in this sense invariant; and (3) the formula $0 \neq 0$ is false in the corresponding sense. We thus have the required finitary proof of the underivability of the formula $0 \neq 0$, when 'derivable' is understood as meaning 'derivable without use of bound variables'. Our further task, in part (ii) of the proof, is to remove this limitation.

(ii) We now suppose that the derivation $(\mathfrak{F}_i)$ with which we begin uses the full resources of the restricted calculus of predicates. This means that the axioms (e) and (f), p. 66, which involve quantification, can now occur as initial formulae, and the two schemata ($\gamma 1$) and ($\gamma 2$) can now be used in addition to the schema (β).

We begin, as in part (i) of the proof, by unravelling the strands of the derivation, and by carrying back all substitutions to the initial formulae. Having done this, we eliminate all propositional and predicate variables as in case (i). But this time, because of the free variables that are essential to the schemata ($\gamma 1$) and ($\gamma 2$), we cannot eliminate all free *individual* variables without invalidating the derivation. Neither can we eliminate the bound (individual) variables that may occur. Consequently we are unable to transform the given sequence of formulae $(\mathfrak{F}_i)$ into an array of numerical formulae that retains the structure of a derivation, and so to prove as in (i) that the end-formula cannot be the false formula $0 \neq 0$. We can, however, use verifiability in place of numerical truth; and then a similar method of proof applies. We show that the initial formulae are all verifiable and that the property of verifiability is inherited by every formula in the modified derivation, and it then follows that $0 \neq 0$ cannot be the end-formula. The details of the argument, which we omit from this summary, are given in full by Hilbert and Bernays.

Here, then, we have in outline the proof of the first consistency theorem for formalized arithmetic, and we must now assess the value of what has been established. According to the formalist programme, in order to justify ordinary mathematics we are to formalize it and then to show that the formal system is free from contradiction. The proof just given has shown that the initial formalization of part of arithmetic by the system (A_0) is indeed consistent; and we must now ask how adequate this formalization is as a representation of intuitive arithmetic. In other words, we must raise the question of the completeness of the system. A formal theory may be said to be (semantically) complete if every intuitively valid statement that can be made in the symbolism of the theory is derivable; and in the present situation we shall make the notion of 'intuitively valid' precise by interpreting it to mean verifiable in the sense already laid down. The question, therefore, is whether every verifiable formula of the system (A_0) is derivable; and the answer is that this is not the case. Hilbert and Bernays prove (*Grundlagen*, p. 252) that the verifiable formula

$$a < b \rightarrow (a' = b \vee a' < b)$$

is not derivable from the axioms. To do this, they use the standard method for proving independence (cf. p. 198 above), devising a suitably distorted property of 'verifiability', which holds for the axioms and is invariant with respect to the rules of procedure, but does not hold for the formula in question. They then go on to prove (pp. 253–260) that all formulae that are verifiable in the original proper sense become derivable if the following five formulae are added to the axioms:

$$\begin{aligned}
&a \neq b \rightarrow (a < b \vee b < a),\\
&a < b \rightarrow a' < b',\\
&0 = a \vee 0 < a,\\
&0 < a \rightarrow (Ex)(x' = a),\\
&(a < c \;\&\; c < b) \rightarrow a' < b.
\end{aligned}$$

When these new axioms are added, some of the original ones become derivable, and hence superfluous. The extended list of axioms can eventually be condensed into the following set of seven only:

$$\left.\begin{aligned}
&a = b \rightarrow (A(a) \rightarrow A(b)),\\
&(a < b \;\&\; b < c) \rightarrow a < c,\\
&a \neq b \rightarrow (a < b \vee b < a),\\
&a < a',\\
&a < b \rightarrow \overline{b < a'},\\
&\overline{a < 0},\\
&a \neq 0 \rightarrow (Ex)(x' = a).
\end{aligned}\right\} \quad (\mathrm{A})$$

It is proved in the *Grundlagen* that these seven axioms are independent, and further that *a formula without propositional or predicate* *variables is derivable from them if and only if it is verifiable.* This last result shows that the system (A) is both consistent and complete.

All of Peano's five axioms except the axiom of induction are derivable in the system (A), but the axiom of induction is not derivable. This last statement is certainly plausible, for the axiom of induction

$$[A(0) \,\&\, (x)(A(x) \rightarrow A(x'))] \rightarrow A(a)$$

involves a predicate variable, and the only one of the axioms (A) in which any variable other than an individual variable occurs is the second axiom for identity (J_2). A formal proof of the independence of the axiom of induction is given by Hilbert and Bernays (p. 273).

We may note, incidentally, that instead of representing the principle of mathematical induction by the axiom just given, we could equally well formalize it by a schema:

$$\frac{\begin{array}{c}\mathfrak{A}(0)\\ \mathfrak{A}(a) \rightarrow \mathfrak{A}(a')\end{array}}{\mathfrak{A}(a).}$$

The two alternative ways of incorporating the principle in the formal system can be shown to have identical deductive power (*Grundlagen*, p. 266).

If we add the axiom of induction to the set of axioms (A), some of these axioms can be weakened or omitted altogether; and we thus arrive at the following revised set of axioms:

$$\left.\begin{array}{l} a = b \rightarrow (A(a) \rightarrow A(b)),\\ \overline{a < a},\\ (a < b \,\&\, b < c) \rightarrow a < c,\\ a < a',\\ a < b \rightarrow (a' = b \vee a' < b),\\ 0 = 0,\\ [A(0) \,\&\, (x)(A(x) \rightarrow A(x'))] \rightarrow A(a). \end{array}\right\} \quad \text{(B)}$$

The two systems (A) and (B) can be shown to be equivalent *for the derivation of formulae without propositional or predicate variables*—that is to say, any such formula that is derivable in one of the systems is also derivable in the other—but the systems are not equivalent for the derivation of formulae in which propositional and predicate variables may occur. The last assertion follows from the non-derivability of the axiom of induction from the set of axioms (A).

In the system (B) we are able to derive the very important arithmetical *principle of the least number* (*Grundlagen*, p. 284), expressed by the formula

$$A(a) \rightarrow (Ex)[A(x) \,\&\, (y)(A(y) \rightarrow (x = y \vee x < y))].$$

This principle is best utilized in conjunction with the ι-symbol, which provides an explicit expression for the least number in question. Let us denote by $\mathfrak{M}(c)$ the formula

$$A(c)\ \&\ (y)(A(y) \rightarrow (c = y \vee c < y)).$$

Then the formula just quoted may be written

$$A(a) \rightarrow (Ex)\mathfrak{M}(x).$$

By means of this formula we can derive (*Grundlagen*, p. 395) the two uniqueness formulae for the formula

$$((z)\overline{A(z)} \rightarrow a = 0)\ \&\ ((Ez)A(z) \rightarrow \mathfrak{M}(a)),$$

in which a is a free variable; and we are therefore at liberty to introduce the corresponding ι-term by means of the explicit definition

$$\mu_x A(x) \equiv \iota_x[((z)\overline{A(z)} \rightarrow x = 0)\ \&\ ((Ez)A(z) \rightarrow \mathfrak{M}(x))].$$

The term $\mu_x A(x)$ is the formal counterpart of the intuitive concept 'the least number with the property A if there is any such number, and 0 otherwise'.

The theorem on the eliminability of the ι-symbol (see above, p. 95) now permits us to assert, without further discussion, that *any formula, not itself involving the μ-symbol, that can be derived from the set of axioms* (B) *with the aid of the μ-symbol is also derivable from these axioms without use of the μ-symbol.*

Looking now at the way in which the axioms (B) have been obtained, we see that all of Peano's axioms are incorporated in the formal system, either implicitly through the symbolism or directly as derivable formulae; and this may seem to imply that the system is no less comprehensive than Peano's arithmetic. Such a conclusion is unwarranted, however, since Peano's treatment of arithmetic is actually based on more than the bare axioms. In the *Formulaire* extensive use is made of definitions, and we have already noted (p. 147) that as well as explicit definitions, which serve merely to introduce abbreviations, there are also *recursive definitions*, which are definitions in quite another sense and which make substantial additions to the system.

A recursive definition of a function $\mathfrak{f}(n)$ of one variable takes the form of a pair of equations

$$\mathfrak{f}(0) = \mathfrak{a},$$
$$\mathfrak{f}(n') = \mathfrak{b}(n, \mathfrak{f}(n)),$$

where $\mathfrak{a}$ is a term that does not involve any variable, $\mathfrak{b}(x,y)$ is a term that involves the variables x and y only, and neither $\mathfrak{a}$ nor $\mathfrak{b}(x,y)$ involves the function $\mathfrak{f}(-)$. For a function $\mathfrak{f}(a, \ldots, k, n)$, with parameters $a, \ldots, k$, the definition takes the more general form

$$\begin{aligned} \mathfrak{f}(a, \ldots, k, 0) &= \mathfrak{a}(a, \ldots, k), \\ \mathfrak{f}(a, \ldots, k, n') &= \mathfrak{b}(a, \ldots, k, n, \mathfrak{f}(a, \ldots, k, n)). \end{aligned}$$

The adoption, within a given formal system, of a particular recursive definition always adds to the formal resources which the system provides, that is to say to the available means of symbolic expression, since we thereby acquire a new function-symbol; but it does not necessarily render the system any more comprehensive. We need, therefore, to distinguish between essential and non-essential extension of a formal system, the extension occasioned by a particular recursive definition being regarded as non-essential if the new function is one already representable in some alternative way in the original system. It is clearly important to give precise metamathematical meaning to the notion of formal representability of a function, and Hilbert and Bernays adopt the following definition (p. 352):

DEFINITION. Let a new function of one or more variables be adjoined to a given formal system by the introduction of a function-symbol $\mathfrak{f}(a, \ldots, k)$, together with associated formulae which permit calculation of the value of the function for any assigned numerical values of its arguments. The function is said to be *representable* in the original system if there is a formula $\mathfrak{A}(a, \ldots, k, l)$ of the system such that, for every substitution of numerical values $\mathfrak{a}, \ldots, \mathfrak{k}, \mathfrak{l}$ for the variables $a, \ldots, k, l$, the formula $\mathfrak{A}(\mathfrak{a}, \ldots, \mathfrak{k}, \mathfrak{l})$ is derivable if $\mathfrak{l}$ coincides with the value of $\mathfrak{f}(\mathfrak{a}, \ldots, \mathfrak{k})$ and the formula $\overline{\mathfrak{A}(\mathfrak{a}, \ldots, \mathfrak{k}, \mathfrak{l})}$ is derivable otherwise.

It can be shown (*Grundlagen*, p. 356) that the sum function $a + b$, which is definable by the equations of recursion

$$\begin{aligned} a + 0 &= a, \\ a + n' &= (a + n)', \end{aligned}$$

is not representable in the system (B). We accordingly take '+' as a new primitive symbol and incorporate this recursive definition in the system of axioms; and the usual sort of reorganization then leads to the following strengthened system:

$$\left.\begin{aligned} & a = a, \\ & a = b \rightarrow (A(a) \rightarrow A(b)), \\ & a' \neq 0, \\ & a' = b' \rightarrow a = b, \\ & a + 0 = a, \\ & a + b' = (a + b)', \\ & [A(0) \mathbin{\&} (x)(A(x) \rightarrow A(x'))] \rightarrow A(a). \end{aligned}\right\} \quad \text{(D)}$$

The system (D) does not contain '$<$' among its primitive symbols, but the predicate $a < b$ can be introduced by explicit definition, thus:

$$a < b \leftrightarrow (Ex)(x \neq 0 \; \& \; a + x = b).$$

The new system, as we have said, is stronger than the old; but once again we are able to assert that the system that we have before us is both consistent and complete. The process of reduction that we used before can be modified in such a way that it applies to formulae in (D), and we can then show that the totality of verifiable formulae of this system coincides with the totality of derivable formulae.

The assertion that the systems (B) and (D) are both complete, although the second is demonstrably wider than the first, has an air of paradox. There is not really any conflict, however, since completeness, as we have been interpreting this term, is always relative to the symbolic resources of the system concerned. And, even though the system (D) is complete in this internal sense, it is still far from complete as a formalization of intuitive arithmetic. We can show, in fact, that the product function $a.b$ is not representable in (D) (*Grundlagen*, p. 369). We accordingly add the symbol '$.$' and the relevant equations of recursion to the primitive elements of the system (D), passing thus to the following extended system of axioms:

$$\left.\begin{array}{l}
a = a, \\
a = b \rightarrow (A(a) \rightarrow A(b)), \\
a' \neq 0, \\
a' = b' \rightarrow a = b, \\
a + 0 = a, \\
a + b' = (a + b)', \\
a.0 = 0, \\
a.b' = a.b + a, \\
[A(0) \; \& \; (x)(A(x) \rightarrow A(x'))] \rightarrow A(a).
\end{array}\right\} \quad \text{(Z)}$$

Although the passage from (D) to (Z) appears to be of exactly the same kind as that from (B) to (D), involving nothing but the addition to the existing axioms of the recursive definition of one new function, this latest extension of the formalism in reality produces an entirely new situation. With addition and multiplication both at our disposal, we are now able to formalize the whole of the elementary theory of numbers, and we can in consequence represent in the system (Z) various propositions concerning the natural numbers that are as yet undecided, and that may even be undecidable by elementary means.

A famous undecided conjecture is Goldbach's hypothesis, according to which every even integer greater than 2 is expressible as a sum of two prime integers. In order to translate this assertion into the symbolism of the system (Z), we first of all formalize the propositional function 'n is prime' by defining a predicate $\mathfrak{Pr}(n)$ explicitly as follows:

$$\mathfrak{Pr}(n) \leftrightarrow n \neq 0 \;\&\; n \neq 0' \;\&\; (u)(v)((u \neq 0' \;\&\; v \neq 0') \rightarrow u.v \neq n).$$

Then we can express Goldbach's hypothesis in the form

$$(x)[0' < x \rightarrow (Ey)(Ez)(\mathfrak{Pr}(y) \;\&\; \mathfrak{Pr}(z) \;\&\; 0''.x = y + z)].$$

A second well-known conjecture concerning prime numbers is that there are infinitely many prime-pairs, or pairs of prime numbers which differ by only 2. It comes to the same thing to assert that there are arbitrarily large prime-pairs, and so we arrive at the formula

$$(x)(Ey)(x < y \;\&\; \mathfrak{Pr}(y) \;\&\; \mathfrak{Pr}(y'')).$$

The very fact that the formal system (Z) is wide enough to allow such translations into its symbolism to be made, which indicates that we are at last within sight of completeness of a mathematically interesting kind, signalizes also the breakdown of the method for proving consistency that has been applicable up to this point. That method depended on the existence of a process of reduction which could be used to define verifiability; and the effect of reduction was to convert any formula, without essential change of its intuitive truth-content, into a formula that could be handled by finitary means. Now since there are, among the formulae of the system (Z), some which correspond to problems in arithmetic that have for centuries defied all efforts to solve them, it seems very unlikely that any process of reduction for this system can be found.

The failure for the system (Z) of one particular method for proving consistency does not of itself imply that no finitary proof of consistency can be given for this system; but such is in fact now known to be the case on other grounds. One of the most famous theorems in metamathematics, proved in 1931 by Kurt Gödel, placed this virtually beyond doubt, and so brought to an abrupt end the phase of the development of formalism that we have been discussing in this chapter. The work of Gödel on the limitations of formalism is the topic of the chapter that now follows.

SUPPLEMENTARY NOTES ON CHAPTER 7

1. *Foundations of projective geometry.* The study of foundations of mathematics can be interpreted in a restricted sense, as an examination of the logical structure of deductive systems, or more widely, as a partly historical and partly critical consideration of the development of mathematical concepts and methods. From the latter point of view the history of projective

geometry is especially instructive, because of the progressive change of outlook that has taken place as this subject has become more thoroughly understood.

The story of projective geometry begins with Gérard Desargues (1593–1662), who in 1639 published his essay *Brouillon proiect d'une atteinte aux éuénemens des rencontres d'un cone auec un plan* [Sketch of an inquiry into the results of the intersection of a cone with a plane]. In this work Desargues introduced a number of ideas characteristic of projective geometry, as for instance point at infinity, pole and polar, and involution of pairs of points on a line. His argument, however, was too abstruse for all but one or two mathematicians of the time, and the essay was soon entirely forgotten.

After a lapse of nearly two centuries, projective geometry was studied again, independently of Desargues, by Jean-Victor Poncelet (1788–1867). A military engineer by profession, Poncelet served with Napoleon's army; and when he eventually published his geometrical discoveries, in his *Traité des propriétés projectives des figures* (1822), he remarked of the book that it was 'the outcome of the investigations which I have carried on, since the spring of 1813, in the prisons of Russia'. In this book Poncelet developed the conception of duality, making use of the transformation by reciprocal polars determined by a fixed conic; and he also introduced (in an intuitive manner) such completely new ideas as that of the circular points at infinity.

A more systematic, though no less original contribution to projective geometry was made by August Ferdinand Möbius in *Der barycentrische Calcul* (1827). Möbius devised a way of representing the points of the plane (or of space) by homogeneous coordinates referred to an arbitrarily selected triangle (or tetrahedron) of reference—a way, moreover, that is essentially projective and that permits projective relationships to be expressed simply in algebraic terms. He defined cross ratio (as a quotient of position ratios) and he established the main properties of this important invariant. He also studied the 'net' of points—now known as a *Möbius net*—which is obtained from the vertices of a quadrangle when the two operations of joining two points of the plane by a line and taking the point of intersection of two given lines are repeated indefinitely often; and he was able to show that (i) in any coordinate system based on three of the vertices of the quadrangle as fundamental points and the remaining vertex as unit point, the points of the net are precisely those points which have rational coordinates, and (ii) every neighbourhood of any given point of the plane contains points of the net.

Up to this stage in its history, projective geometry had been conceived as just one particular division of the study of figures in ordinary space, namely that part which deals exclusively with relationships that are projectively invariant; but now a more radical way of treating the subject emerged in the work of Georg Karl Christian von Staudt (1798–1868), who was professor of mathematics at Erlangen. Realizing that projective geometry is essentially non-metrical, von Staudt determined to treat it from the outset as a 'geometry of position'; and he carried this project through in his *Geometrie der Lage* (1847) and *Beiträge zur Geometrie der Lage* (1856–1860). He began with an intuitively conceived space, in which the concepts of straight line and plane had meaning, but no concept of distance was introduced; and he then attempted to build up the whole of projective geometry in terms of relations of incidence. He had no means of introducing the metrical notion of cross ratio, but he was nevertheless able to define the harmonic relation by the quadrangle construction and then to make use of the properties of the Möbius net. He defined two ranges of points (and similarly two two-dimensional or three-dimensional systems) to be projectively related when there is a correspondence between them which is such that harmonic tetrads correspond always to harmonic tetrads. Appealing to considerations of continuity, he then attempted to justify the fundamental theorem that a projectivity between ranges is uniquely determined by three corresponding pairs; but in this one particular he went slightly wrong, since the argument that he used is invalid unless the line can be asserted to be a continuum in the sense of Dedekind. The need for a special postulate to ensure this was pointed out in 1873 by Felix Klein, then in his turn professor at Erlangen.

Von Staudt's methodological principle that since projective geometry is logically independent of notions of spatial magnitude it ought to be developed non-metrically gained general acceptance; and towards the end of the nineteenth century many attempts were made to improve still further on the rigour of von Staudt's treatment by making the presentation strictly axiomatic. An early contribution to this movement was made by Moritz Pasch, in his *Vorlesungen über neuere Geometrie* (1882). Although Pasch believed that geometry ought to be grounded in intuition—and in consequence of this belief he chose to begin his treatment with finite linear segments rather than with straight lines of infinite extent—he considere the same time that the logical basis of the deductive system must be absolutely precise. He accordingly based the development on a numbe *Kernsätze*, in which were expressed the fundamental facts concerning incidence. Other mathematicians (in particular Peano and Hilbert) soon went further still, recognizing that the logical structure of geometry is in fact independent of intuition. They saw, in other words, that only *abstract* primitive notions and primitive propositions are needed, and that geometrical theorems are valid for all systems of entities that satisfy the appropriate axioms.

The formal properties of the relation of incidence constitute the most elementary part of projective geometry; and when incidence geometry is presented axiomatically it is seen to be a common substructure of many different systems of geometry, for instance of euclidean geometry and of the non-euclidean geometries as well as of projective geometry. In particular, metrical geometries can be obtained when a suitable theory of congruence is set up. For this aspect of the foundations of geometry see Hilbert [2] and Whitehead [2, 3].

A very careful investigation of the minimal assumptions that will suffice for the construction of a system of projective geometry of n-dimensional space was made by Gino Fano in a paper 'Sui postulati fondamentali della geometria proiettiva', published in 1891. Fano showed that an explicit existential postulate is necessary in order to ensure that a line always contains more than two points, and that a further postulate is then necessary in order to ensure that points are not always their own harmonic conjugates. He did this by setting up models for which the postulates in question fail to hold, showing, for instance, that a two-dimensional projective geometry is possible in which there are only seven points, lying in threes on seven lines.

A complete axiomatic presentation of projective geometry, worked out with the aid of Peano's logical symbolism, but retaining few of the symbols in the published version, is contained in a paper of Mario Pieri, 'I principii della geometria di posizione composti in sistema logico deduttivo' (1899). Pieri's system is based on two primitive notions (point and the join of two points) and nineteen primitive propositions or postulates. The earlier postulates are concerned with properties of incidence, while the later ones deal with the relations which give rise to an order of the points of a line; and among these later postulates there is one which ensures that the line is a continuous series in the sense of Dedekind. Pieri considers that his set of postulates is complete, since he is able to derive all the principles used by von Staudt, and von Staudt has already derived the further theorems of projective geometry in detail, and has shown moreover that his points can be represented by real coordinates.

The attempts to make projective geometry rigorous that we have mentioned so far have all set out from a totality of 'geometrical' points, either supposed given intuitively or else postulated as primitive; but an analytical approach is also a possibility, and this has on the whole been preferred in recent times. The relation between the two possible approaches may be expressed in the following way. In a synthetic treatment such as that of Pieri, coordinates may be introduced by von Staudt's method. Rational coordinates are first of all determined for all the points of a Möbius net, and then real coordinates are determined by continuity for all other points. When this is done, points become in effect pairs of ratios $x:y:z$ of real numbers. But the same result would have been obtained more directly if a point had initially been *defined* as such a pair of ratios, a straight line as the totality of points which satisfy a given homogeneous equation, and so forth; and this is precisely the analytical approach.

When all geometrical entities are defined algebraically, it appears that there is no theoretical necessity for the coordinates to be *real* numbers, since the algebraic development requires only that they should be drawn from a field. Every field F thus yields corresponding spaces of 2, 3, or n dimensions; and if F happens to be a Galois field $GF(p^s)$, with only a finite number of elements, the corresponding projective spaces have each only a finite number of points. Since there are infinitely many Galois fields, one for each prime-power p^s, there are infinitely many finite projective geometries of given dimensionality. In the simplest case of all, when the ground-field is $GF(2)$, the projective plane has seven points, and projective space of three dimensions has fifteen. The finite geometries were first discussed in relation to Galois fields by Veblen and Bussey [1] in 1906.

2. *Models of non-euclidean geometry.* A brief account of the models of Klein and Poincaré for two-dimensional hyperbolic geometry is given by

Courant and Robbins, [1], pp. 219–224. Poincaré's model is mentioned also by Pedoe, [1], p. 58.

Klein developed the ideas involved in his model in his fundamental paper 'Über die sogenannte Nicht-Euklidische Geometrie' (1871), and they are treated very fully in his book *Vorlesungen über Nicht-Euklidische Geometrie* (1928). Hyperbolic geometry results when, in the real projective plane, a non-virtual conic is taken as absolute conic and only the points of its interior (i.e. those points from which no real tangent can be drawn) are treated as actual points. Angular measure can be introduced by the natural generalization of Laguerre's formula for euclidean geometry, with the proper absolute conic taking the place of the absolute point-pair (I,J); and distance can be defined in terms of cross ratio by the dual procedure. Collineations which leave the absolute conic invariant can then be interpreted as non-euclidean rotations. If a virtual conic is taken instead of a non-virtual one as the absolute conic, an elliptic metric is obtained instead of a hyperbolic metric.

3. *The literature of Hilbert's metamathematics.* Whereas Hilbert's *Grundlagen der Geometrie* has been translated into English (see the Bibliography), the *Grundlagen der Mathematik* of Hilbert and Bernays, which supplies the definitive account of Hilbert's later metamathematical work, at present exists in German only. Much of the substance of this book is contained, however, together with material from other sources, in Kleene's *Introduction to Metamathematics*. Kleene's book is also provided with a full and very useful bibliography.

Hilbert's many-sided contribution to mathematics, and his enormous influence on the creative work of other mathematicians, form the subject of a long commemorative article 'David Hilbert and his mathematical work', contributed by Hermann Weyl to the *Bulletin of the American Mathematical Society*, **50** (1944), 612–654. Weyl gives a clear and concise summary of Hilbert's achievement in each of the many fields in which he worked. There is a shorter notice by Weyl in the *Obituary Notices of Fellows of the Royal Society*, **4** (1942–1944), 547–553, and this also conveys clearly the unique position of Hilbert in the mathematical world of his time.

tremely useful and even indispensable from the didactic point of view in the early teaching of the calculus if too much time is not to be lost. But no one will deny that this way of introducing the calculus can make no claim to being systematic. My feeling of dissatisfaction at that time was so overwhelming that I firmly resolved to go on reflecting until I had found a purely arithmetical and absolutely rigorous basis for the principles of the calculus. It is so often said that the calculus deals with continuous quantities, and yet no explanation of this continuity is ever given, and even the strictest presentations of the calculus do not base their proofs on continuity, but either appeal more or less consciously to geometrical or geometrically inspired ideas or else make the proofs rest on theorems which are never themselves proved arithmetically. One such theorem is the one that I have mentioned, and closer investigation convinced me that this or any equivalent theorem can be taken as a sufficient foundation for infinitesimal analysis. It only remained to discover its origin in the elements of arithmetic, and so at the same time to obtain a real definition of the essence of continuity. This I succeeded in doing on 24 November 1858. . . .'

Dedekind found the solution of the problem that had been troubling him in his new definition of real numbers as sections of the ordered set of rational numbers, and in his theorem that to every section of the ordered set of real numbers there corresponds a real number. This is only one example of the fundamental work that he did in giving strictly conceptual definitions of mathematical ideas that had hitherto been vague or intuitive. Another example is his replacement of Kummer's fictitious ideal factors, in the theory of algebraic number fields, by ideals, in the now familiar sense, defined as certain sets of actual numbers (see Note 2, p. 153).

We shall have occasion to say more about Dedekind in the next chapter (p. 158), when we discuss the logical analysis of mathematical concepts, but here we must turn to another great pioneer in the field of foundations of mathematics, Giuseppe Peano.

5 Peano's 'Formulaire de Mathématique'

Even though Dedekind had a more lively interest in questions of logical analysis than men such as Cauchy and Weierstrass, who were only concerned with logic in so far as it was involved in their purely mathematical work, he was still essentially a mathematician, and not a logician or a philosopher. But a turning point in the whole critical movement was reached with Peano, who, after having begun his career as a critical mathematician of a somewhat similar type to Dedekind, devoted himself specifically to the study of foundations of mathematics for its own sake. For this reason alone, Peano must be looked upon as a pivotal figure in the history of this particular branch of study. His was, moreover, an unusual and engaging personality; and since some knowledge of the man is necessary for the proper understanding of his thought, we give here a few biographical details.

Giuseppe Peano was born in 1858 (the very year of Dedekind's great discovery) and died in 1932, having spent almost the whole of his life at Turin, where for many years he was professor of infinitesimal analysis. He had wide mathematical interests, as well as major interests outside mathematics, and the number of his published papers exceeds two hundred. Although he was a meticulous scholar, who always liked, for example, to trace statements and discoveries to their original sources, he was no pedant; and he is also said to have been a remarkably enthusiastic and inspiring teacher. He never tired of trying to persuade other teachers that they fail in their task unless they are able to make every fact which they have to communicate come to life in the student's mind, so that he sees it as something directly relevant to his own thinking.

Peano's career falls naturally into three phases, since his chief interest was successively in the infinitesimal calculus, in foundations of mathematics, and in linguistic studies; but all three preoccupations were in some measure with him throughout his life.

Like Dedekind, Peano was made aware of the need for a higher standard of rigour in mathematics by his experience of teaching the infinitesimal calculus. His first book[1]—which he published under the name of Angelo Genocchi, his revered former teacher at Turin—was a treatise on the calculus, of the customary form but very much improved in the details of the exposition. In all his mathematical work Peano strove towards a twofold ideal of simplicity and rigour, and his book on the calculus is exemplary in both these respects. Beginning with a strict definition of real number, essentially that of Dedekind, he develops the calculus systematically, formulating every theorem with the greatest possible accuracy and precision, and strictly avoiding in the proofs any illegitimate appeal to intuitive properties of curves. When the customary enunciations of theorems are too loose, or conditions that need to be satisfied are not as a rule clearly stated, Peano often constructs counter-examples to show that assertions made in standard textbooks are incomplete or erroneous.

Both Peano and Dedekind traced much of the still prevalent lack of rigour in analysis to unwarranted reliance upon intuition. The languages of analysis and geometry are to some extent translatable into each other, by reason of the connexion between functions and their graphs, but their equivalence is by no means as complete as has often been supposed. At a comparatively naive level of mathematical thinking (corresponding historically to the state of mathematics before the beginning of the critical movement), where the concepts of function and curve are interpreted in a common-sense way, it is reasonable to regard these concepts as interchangeable. As a result of the critical movement, however, the concepts of number and function are now no longer intuitive, and they have been found to require elaborate logical definition. If, therefore, we reason intuitively about curves—arguing, for example, that if a continuous curve has points on both sides of a straight line then it must 'obviously' have at least one point of intersection with the line—we are not justified in translating our conclusions into statements about functions in the sense in which they are now understood in analysis. Since the concepts of analysis are abstract concepts, having strictly logical definitions, we can only prove the theorems of analysis by arguing exclusively from these definitions. The intuitive properties of graphs may suggest to us new analytical theorems, and they may also make existing theorems more readily intelligible, but they can never be grounds of proof.

---

[1] A. Genocchi: *Calcolo differenziale e principii di calcolo integrale, pubblicato con aggiunte dal D.r Giuseppe Peano* (Turin, 1884).

Peano gave a striking illustration of the way in which intuitively evident conclusions may cease to be valid if the concepts involved in them are idealized theoretically when he devised his famous space-filling curve. He published this discovery in a short paper entitled 'Sur une courbe, qui remplit toute une aire plaine' (*Math. Ann.*, **36** (1890), 157–160), introduced as follows:

> 'In this note we determine two one-valued and continuous functions x and y of a single (real) variable t, which, as t varies in the interval (0,1), take all pairs of values such that $0 \leqslant x \leqslant 1$, $0 \leqslant y \leqslant 1$. If, in accordance with custom, we use the term *continuous curve* for the locus of those points whose coordinates are given continuous functions of one variable, we obtain in this way a curvilinear arc which passes through all the points of a square. Hence, if an arc of a continuous curve is given, about which nothing further is assumed known, it is not always possible to enclose the arc in an arbitrarily small area.'

It is thus clearly demonstrated that idealization of the notion of function makes impossible the retention of the simple intuitive notion of the dimensionality of a set of points. Details of the functions which Peano used in the definition of his curve are to be found in Note 1, p. 152, at the end of the present chapter.

As a result of his work on the properties of functions, Peano arrived at the conclusion that, in the refounding of mathematics, half-measures are useless. It is of no avail to tinker with common sense and intuition; for we are now committed to defining such notions as number and function in a more formal way, and this means that intuitive mathematics and abstract mathematics have entirely different presuppositions. As mathematicians, therefore, we must renounce intuition altogether, and develop mathematics strictly by its own proper means. With the clear recognition of this principle, Peano entered upon the second phase of his career, devoted to the transformation of mathematics into a self-contained formal system.

Peano followed the ancient Greek precedent in presenting his system of mathematics in demonstrative form; but his abandonment of intuition as a sufficient foundation made it necessary for him to modif the Greek method in several essential respects. In the first place, th entities to be considered—numbers, functions, points, etc.—are neithe entities given in intuition nor entities whose properties are dependen on their being idealizations of something given in intuition (althoug they may in fact have originated in that way); and it follows from this that they must all be either postulated or defined. Again, since mathematics is to be logically independent of intuition the axioms of the demonstrative system cannot be justified by appeal to self-evidence. They too must be simply postulated, and they neither require nor admit of any further justification within the formal theory. When once the entities in the system and their initial properties have been postulated, the theorems must all be derived by purely logical processes; and here it is particularly necessary to guard against involuntary appeal to intuition. To this end Peano introduced two safeguards, each of which inaugurated an enduring tradition in the study of mathematics and its foundations. In the first place, he renounced ordinary language and determined to rewrite mathematics entirely in terms of a new symbolism. He had a number of reasons for doing this—the fact that ordinary language is often imprecise, and that its structure does not always match the structure of mathematical demonstration; the desirability of using entirely neutral symbols, so that there is no danger of appealing tacitly to the intuitive associations of common words (as the older analysts were led to do when they inferred properties of functions from those of curves); and the universality of mathematical symbolism, as compared with the diversity of national languages. And secondly, he formalized the logic of mathematical argument as well as the language in which mathematics is expressed, undertaking for this purpose the task of replacing intuitive inference by application of a limited number of stated logical rules. In other words, he constructed and used a symbolic logic, by the aid of which the inferring of a conclusion from premisses was replaced by the derivation of one symbolic expression from other such expressions by quasi-algebraic calculation.

The new form that the theories of pure mathematics were to assume, then, was of the following nature. Each theory would involve a small number of primitive ideas, to be represented by suitably chosen symbols; and these ideas would be left undefined, simply being enumerated at the beginning of the exposition. There would also be a small number of primitive propositions, containing the primitive ideas, which would likewise be enumerated. Development of the theory would be wholly by derivation of symbolically formulated propositions, either from the primitive propositions themselves or from propositions already derived, in accordance with the stated principles of symbolic logic. New entities might be introduced in the course of the development, either by explicit definition as some particular combination of given entities or, in the case of arithmetic, by the special process of 'recursive definition' (see p. 147).

The work of formalization of mathematics involved the rewriting of existing theories in symbolic form, and it also involved a great deal of amplification and reorganization of the deductive sequence in order to make the system conform to the new logical canons, which were much more exacting than any that had been recognized previously. This vast work was carried out by Peano, in collaboration with a number of colleagues and assistants, and the results were published in the *Rivista di Matematica* and the *Formulaire de Mathématique*. The first of these two publications was a journal, founded by Peano in 1891 for the dissemination of the results obtained in his circle, and published until 1906, while the second was a cumulative exposition of the whole system as worked out to date.

The *Formulaire* appeared in five successive editions or volumes. The series began in 1894, with an introductory pamphlet entitled 'Notations de logique mathématique. Introduction au Formulaire de Mathématique', and in 1895 there followed the first full volume of the *Formulaire* itself, in nine sections written by Peano and his collaborators: I. Mathematical logic; II. Algebraic operations; III. Arithmetic; IV. Theory of magnitudes (*grandeurs*) [Burali-Forti]; V. Classes of numbers; VI. Theory of sets (*ensembles*) [Vivanti]; VII. Limits [Bettazzi]; VIII. Series [Giudice]; IX. Contributions to the theory of algebraic numbers [Fano]. The second volume of the *Formulaire* was published in three parts in 1897, 1898, and 1899; and the third, fourth, and fifth volumes appeared respectively in 1901, 1902–1903, and 1908.

The relation between the different volumes is confused, since these are neither complementary volumes of a single work, like the three volumes of *Principia Mathematica*, nor successive editions of one and the same work. Central topics, such as mathematical logic and arithmetic, are treated again and again, now briefly and now at much greater length, but peripheral theories may appear only once, when first formalized. Thus the earlier volumes are not altogether superseded by the later ones, although the different volumes overlap to a considerable extent.

The version of the *Formulaire* that we shall discuss here is that of 1901, which is arranged in the following five parts: I. Mathematical logic; II. Arithmetic; III. Analytic functions; IV. Complex numbers; V. Vectors.

The section on mathematical logic is now of no more than historical interest; for Peano did not develop symbolic logic beyond a comparatively rudimentary stage, and the propositional calculus and the calculus of predicates, as formalized by him, were first worked out in full detail, as we shall describe in Chapter 6, by Russell and Whitehead in *Principia Mathematica* (1910). Nevertheless, the credit for introducing the essential notions and symbols belongs to Peano, as Russell himself has freely acknowledged. Peano used letters to denote propositions and propositional functions, devised notations[1]—of which some are still in use, while others have now been supplanted—for the logical constants 'not', 'implies', 'implies for all x', etc., and pointed out the fundamental significance of the relation of class-membership, reserving for it the initial letter of the Greek word ἐστί (*is*).

Apart from the section devoted to logic, the most important of the five divisions of the *Formulaire* of 1901 is undoubtedly the second one, on arithmetic. To this formulation of the basic properties of numbers (which owes much to Dedekind's essay *Was sind und was sollen die Zahlen?*, to be discussed in §2 of the next chapter) almost all subsequent work on the foundations of arithmetic can ultimately be traced back. Peano bases his treatment on three primitive ideas:

(i) N_0, the class of natural numbers;
(ii) 0, the particular number zero;
(iii) $a+$, the successor of the number a.

There are six primitive propositions, which we may write in a slightly modernized form as follows:

(i) $\mathrm{N}_0 \in \mathrm{Cls}$;
(ii) $0 \in \mathrm{N}_0$;
(iii) $a \in \mathrm{N}_0 \rightarrow a+ \in \mathrm{N}_0$;
(iv) $[s \in \mathrm{Cls}\ \&\ 0 \in s\ \&\ (x)(x \in s \rightarrow x+ \in s)] \rightarrow \mathrm{N}_0 \subset s$;
(v) $(a,b \in \mathrm{N}_0\ \&\ a+ = b+) \rightarrow a = b$;
(vi) $a \in \mathrm{N}_0 \rightarrow a+ \neq 0$.

With the exception of (i), which belongs more to Peano's way of presenting arithmetic than to arithmetic itself, these primitive propositions are simply the well-known 'Peano axioms' for the natural numbers.[1] They may be expressed in familiar language as follows: (i) N_0 is a class; (ii) 0 is a number; (iii) The successor of any number is a number; (iv) If a class s is such that (a) it contains 0, and (b) if it contains any number a then it also contains the successor $a+$ of that number, then s includes the whole of N_0; (v) No two numbers have the same successor; (vi) 0 is not the successor of any number.

---

[1] Peano, and Russell likewise, wrote 'p implies q' as '$p \supset q$'. Peano also wrote '$p\,.\!\supset_x.\,q$' to mean 'for all x, p implies q', where p and q are propositional functions involving the variable x; and Russell continued to use this notation, in the more explicit form '$\phi x \supset_x \psi x$', as an alternative to '$(x)\,.\phi x \supset \psi x$'. Hilbert subsequently replaced '$\supset$' by '$\rightarrow$', at the same time discontinuing the use of subscripts to indicate universal quantification. For 'x is a member of a' Peano wrote '$x \varepsilon a$'. and for 'the class of entities x which satisfy the propositional function p' he wrote '$x \ni p$'. Russell changed this last usage to '$\hat{x}(\phi x)$'.

The fourth of the primitive propositions is the axiom of induction, whose function in the system is to formalize the demonstrative procedure known as *mathematical induction*. This is the mode of argument that we commonly use in demonstrating a theorem $\mathfrak{A}(n)$, the statement of which involves an undetermined integer n as a parameter. We prove (a) that $\mathfrak{A}(0)$ holds, and (b) that if $\mathfrak{A}(n)$ holds then so also does $\mathfrak{A}(n+)$; and we then conclude that $\mathfrak{A}(n)$ is valid for every value of n. Proof by mathematical induction is fundamental to Peano's whole system, and indeed it is the only specifically arithmetical form of argument that is provided by the primitive propositions. In the working out of the system, Peano also makes essential use of the constructive counterpart of this demonstrative procedure, namely *recursive definition*. An arithmetical function $\mathfrak{f}(n)$ is said to be defined recursively if (a) an explicit definition of $\mathfrak{f}(0)$ is given, and (b) $\mathfrak{f}(n+)$ is defined in terms of $\mathfrak{f}(n)$ by means of functions that are already available. Interpreted intuitively, a recursive definition of $\mathfrak{f}(n)$ plainly provides a means of determining in succession the values $\mathfrak{f}(0)$, $\mathfrak{f}(1)$, $\mathfrak{f}(2), \ldots$ of the function. Peano uses the method in order to define the arithmetical sum and product, $a + b$ and $a \times b$, doing this in each case by recursion with respect to b:

$$a + 0 = a, \qquad a + (b+) = (a + b)+,$$

and

$$a \times 0 = 0, \qquad a \times (b+) = (a \times b) + a.$$

The familiar associative, commutative, and distributive laws can now be established in the formal system, and much of the elementary theory of numbers is then readily derivable by formal means.

Having proceeded thus far with the systematic construction of his system of arithmetic, Peano goes on to indicate much more briefly how rational numbers and real numbers can be obtained formally from the natural numbers; and he then turns, in the next two sections of the *Formulaire*, to a consideration of various topics in elementary analysis.

---

[1] In the literature, the 'natural numbers' are taken sometimes as 0, 1, 2, ... and sometimes as 1, 2, 3, ... Peano began the series with 0, and Hilbert adopted the same convention. Dedekind, on the contrary, took 1 as the first natural number, and this is now the normal practice in mathematics. The choice between the two possible conventions is of no theoretical importance, and we shall ordinarily conform to the usage of the author whose work we are discussing.

The concluding section of the work, which has the heading 'Vectors', is devoted to geometry.

Geometry was indeed yet another subject to which Peano gave a considerable amount of attention, and on which he even wrote a separate book[1]; but although his work on geometry is by no means without interest, it is of much less significance in the history of foundations of mathematics than his contribution to arithmetic. It arose out of the dissatisfaction which he, in common with certain other nineteenth-century mathematicians, felt with the way in which modern geometry had developed. The use of cartesian coordinates had made geometry less elementary than it was in classical times, and also, by rendering it dependent on processes of calculation, had reduced to a minimum its intuitive content. But the cartesian method relies on the introduction of a set of arbitrarily chosen axes, having no connexion with the figure under investigation; and during the nineteenth century several attempts were made to perfect a symbolic calculus which would apply more directly to geometrical entities, without intervention of an extraneous frame of reference. Möbius with his barycentric calculus (1827), Hamilton with his quaternions (1843), and Grassmann with his *Ausdehnungslehre* or calculus of extension (1844 and 1862) had all made contributions to this movement; and prompted by their example, Peano gave a new formal treatment of certain parts of geometry by means of a calculus of vectors, similar to the system now widely used in theoretical physics.

The adoption of vectorial ideas in physics and applied mathematics is not, however, due directly to Peano's influence, since the use of vectors was developed independently of him by Josiah Willard Gibbs (1839–1903) and Oliver Heaviside (1850–1925); and already in 1881 Willard Gibbs had some notes on vectors printed for circulation among his students. And even in the field of geometry, Peano's vectorial treatment has perhaps become something of a historical curiosity,[2] for geometry has in the meantime developed along quite other lines, becoming less and less dependent on geometrical intuition of any kind. Differential geometry is now handled, in fact, by the calculus of tensors, and algebraic geometry by means of a coordinate representation over a postulated ground-field, which makes possible the application to it of the no less powerful methods of modern algebra and topology.

In his later years Peano turned away from mathematics and its foundations, and devoted almost all of his time and energy to the task of winning support for a new international auxiliary language, Interlingua, that he had invented. His interest in linguistic studies had already been awakened much earlier in his career, and this part of his activity, seemingly remote from mathematics, made a far from negligible contribution to the success of his mathematical and logical researches.

---

[1] G. Peano: *Calcolo Geometrico, secondo l'Ausdehnungslehre di H. Grassmann, preceduto dalle operazioni della logica deduttiva* (Turin, 1888).

[2] This is not to say that it must always remain so. New ideas in mathematics are not always significant in the way that their originators intend, and history shows that an apparently barren innovation may become abundantly fruitful when a later age provides it with fresh soil.

Peano had expert knowledge of classical languages, as well as a lively interest in comparative philology. At one time he made a number of attempts to reduce the grammatical structure of various languages to essentially mathematical form, in order to see if he could find any common structure belonging to all languages, and so, perhaps, inherent in language as such. He became convinced in the end that no such structure exists, and that both grammar and idiom are wholly dependent on the fortuitous circumstances of history. As time went on, he became more and more concerned with communication in its various aspects. The problems presented by communication of abstract or mathematical knowledge were manageable, and Peano solved them so successfully that his symbolic methods led directly to the creation of modern mathematical logic. Communication of more concrete experience—thoughts, impressions, emotions, etc.—is very much more difficult, since the substance of what is to be communicated can exhibit infinite variety, and so linguistic representation of elements in experience can only be approximate. In many of its functions, language is evocative rather than representational; but even in so far as it is representational its effective use is much impeded by the existence of a multiplicity of different national forms. In his mathematical writing, addressed to mathematicians at large, Peano changed over early on from his own language of Italian to French, which is more widely known; but even French is not fully international, and he looked back with regret to the time, not so very distant, when Latin had been the universal language of scholars.[1] In his day, unfortunately, comparatively few people could write Latin, and the difficulty of the language was a bar to its revival; but the idea came to him that most of the difficulty could be avoided by the simple expedient of dispensing with the complexity of Latin grammar (which is in any case historically fortuitous, and in no way essential to the language as a medium of communication). Peano thus arrived at his auxiliary international language of *latino sine flexione*, afterwards named *Interlingua*. The vocabulary is that which is to be found in any Latin dictionary, and there is virtually no grammar. Nouns are undeclined and verbs unconjugated, every noun taking the invariable form of the Latin ablative singular and every verb that of the singular imperative. Case is indicated, as in many modern languages, by means of prepositions, and tense by means of adverbs. In his later mathematical publications, Peano consistently used Interlingua. The *Rivista di Matematica* was then called *Revista de Mathematica*, and when the final version of the *Formulaire* appeared in 1908 it was as *Formulario Mathematico*.

---

[1] In 1889 there had in fact appeared an essay of twenty-nine pages, written in Latin, with the title *Arithmetices Principia nova methodo exposita, a Ioseph Peano.*

It emerges clearly, even from the present superficial account of his work, that Peano was a man of quite remarkable originality—original not merely in his ability to carry out mathematical research of the customary kind, but even more in his capacity for detaching himself from prevailing traditions and looking at them critically and dispassionately. He was able to confront in this way some of the most widely accepted presuppositions of his age, and to ask himself whether they really corresponded to the needs of the actual situation. He considered afresh, as we have already described, the whole question of communication between one mind and another, and he was led by his inquiries to advocate radical reforms in the two very different spheres of mathematics and linguistics. His mathematical innovations were to exercise a profound influence on the thought of mathematicians and philosophers of mathematics; but his long championship of Interlingua as an auxiliary language met with no lasting response. In mathematics, he recognized that there is an unbridgeable gulf between the intuitive outlook of common sense and the logical rigour that, by his day, had come to be looked upon as essential in the construction of mathematical theories. He came to the conclusion that mathematics must be constructed, independently of intuition, in a way that guarantees absolutely the validity of its theorems; and in order to satisfy this requirement he set to work to rewrite mathematics in symbolic form as an axiomatic system, based exclusively on postulated primitive notions and primitive propositions. This was an epoch-making step to take; and we shall see how heavily later writers on the foundations of mathematics have been indebted to Peano for his initiative.

6 The symbolic language of Leibniz

Although Peano was a man of outstanding ability he also had, to a most unusual degree, the quality of humility. This was so strong an element in his personality that he could never bring himself to accept the credit for his own achievements.[1] He would certainly never have admitted to being an original thinker, and it was his nature to see his own work always as nothing but a continuation or fulfilment of someone else's—as for instance of Genocchi's when he wrote his book on the infinitesimal calculus. In the case of symbolic logic, it was Leibniz who received the credit. Peano had especial reverence for Leibniz, which is partly accounted for by the fact that he was probably the first man ever fully to appreciate some of the things that Leibniz did or conceived the idea of doing. In the preface to the *Formulaire* of 1901 we find these words:

---

[1] It is wholly characteristic of Peano that he expressed the wish that when he died, honoured though he was as a man of acknowledged eminence in the world of learning, he should be buried in the part of the cemetery that was reserved for the paupers of the city of Turin. And in the brief report of Peano's funeral that is printed in *Schola et Vita*, **7** (1932), 103, we read that indeed, after a ceremony in the great hall of the university, 'funere move ad cæmeterio, ubi nostro caro et venerato prof. Peano es sepulto in campo commune, 3° sud, in fossa n. 674, inter pauperes'.

'Mathematical logic studies the properties of logical operations and relations, which it denotes by symbols. A few of the principles of this science are to be found in general logic (see Aristotle). Its true founder is Leibniz, who enunciated the principal properties of the ideas now represented by $\cap$, $\cup$, $-$ [not], $=$, $\supset$, Λ.'

Leibniz, as is generally acknowledged, may be compared to Aristotle in the range of his abilities. He had prodigiously wide interests and made highly original contributions to many different branches of learning; and among his numerous projects was the construction of a symbolic logical language. But the men of his time did not take him seriously, and he himself never found the leisure needed to carry through the immense task of working out a suitable symbolism in detail, starting from the very beginning. Although, however, his project remained largely a dream, he worked at it intermittently and obtained a number of fragmentary results. These were preserved among his manuscripts in the royal library at Hanover, and some of them were at length published in selections from his works; but once again their significance was not appreciated. Eventually, when Peano had been led by his own researches into the foundations of mathematics to reflect independently on the same matters, he realized for the first time the meaning of the results noted down by his great predecessor. And so at last, just before the close of the nineteenth century, Peano's colleague Giovanni Vacca went to Hanover to make an examination of the manuscripts there. The extracts which Vacca published in the *Formulaire* of 1899 inspired Louis Couturat to go more fully into the matter; and in 1901 Couturat published *La Logique de Leibniz*, which was followed in 1903 by a large volume containing the logical fragments themselves.

Now that Peano had actually produced a logical calculus, and had thus demonstrated that the project was not illusory, the true significance and importance of Leibniz's work could at last be appreciated. That Leibniz himself had seen clearly, all the time, what he was about, is proved by some words that he wrote in an often-quoted letter of 1714:

'If I had been less distracted, or if I had been younger or assisted by young men in a position to help me, I would have hoped to give a kind of *spécieuse générale*,[1] in which all truths of reason would be reduced to a calculus. This would be at the same time a sort of universal speech or writing, but infinitely different from all those proposed hitherto; for the characters, and the words themselves, would be governed by Reason; and errors, with the exception of those of fact, could only be mistakes in calculation. It would be very difficult to create or invent this language or characteristic, but very easy to learn it without the aid of a dictionary.'

The symbolic logic of Peano, though limited to a narrow range of discourse (namely the exposition of demonstrative theories) is just such an instrument as Leibniz had in mind.

SUPPLEMENTARY NOTES ON CHAPTER 5

1. *Peano's space-filling curve.* Peano's procedure for defining a curve which passes through every point of the square $0 \leqslant x \leqslant 1$, $0 \leqslant y \leqslant 1$ (cf. p. 143) may be summarized as follows. Let t be any real number in the range $0 \leqslant t \leqslant 1$, expressed in the scale of 3 in the form

$$a_1/3 + a_2/3^2 + \ldots + a_n/3^n + \ldots.$$

Denoting by $\mathbf{k}$ an operator which converts 0, 1, or 2 into its complement with respect to 2, so that $\mathbf{k}0 = 2$. $\mathbf{k}1 = 1$, $\mathbf{k}2 = 0$, we define two sequences $\{b_n\}$ and $\{c_n\}$ in the following way:

$$\begin{aligned} b_1 &= a_1, \\ b_2 &= \mathbf{k}^{a_2} a_3, \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \\ b_n &= \mathbf{k}^{a_2 + a_4 + \ldots + a_{2n-2}} a_{2n-1}; \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \end{aligned}$$

and

$$\begin{aligned} c_1 &= \mathbf{k}^{a_1} a_2, \\ c_2 &= \mathbf{k}^{a_1 + a_3} a_4, \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \\ c_n &= \mathbf{k}^{a_1 + a_3 + \ldots + a_{2n-1}} a_{2n}, \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \end{aligned}$$

If, now, we put

$$X = b_1/3 + b_2/3^2 + \ldots, \qquad Y = c_1/3 + c_2/3^2 + \ldots$$

X and Y are continuous functions of t; and the parametric representation $x = X$, $y = Y$ then defines a curve with the required property. A number of details still have to be taken care of, but even when this is done Peano's entire paper occupies only four pages.

---

[1] Literally, 'generalized algebra'. The name *arithmétique spécieuse* was formerly used for algebra; cf. the article *Spécieuse* in the *Encyclopédie* of Diderot and d'Alembert (Paris, 1751–1765).

2. *Ideal numbers and ideals.* Kummer introduced ideal numbers into arithmetic with the aim of simplifying the discussion of algebraic number fields

By an *algebraic number* is meant a (complex) number which satisfies an algebraic equation

$$x^n + a_1x^{n-1} + \ldots + a_n = 0,$$

in which the coefficients $a_1, \ldots, a_n$ are rational numbers, i.e. elements of the rational field Q. If, more specifically, these coefficients happen to be rational integers, the algebraic number is said to be an *algebraic integer*. Now the set of all algebraic integers is a ring, and the set of all algebraic numbers is the field of quotients of this ring; but the arithmetical analogy with the rational integers and the rational numbers does not go very far, since there are no algebraic integers that are irreducible, i.e. prime.

The situation becomes much more like that in ordinary arithmetic if, instead of the field of *all* algebraic numbers, some restricted field $Q(\theta)$ is taken, that is to say the smallest field, containing Q, which has some specified algebraic number θ as one of its elements. The algebraic integers which belong to $Q(\theta)$ then form a ring, and $Q(\theta)$ is the field of quotients of this ring.

For some choices of θ, the arithmetic of $Q(\theta)$ is very similar to that of Q. In the case $\theta = \sqrt{3}$, for instance, we have a direct analogue of the theorem that every rational integer is expressible in one and essentially only one way as a product of prime factors; but in other cases there is no such analogy. Thus the number 21 has two distinct resolutions into factors which are irreducible in the field $Q(\sqrt{-5})$, namely 3.7 and $(1 + 2\sqrt{-5})(1 - 2\sqrt{-5})$. This is possible because, although the algebraic integers 3, 7, $1 + 2\sqrt{-5}$, $1 - 2\sqrt{-5}$ are all irreducible in the field $Q(\sqrt{-5})$, they have as common factors certain algebraic integers which do not belong to this field. We have, in fact,

$$1 + 2\sqrt{-5} = \sqrt{\lambda}\sqrt{-\varkappa'}, \quad 1 - 2\sqrt{-5} = \sqrt{\lambda'}\sqrt{-\varkappa},$$
$$3 = \sqrt{\lambda}\sqrt{\lambda'}, \quad 7 = \sqrt{\varkappa}\sqrt{\varkappa'},$$

where

$$\varkappa = 2 + 3\sqrt{-5}, \quad \varkappa' = 2 - 3\sqrt{-5}; \quad \lambda = 2 + \sqrt{-5}, \quad \lambda' = 2 - \sqrt{-5}.$$

The arithmetic of $Q(\sqrt{-5})$ is thus anomalous in that common factors, which have an effect on the multiplicative properties of the integers of the field, are sometimes missing from the field; and Kummer's idea was to postulate 'ideal' numbers of the field in order to fill any gaps that may exist. The field that he originally considered was not in fact $Q(\sqrt{-5})$ but a cyclotomic field, generated from Q by adjunction to it of a complex pth root of unity. In his own words:

> 'Es ist mir gelungen, die Theorie derjenigen complexen Zahlen, welche aus höheren Wurzeln der Einheit gebildet sind und welche bekanntlich in der Kreistheilung, in der Lehre von den Potenzresten und den Formen höherer Grade eine wichtige Rolle spielen, zu vervollständigen und zu vereinfachen; und zwar durch Einführung einer eigenthümlichen Art imaginärer Divisoren, welche ich *ideale complexe Zahlen* nenne; worüber eine kurze Mittheilung zu machen ich mir erlaube.

Wenn α eine imaginäre Wurzel der Gleichung $\alpha^\lambda = 1$, λ eine Primzahl ist und a, a_1, a_2, etc. ganze Zahlen sind, so ist $f(\alpha) = a + a_1\alpha + a_2\alpha^2 + \ldots a_{\lambda-1}\alpha^{\lambda-1}$ eine complexe ganze Zahl. Eine solche complexe Zahl kann entweder in Factoren derselben Art zerlegt werden; oder auch nicht. Im ersten Fall ist sie eine zusammengesetzte Zahl: im andern Fall ist sie bisher eine complexe Primzahl genannt worden. Ich habe nun aber bemerkt, daß, wenn auch $f(\alpha)$ auf keine Weise in complexe Factoren zerlegt werden kann, sie deshalb noch nicht die wahre Natur einer complexen Primzahl hat, weil sie schon gewöhnlich der ersten und wichtigsten Eigenschaft der Primzahlen ermangelt: nämlich, daß das Product zweier Primzahlen durch keine von ihnen verschiedene Primzahl theilbar ist. Es haben vielmehr solche Zahlen $f(\alpha)$, wenn gleich sie nicht in complexe Factoren zerlegbar sind, dennoch die Natur der zusammengesetzten Zahlen; die Factoren aber sind alsdann nicht wirkliche, sondern *ideale complexe Zahlen*.' ('Zur Theorie der complexen Zahlen', *J. reine angew. Math.*, **35** (1847), 319–326.)

The further step taken by Dedekind was the recognition that, in order to handle the arithmetic of a given algebraic field $Q(\theta)$, we do not need to be able actually to produce irreducible factors, since we can do all that is required by arguing in terms of those totalities of integers of the field that behave as if they were divisible by some common irreducible factor. These totalities are what are now known as *ideals*. The procedure here adopted by Dedekind may be compared with his own identification of real numbers with totalities of rational numbers which behave as if separated off by boundary numbers, and also with Frege's identification of the cardinal number of a class with the totality of all classes which behave as if possessing just as many members as that class.

For the use of ideals in the study of algebraic number fields see E. Hecke: *Vorlesungen über die Theorie der algebraischen Zahlen*, Chapter 5.

3. *Sources of historical information.* (a) *General.* The standard history of Greek mathematics is Heath [3].

A very comprehensive survey of the history of mathematics up to 1799, in four volumes, is M. Cantor [1]. For the subsequent development of modern mathematics, in the course of the nineteenth century, see Klein [2].

A collection of essays on the greatest mathematicians from the fifth century B.C. onwards, which is perceptive and informative beneath a somewhat racy style, is E. T. Bell: *Men of Mathematics*. The same author has also written a less popular work [2], in which the emphasis is more on mathematical discoveries than on biographical anecdotes.

Biographical details of modern mathematicians, as well as information concerning their work, are often most readily obtained from the obituary notices published by learned societies. See, in particular, the series *Obituary Notices of Fellows of the Royal Society* (1932–1955) and its continuation since 1956 as *Biographical Memoirs of Fellows of the Royal Society*, and also the obituary notices in the *Journal of the London Mathematical Society*.

(b) *For Peano.* There are a number of articles which give details of Peano's life and work. His contributions to mathematics are outlined in Levi [1] and his contributions to logic in Cassina [3]. Cassina's more elaborate notice [2] covers the whole of Peano's mathematical and logical work, and includes a full list of his publications. Yet another account of Peano's life and work, Cassina [1], is essentially the same as an article which Cassina wrote in 1928, with Peano's assistance, to mark Peano's seventieth birthday. For Peano's own writings, see the three volumes of *Opere scelte*, published 1957–1959.

THE –EST

Newton's law of gravity holds up in miniature

Even teeny objects obey the law of gravity. A gold ball just 2 millimeters wide, with a mass of about 90 milligrams, is now the smallest object to have its gravitational pull measured. Observations of that sphere tugging on another similarly sized sphere confirm that gravity behaves as expected even for extremely weak gravitational fields, physicists report in the March 11 *Nature*.

Newton's law of universal gravitation states that the gravitational force between two masses is inversely proportional to the square of the distance between them. Physicists in Austria tested whether that law applies to tiny masses by attaching a gold sphere to a horizontally suspended beam. The sphere was free to rotate in response to the gravitational pull of another gold sphere a few millimeters away. Measurements of the motions of the first sphere as the second sphere moved closer and farther away matched predictions of Newton's law and Einstein's general theory of relativity, two theories of gravity that are equivalent under most everyday conditions.

Researchers want to test how gravity behaves on even smaller scales, and this test inches them closer to exploring gravity's quantum side. — *Emily Conover*

A gold sphere (left) on a horizontal glass beam responds to the gravitational pull of a neighboring sphere (right). The measurement confirms that gravity behaves as expected even for very small objects.

Chapter 13

Geometric Iterations

13.1 Introduction

In this chapter the focus of study, which till now has been confined to arithmetic and algebra, shifts to geometry. We start by giving a few illustrations that show how iterations arise in geometry.

Reflections. Let f denote reflection in a line ℓ (so that ℓ acts like a mirror). Then $f \circ f = I$, because two successive reflections in the same line take us right back to the starting point; here I denotes the identity operation, which in geometry means "*do nothing, let the point stay where it is*". So reflection in a line is a 2-cycle function.

Half-turns. Let H denote a half-turn (a rotation through 180°) about a fixed point O; then $H \circ H = I$ (for two successive half-turns about the same point are equivalent to a 360° turn and therefore to the identity map I). So a half-turn too is a 2-cycle function.

On the other hand, two successive half-turns about two distinct points, P and Q, are equivalent to a displacement through the vector $2\overrightarrow{PQ}$.

More generally, if θ is any angle ($\theta \neq 0^\circ, \theta \neq 360^\circ$) then the effect of two successive rotations f,g, with f centered at P and through an angle θ, and g centered at Q and through an angle $-\theta$, is a displacement. This fact comes of use when we have to move heavy furniture!

Quarter-turns. Let Q denote a quarter-turn about a fixed, point O; then $Q \circ Q = H$ and $Q(4) = H \circ H = I$. Here we have an example of a 4-cycle function.

An identity involving half-turns. For any quadrilateral ABCD, let P,Q,R,S be the midpoints of the sides AB,BC,CD,DA respectivey. Then we have the curious relation

$$HP \circ HQ \circ HR \circ HS = I.$$

i.e., $HP \circ HQ \circ HR \circ HS(X) = X$ for all points X.

Frieze patterns. Here is an illustration from art. Let a design $\mathcal{B}$ (a "motif") be selected, and let the sequence $\langle \mathcal{B};f \rangle$ be sketched for some appropriate function f. This simple action can result in rich geometrical patterns, depending on the choice of $\mathcal{B}$ and f. Many of the famous artifacts of Islamic art (e.g., those found in the Alhambra fortress in Granada, Spain, or in parts of the Islamic world) can be studied and appreciated from this perspective.

We give an example of such a sequence. Choose the motif to be the clubs symbol, ♣, and let f be, '*move the motif one unit to the right*'. Then the sequence ⟨♣;f⟩ is an infinite strip:

···♣♣♣♣♣♣♣♣♣···

Designs of this type are known as frieze patterns, and they are often seen on temple walls, saree borders, pullovers, and so on.

Wall-paper patterns and crystals. The idea of a repeating one-dimensional pattern can easily be extended to two dimensions, resulting in wall-paper patterns. The three-dimension version of this is obviously a crystal; here a structure gets repeated in some definite manner in three dimensions. Other objects not typically referred to as crystals may possess such repetitive structures; for example, the DNA double helix, and in general other spiral forms that occur in nature.

We now study a few iterations involving geometric themes; *en route* we shall discover some pretty mathematics!

13.2 Perpendiculars

Let △ABC be acute-angled, and let P0 be a point on BC. We locate another point P1 on BC (i.e., on the same side) by dropping perpendiculars as follows: P0Q, from P0 to *AB*; QR, from *Q* to CA; and then RP1, from R back to BC. The position of P1 clearly depends on that of P0, so we write P1 = f(P0), where f is a function that 'acts' on the points on line BC, permuting them amongst themselves (see Figure 13.1). We regard the movement from P0 to P1 as the first round of an iteration.

We now repeat this sequence of actions: we drop perpendiculars in turn to AB, to CA, to BC,…, and obtain the points

$$P2 = f(P1), P3 = f(P2), P4 = f(P3), \ldots.$$

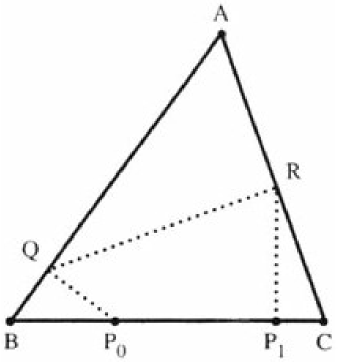

Figure 13.1. *After 1 round*

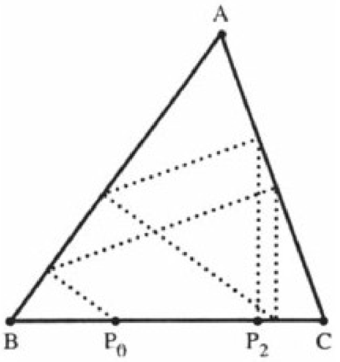

Figure 13.2. *After 2 rounds*

with the points P2,P3,P4,… all lying on BC. Figure 13.2 shows the path taken during the first two rounds of the iteration.

After a few.iterations, we notice something curious—*the path starts* to *close in on itself.* More precisely, the path converges to a triangular path inscribed in $\triangle ABC$. Note that this means that the sequence of points ⟨P0,P1,P2,P3,…⟩ tends to some limiting position on BC. Figure 13.3 displays the limiting path as an inscribed triangle (shown in a thick line). Observe that the inscribed triangle is similar to the original triangle (its sides are perpendicular to the sides of the original triangle, so the angles of the two triangles have the same measures; this explains the similarity).

It is natural to ask what happens when we change the position of P. Experimentation reveals that we reach the very same inscribed triangle each time! Figure 13.4 shows the path followed for another choice of P.

You may wonder what happens if the foot of the perpendicular lies not on the side on which it is dropped, but on its extension. The answer is that it does not matter. In Figure 13.5 the choice of figure is such that for the first few iterations, the feet of the perpendiculars lie on the extensions of the sides. After a few iterations, however, the situation "corrects" itself: the feet of the perpendiculars once again lie upon the sides, and we reach the very same inscribed triangle.

* * * * * * * * * * * * * * * * * * * *

Till now our iteration has followed a clockwise direction: we dropped a perpendicular first to AB, then to CA, then to BC,.... But we could also opt for an anticlockwise direction, dropping a perpendicular first to CA, then to AB, then to BC,.... What happens if we do it this way?

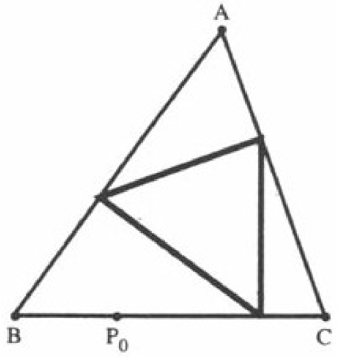

Figure 13.3. *Limiting path–1*

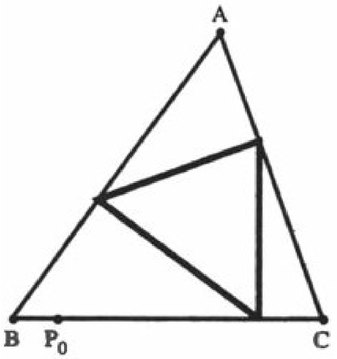

Figure 13.4. *Limiting path–2*

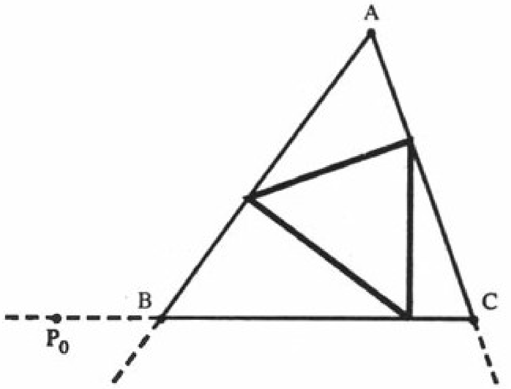

Figure 13.5. *Starting from a "wrong point"*

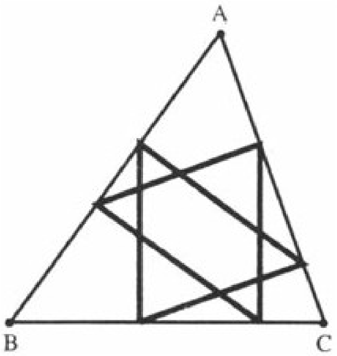

Figure 13.6.

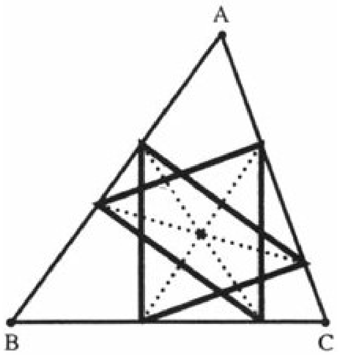

Figure 13.7.

Not surprisingly, we reach an inscribed triangle yet again; but, most pleasingly, the triangle turns out to be congruent to (and yet distinct from) the one got earlier! (See Figure 13.6.)

A surprising connection

An examination of the figure reveals that corresponding sides of these two triangles are parallel to one another (this owes to the perpendicularity relations noted earlier). Pairs of such objects are said to be *homothetic* to one another. If we draw the joins of corresponding pairs of points belonging to homothetic figures, the joins meet in a point called the *homothetic center* of the two figures. For example, an enlargement mapping yields pairs of homothetic figures, and the center of homothety is simply the center of the enlargement. A half-turn also yields pairs of homothetic figures, and the center of homothety in this case is the center or "pivot" of the half-turn ; it bisects the joins of corresponding pairs of points. (Comment: A half-turn is the same as an enlargement with scale factor equal to –1. Note that a half-turn is the only homothety in which the input figure is congruent to the output figure.)

In the current example the two figures are congruent to one another, so the homothety is a half-turn . The homothetic center turn s out to be a "known" point— it is the *symmedian point* of the triangle. The point is constructively defined as follows: we locate G, the centroid of the triangle, draw the medians GA,GB and. GC, then reflect them, respectively, in the lines internally bisecting the angles at A,B and C. The reflected segments are known as *symmedians*, and they meet in the symmedian point of the triangle.

Another way of finding the same point is as follows: draw the circumcircle of triangle ABC, then draw tangents to the circle at A,B and C. Let the triangle enclosed by the tangents be XY Z, with the vertices labelled so that X is opposite A (i.e., the tangents at B and C meet at X), Y is opposite B and Z is opposite C; then the lines AX, *B*Y and CZ meet in the symmedian point.

Exercises

13.2.1 Prove that the inscribed triangle referred to above is similar to the original triangle.

13.2.2 What happens if the original triangle is right-angled? How many iterations are needed in this case to reach the limiting path?

13.2.3 What happens if the original triangle is obtuse-angled?

13.2.4 What happens if we work with a convex quadrilateral instead of a triangle?

13.2.5 Prove that the sequence

$$\langle P,f(P),f(f(P)),\ldots,\rangle$$

converges to a limiting point, which moreover is the same for all points P on BC. (Hint: Use trigonometry to find the distances from B to the sequence of iterates of P.)

Explanations

We now justify the claim made that the two inscribed triangles obtained “in the limit” above are congruent and homothetic to one another, the center of homothety being the symmedian point. Our proof will be based on computation.

We note firstly that the sides of the inscribed triangles are respectively perpendicular, in some order, to the sides of the parent triangle, implying that each triangle is similar to the parent triangle. Therefore, the two triangles are similar to one another; and homothetic too, as their sides are parallel to one another.

In Figure 13.8, the two inscribed triangles are labelled A′B′C′ and A″B″C″, respectively; for convenience, we refer to them as T′ and T″, respectively, and to $\triangle$ABC as T. The labelling of T′ and T″ has been done in the obvious manner, to draw attention to their similarity (note how their angles correspond to one another). Thus we have angle equalities such as

$$\angle B'A'C' = \angle BAC = \angle B''A''C'', \angle A'B'C' = \angle ABC = \angle A''B''C''$$

and so on.

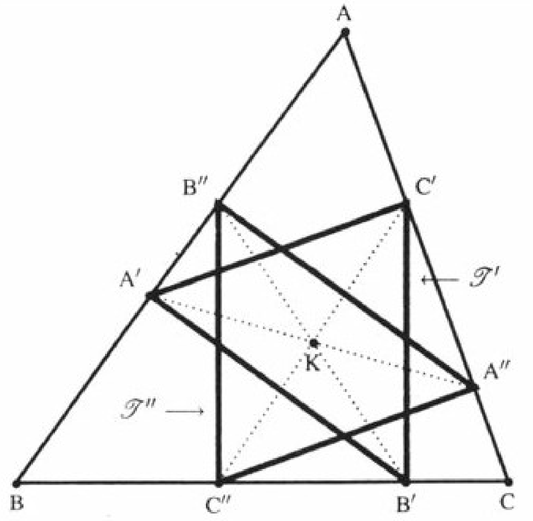

Figure 13.8. *Study of the two homothetic triangles*

We first show that triangles T′ and T″ are congruent to one another. Write a′,b′,c′ for the sides of T′, and a″,b″,c" for the sides of T″. Using elementary trigonometry we obtain the following relations:

$$a = BC = BB' + B'C = c' \sin B + a' \tan C'$$

$$b = AC = AC' + C'C = b' \tan A + a' \sin C,$$

$$c = AB = AA' + A'B = b' \sin A + c' \tan B.$$

The relations may be displayed in matrix form thus:

cotC 0 cscBcscC cotA0 0 cscAcotB · a′ b′ c′ = a b c .

Using well known formulas such as

$$\cos A = b2 + c2 - a2\ 2bc\ ,\sin A = a\ 2R,$$

where R is the radius of the circumcircle of the triangle, and doing a bit of simplification, the equations take the form shown below (here $\Delta = abc/4R$ denotes the area of the triangle):

$$1\ 4\Delta \cdot a2 + b2 - c2\ 0\ 2ca\ 2ab\ b2 + c2 - a2\ 0\ 0\ 2bc\ c2 + a2 - b2\ \cdot a'\ b'\ c' = ab\ c$$

The equations may be solved for a',b',c', and we get a most pleasing result:

$$a'\ b'\ c' = 4\Delta\ a2 + b2 + c2 \cdot ab\ c$$

Using the (certainly not too well known!) fact that

$$4\Delta\ a2 + b2 + c2 = \tan\omega,$$

where ω is the Brocard angle of the triangle, we may write this as

$$a'\ b'\ c' = \tan\omega \cdot ab\ c$$

The symmetry of the result tells us immediately that the very same equations will be obtained for a'',b'',c''. It follows that $a' = a'',b' = b''$ and $c' = c''$, and the congruence of the two inscribed triangles follows.

As segments $B''C''$ and $C'B'$ are congruent and parallel to one another, their center of homothety, K, lies at the center of rectangle $B''C''B'C'$. This means in particular that the perpendicular distance of K from side BC is

$$1\ 2a' = 1\ 2\tan\omega\ \cdot\ a = ka, \quad \text{where } k = 1\ 2\tan\omega.$$

We find similarly that the distances of K from sides CA and AB are kb and kc respectively. The ratios of the distances of K from the sides BC,CA,AB are therefore as $a : b : c$. But this is precisely the property which characterizes the symmedian point! The claim we made earlier therefore stands justified.

13.3 Angle bisectors

The iteration we study next deals with angle bisectors. We start by defining the relevant terms.

Incenter of a Triangle The internal angle bisectors of a triangle meet in a point—the *incenter* of the triangle, or the center of the circle that fits snug within the triangle. The circle is the *incircle* of the triangle. (To see why the bisectors meet in a point, use the fact that each point on an angle bisector is equidistant from the two arms of the angle; see Figure 13.9.)

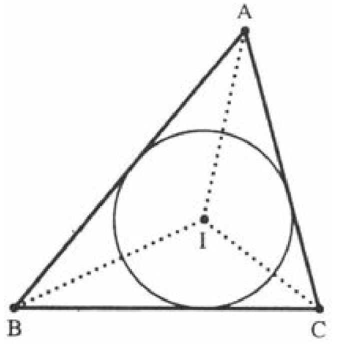

Figure 13.9.

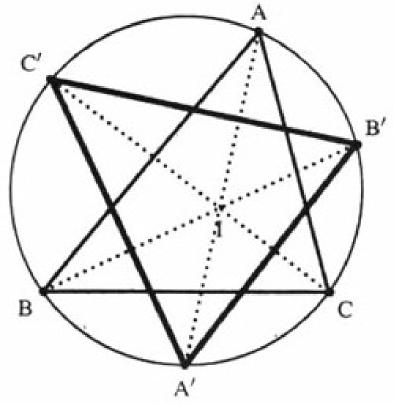

Figure 13.10.

The iteration

Let A,B,C be three distinct points on a circle Γ, and let $\triangle ABC$ be called T0; this triangle will serve as the seed of the iteration. Let the angle bisectors of T0 be drawn. and let them be extended beyond the sides of the triangle to meet the circle Γ. Let T1 be the triangle whose vertices are the three points of intersection so formed. (See Figure 13.10; the angle bisectors are shown in a dotted line; T1 is $\triangle A'B'C'$.)

Take the actions done so far to be one round of an iteration f; that is, take T1 = f(T0) to be the output produced with T0 as input. Let T2,T3,… be computed as follows:

$$T2 = f(T1), T3 = f(T2), T4 = f(T3), \ldots.$$

(Thus, to get T3 from T2, the angle bisectors of T2 are drawn and extended till they meet Γ. The three points of intersection are the vertices of T3; and so on.) What happens now? Figures 13.11 and 13.12 show the results of the iteration after 5 and 10 rounds respectively.

Observations

An interesting fact emerges when we examine these sketches: as we continue the iterations, *the triangles start to look more and more equilateral in shape*, and this happens regardless of the shape of the original triangle. Figures 13.13 shows the result of 10 rounds of the iteration using a differently shaped triangle as seed; the original triangle is shown in a light line and the final triangle in a thick line.

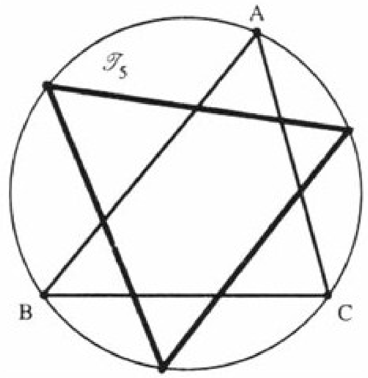

Figure 13.11. *After* 5 *rounds*

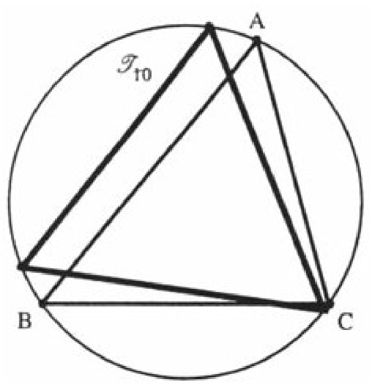

Figure 13.12. *After* 10 *rounds*

Note that the triangle itself does not stay fixed: T100 is distinct from T101, but they are both close to being equilateral. But T100 and T102 are "almost" the same triangle (they very nearly coincide), and likewise for T101 and T103.

Analysis

To see why convergence takes place, we compute the angles of T1 and check whether they are closer to one another than the angles of T0. This is easy to do.

In Figure 13.14, T0 is △ABC and T1 is △DEF. We compute the angles of T1 in terms of the angles of T0, using the well known theorem concerning "angles in the same segment." (If P,Q are points on an arc XY of a circle, then $\angle XPY = \angle XQY$.) We argue as follows. We have, $\angle FDE = \angle FDA + \angle ADE$. Next,

$$\angle FDA = \angle FCA = C\ 2\ , \angle ADE = \angle ABE = B\ 2\ ,$$

therefore $\angle FDE = 1\ 2(B + C) = 90\ \text{-}1\ 2A$. Similarly we get, $\angle FED = 90\ \text{-}1\ 2B$ and $\angle DFE = 90\ \text{-}1\ 2C$. Therefore the angles of △DEF are

$$90^\circ\text{-}A\ 2\ ,90^\circ\text{-}B\ 2\ ,90^\circ\text{-}C\ 2\ .$$

(Check that the angle sum is 180°.) So we have an iteration on triples that acts as follows:

$$(x,y,z) \mapsto 90\ \text{-}x\ 2,90\ \text{-}y\ 2,90\ \text{-}y\ 2.$$

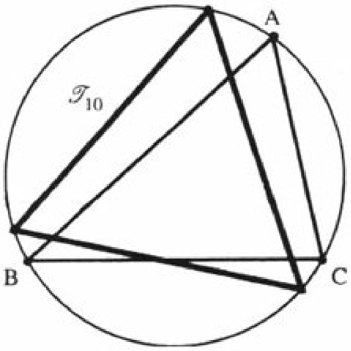

Figure 13.13. *A different* T0

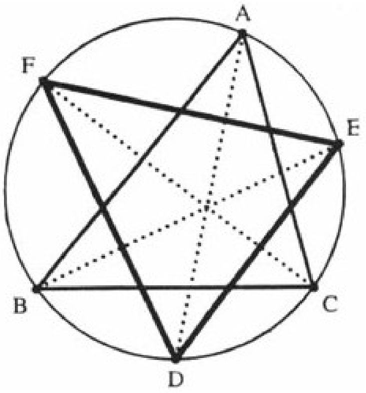

Figure 13.14. *Angle computations*

Consider the function f given by f(x) = 90 -1 2x. Let any number x0 be chosen, and let its f-orbit ⟨x0;f⟩ be computed. Does the sequence converge to a limit? We do a few trials to find out.

- x0 = 20 60.31,59.84,... The sequence produced is: 20, 80, 50, 65, 57.5, 61.25, 59.38,
- x0 = 40 60.16,59.92,... The sequence produced is: 40, 70, 55, 62.5, 58.75, 60.63, 59.69,
- x0 = 5 59.14,60.43,59.78,... The sequence produced is: 5, 87.5, 46.25, 66.88, 56.56, 61.72,

The figures clearly suggest that regardless of the seed chosen, the sequence converges to a limiting value of 60. Indeed this is so, and the exercise set below asks you to find a proof. As the iteration is the same for each angle of the triangle, it follows that each angle converges to 60°, and so the triangles do indeed converge to an equilateral shape.

Degree of 'non-equilateralness' of a triangle

Here is one way (the exercise set asks you to find another way!) of showing that the f-orbit of any starting number converges to a limiting value of 60. We have already seen that if T0 has angles $x^{\circ}, y^{\circ}, z^{\circ}$, then T1 has angles

$$90 - x\ 2^{\circ},\ 90 - y\ 2^{\circ},\ 90 - z\ 2^{\circ}$$

Consider the *differences* between the angles of T0; they are

$$|x - y|^{\circ}, |y - z|^{\circ} \text{ and } |z - x|^{\circ}$$

respectively. In the case of T1, the differences come out to be

$$|x - y|^{\circ}\ 2\ ,\ |y - z|^{\circ}\ 2 \text{ and } |z - x|^{\circ}\ 2\ ,$$

respectively. *So the differences have all been halved.*

Given any triangle, the extent to which it is *not* equilateral can be measured; it seems reasonable, surely, to describe a triangle with angles of $55^{\circ}, 60^{\circ}, 65^{\circ}$ as "closer to being equilateral" than one with angles of $10^{\circ}, 60^{\circ}, 110^{\circ}$. Given a triangle T with angles α, β, γ, a possible index for measuring how close it is to being equilateral is the quantity δ (T) given by

$$\delta(T) = |\alpha - \beta| + |\beta - \gamma| + |\gamma - \alpha|.$$

Observe that $\delta \geq 0$ for all triangles, and moreover that $\delta(T) = 0$ if and only if $\alpha = \beta = \gamma$; that is, if and only if T is equilateral.

In terms of this measure, the result obtained above can be stated succinctly as:

$$\delta(T1) = 1\ 2\delta(T0).$$

Similarly, $\delta(T2,) = \delta(T1)/2$, and so on. Since the δ-value is halved each time, it follows that $\delta(Tn)$ tends to 0 as n increases indefinitely. so the T's do indeed tend towards the equilateral shape.

Exercises

13.3.1 Let I0,I1,I2,… be, respectively, the incenters of the triangles T0,T1,T2, …. Does the sequence

$$\langle I0, I1, I2, \ldots \rangle$$

possess a limit?—i.e., do the incenters converge to a point? If so, what is this point?

13.3.2 Find another proof for the claim that for the iteration function given by f(x) = 90 -1 2x, the f-orbit corresponding to any seed converges to 60.

13.4 Medians

From angle bisectors we move on medians. Here are two definitions.

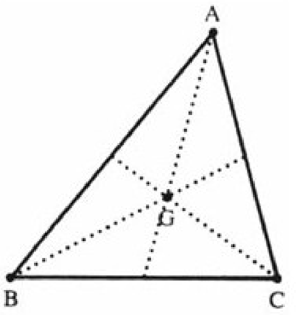

Figure 13.15.

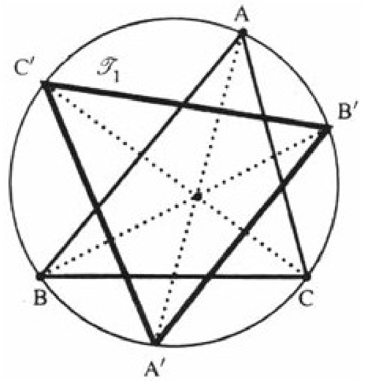

Figure 13.16.

Median of a Triangle; Centroid The line segment connecting a vertex of a triangle to the mid-point of the opposite side is called a *median* of the triangle. The three medians of any triangle meet in a point, called the *centroid* of the triangle; see Figure 13.15.

The iteration

We start with triangle T0, with vertices A,B and C, inscribed in a circle Γ. Let its medians be drawn, and let them be extended, as was done with the angle bisectors, to meet Γ. Let T1 be the triangle whose vertices are the three points of intersection; see Figure 13.16.

Let the actions performed so far be considered as one round of an iteration f; take T1 = f(T0) to be the output produced from the input T0.

Since T0 and T1 share the same circumcircle, the iteration can be continued. So we get

$$T2 = f(T1), T3 = f(T2), T4 = f(T3), \ldots,$$

and so on. (To produce T3 from T2, the medians of T2 are drawn and extended till they meet Γ; the three points of intersection are the vertices of T3.)

What happens now? Figures 13.17 and 13.18 show the results of the iteration after 5 and 15 rounds respectively. (In each case T0 has been drawn in a light line and the final Ti in a heavy line.)

Remarkably, we find exactly the same thing happening as in the angle-bisector iteration: *the triangles start to look more and more equilateral in shape*. And as earlier, this happens regardless of the shape of the seed triangle. Figure 13.19 shows the result after 15 rounds of the iteration, with a differently shaped triangle as seed.

⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆ ⋆

In order to do an analysis of this problem, we must compute the angles of

T1 and check whether they are in some sense closer to one another than the angles of the parent triangle; or we could work with the sides rather than the angles. This was easy to do in the case of the angle-bisector iteration. Unfortunately the analysis in this case is rather more involved. The ambitious reader may want to try finding a proof independently, before proceeding to the analysis given at the end of this chapter (in the Appendix).

Exercises

13.4.1 Let Gi denote the centroid of Ti,i = 0,1,2,…, and consider the sequence

$$\langle G0,G1,G2,G3,\ldots\rangle.$$

Does the sequence possess a limit? That is, do the centroids converge to some limiting position?

13.4.2 Instead of drawing medians, we could draw lines according to the following scheme.

Let k denote a fixed number, $0 < k < 1$. Labelling T0 as ABC, we locate points P on BC,Q on CA and R on AB according to the rule

$$BP\ PC = CQ\ QA = AR\ RB = k,$$

draw the lines AP,BQ,CR, then extend them to meet the circle Γ; the three points of intersection are then the vertices of T1. Likewise we generate T2 from T1,T3 from T2, and so on.

Let Gi be the centroid of Ti. Does the sequence ⟨G0,G1,G2,…⟩ converge to a point? Does convergence depend on the choice of k? Use a computer to do experiments and make a guess based on your findings. (Observe that $k = 0.5$ corresponds to the original iteration.)

Numerical analysis

As mentioned earlier, the analysis of the medians iteration is rather involved. We shall give the full details later. For now, we shall only show how the iteration can be described in algebraic terms; this then allows a numerical investigation.

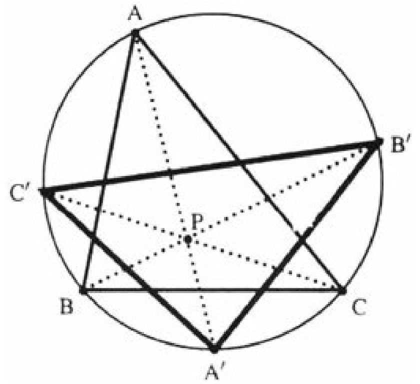

Figure 13.20. *A subsidiary result*: $B'C' : C'A' : A'B' = AP \cdot BC : BP \cdot CA : CP \cdot AB$

We first establish a subsidiary result. In Figure 13.20, we see a triangle ABC, inscribed in its circumcircle Γ, with an interior point P. The lines AP,BP and CP, when extended, meet the circumcircle again in the points A′,B′ and C′, respectively. We shall show that

$$B'C' : C'A' : A'B' = AP \cdot BC : BP \cdot CA : CP \cdot AB.$$

The proof is as follows. From the chord theorem, we get:

$$AP \cdot PA' = BP \cdot PB' = CP \cdot PC'.$$

Let k be the common value of these three products. From the similarity of triangles B′PC′ and CPB, we get:

$$B'C' \; BC = PB' \; PC \,, \therefore B'C = BC \cdot PB' \; PC = k \cdot BC \; BP \cdot CP = k \cdot AP \cdot BC \; AP \cdot BP \cdot CP.$$

It follows that $B'C' : C'A' : A'B' = AP \cdot BC : BP \cdot CA : CP \cdot AB$, as claimed.

★★★★★★★★★★★★★★★★★★★★

If P happens to be the centroid of triangle ABC, then the lengths AP,BP,CP are two-thirds of the lengths of the medians through A,B,C, respectively. Writing ma,mb,mc for the lengths of these three medians, and a′,b,c′ for the lengths of the sides of triangle A′B′C′, we see that

$$a' : b' : c' = am\ a : bmb : cmc,$$

certainly a pretty and compact result!

From **Apollonius's theorem** we know that

ma2 = b2 2 + c2 2 -a2 4 ,mb2 = c2 2 + a2 2 -b2 4 ,mc2 = a2 2 + b2 2 -c2 4 .

Using these relations, we are now able to make a numerical study of the convergence profile of the medians-iteration. Writing the relations a′ : b′ : c′ = ama : bmb : cmc as

a′2 : b′2 : c′2 = a2m a2 : b2m b2 : c2m c2,

we see that a′2 : b′2 : c′2 is the same as

a2(2b2 + 2c2 - a2) : b2(2c2 + 2a2 - b2) : c2(2a2 + 2b2 - c2).

It will be evident now that it is more convenient to deal with the *squares* of the sides of the triangle than with the sides themselves. Further, as it is only the *ratios* that the sides bear to one another that are of relevance to us, we define quantities x,y,z,x ′,y′,z′ as follows:

x = a2 a2 + b2 + c2,y = b2 a2 + b2 + c2,z = b2 a2 + b2 + c2,

and

x′ = a′2 a′2 + b′2 + c′2,y′ = b′2 a′2 + b′2 + c′2,z′ = b′2 a′2 + b′2 + c′2;

then x + y + z = 1 = x′ + y′ + z′,x : y : z = a2 : b2 : c2, and x′ : y′ : z′ = a′2 : b′2 : c′2.

Now we describe what iteration "does" to the triple (x,y,z). From the above we see that the iteration maps (x,y,z) to the triple (x′,y′,z′), where

x′ = x(2y + 2z - x) 4(xy + yz + zx) - (x2 + y2 + z2),

y′ = y(2z + 2x - y) 4(xy + yz + zx) - (x2 + y2 + z2),

z′ = z(2x + 2y - z) 4(xy + yz + zx) - (x2 + y2 + z2).

The common denominator here is the sum

x(2y+2z-x)+y(2z+2x-y)+z(2x+2y-z) = 4(xy+yz+zx)-(x2+y2+z2).

The important consequence of this formulation is that we have at hand a fully numerical version of the iteration. We now test it out.

Example 1. Consider a triangle with sides a = 3,b = 4,c = 5. As a2 : b2 : c2 = 9 : 16 : 25 and 9 + 16 + 25 = 50, the starting triple is (x0,y0,z0) = (0.18,0.32,0.50). The subsequent triples, computed via the formula displayed above, are:

$$(0.1800, 0.3200, 0.5000), \quad (0.3108, 0.3936, 0.2956),$$
$$(0.3374, 0.3279, 0.3347), \quad (0.3333, 0.3333, 0.3333),$$
$$(0.3333, 0.3333, 0.3334), \quad (0.3333, 0.3333, 0.3333).$$

The speed with the triple (0.3333, 0.3333, 0.3333) (which corresponds to the equilateral triangle) is reached is most impressive! (There is a small amount of round-off error in the displays: the last two triples sum to 0.9999 rather than to 1.)

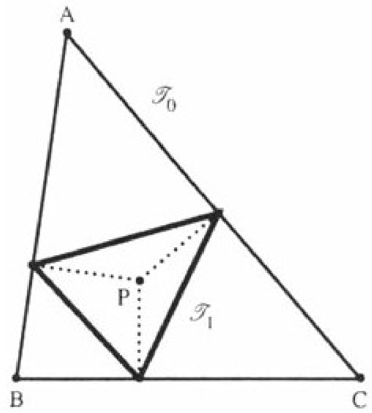

Figure 13.21. *The pedal triangle*

Example 2. Now consider a triangle with sides a = 2,b = 5,c = 6. We get the following result:

$$(0.0615, 0.3846, 0.5538), \quad (0.1789, 0.5210, 0.3001),$$
$$(0.3194, 0.2778, 0.4028), \quad (0.3410, 0.3322, 0.3268),$$
$$(0.3333, 0.3334, 0.3333), \quad (0.3333, 0.3333, 0.3333).$$

Once again the swift rate of convergence is in full view.

★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★

The full proof that the sequence of iterates converges to an equilateral shape is given at the end of the chapter.

13.5 Pedal triangles

We start with an acute angled triangle T0, with vertices A,B,C, and a point P lying within the region enclosed by the triangle. Let perpendiculars be dropped from P to each side of T0, and let the feet of these perpendiculars be the vertices of a new triangle T1. This triangle is the *pedal triangle* of P relative to T0. Note that T1 is "inscribed" in T0, for its vertices lie on the sides of T0, one to each side (see Figure 13.21).

As P lies within T1, we can repeat these actions and construct the pedal triangle of P relative to T1, by dropping perpendiculars from P to the sides of T1 and joining the feet of the perpendiculars to one another. In this manner we obtain another triangle T2, and P lies within this triangle too. We now construct the pedal triangle of P relative to T2, obtain another triangle, T3, and we continue thus, obtaining a sequence ⟨T0,T1,T2,T3,…⟩, in which each Ti is inscribed within the preceding one. The triangles shrink in size very rapidly, and soon the eye is unable to distinguish the triangles from the point P itself. Figure 13.22 shows the T's till T3.

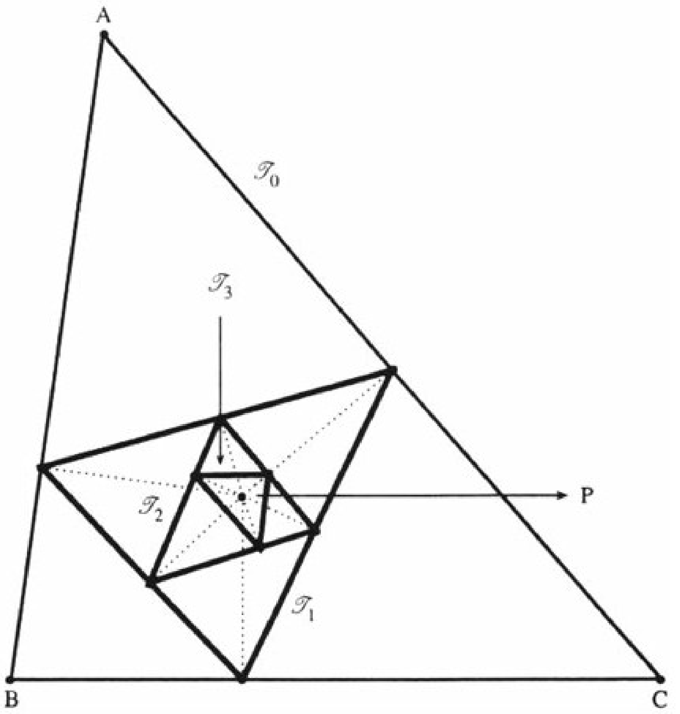

Figure 13.22. *Inscribed pedal triangles*

There is a nice feature about the sequence that could easily escape the eye: T3 is similar to T0! Examine the figure carefully; you should be able to see the similarity on your own. (The two triangles are in fact homothetic to one another, and P is the center of homothety.)

Exercises

13.5.1 Prove that T3 is similar to T0. (*Hint*. Compute the angles of T1. Do not draw the pedal triangles after T1, else the figure becomes too confusing!)

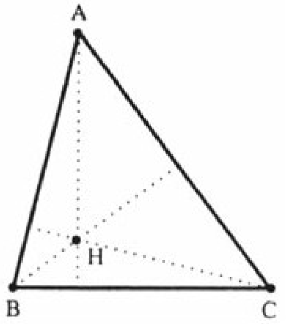

Figure 13.23.

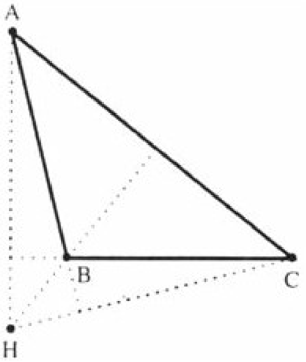

Figure 13.24.

13.6 Altitudes

Having studied iterations associated with the angle bisectors and the medians of a triangle, it is natural to consider the case of altitudes. The iteration turn s out to be quite exotic, producing complete chaos! The earlier iterations were both fairly "well behaved." in terms of yielding predictable results, but that is not the case here. Before we start we need two definitions.

Altitude, Orthocenter The line drawn from a vertex of a triangle perpendicular to the opposite side is called an *altitude* of the triangle. The three altitudes of a triangle always meet in a point, called the *orthocenter* of the triangle. The orthocenter can lie either inside or outside the triangle (see Figures 13.23 and 13.24).

The iteration

We start the iteration with triangle ABC inscribed in a circle Γ; call the triangle T0, and let its orthocenter be H0. The altitudes of T0 are drawn and extended till they meet Γ. Let T1 be the triangle whose vertices are the three new points of intersection, and let H1 be its orthocenter. Take T1 to be the output arising from the input T0.

We now iterate these actions: we draw the altitudes of T1, extend them till they meet Γ, and join the three points of intersection to one another; then the resulting triangle is T2, and its orthocenter is H2. We continue in this manner, obtaining a sequence of triangles,

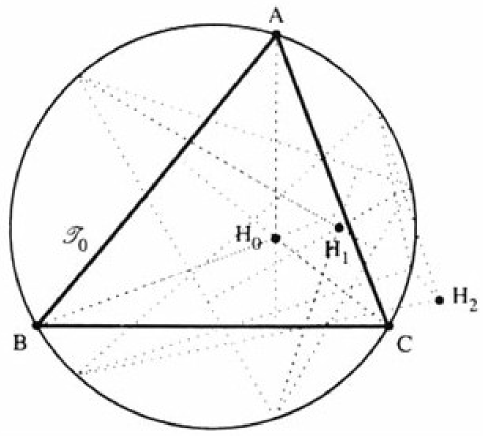

Figure 13.25. *Altitude iteration, after* 2 *rounds*

$$\langle T0,T1,T2,T3,\ldots\rangle,$$

and a corresponding sequence of orthocenters,

$$\langle H0,H1,H2,H3,\ldots\rangle.$$

Having studied in some detail the iterations with angle bisectors and medians, we may now be tempted to guess that the sequence of orthocenters will converge to a point. But we are in for a surprise!

Figure 13.25 shows the result after 2 rounds of the iteration (the orthocenters are shown, but some details have been hidden so as to avoid a visual mess).

Figure 13.26 shows the result after 25 rounds of the iteration (the labelling of the Hi's has been suppressed, for obvious reasons; likewise for the construction lines used). Note the dust-like scatter.

Figure 13.27 shows the result after 85 rounds. There appears now to be a random scatter! (There is a curious star-like effect, with streaks in six directions symmetrically placed about the circle; but this is hard to explain.) If we continue the iterations still further, we find a circular region entirely covered with dots. A careful analysis reveals that the radius of this circle is three times the radius of the circumcircle of T0.

Remark. For some choices of the starting triangle T0, a dust-like effect is *not* obtained; instead, we get a cycle. The reader may want to investigate under what conditions this will happen.

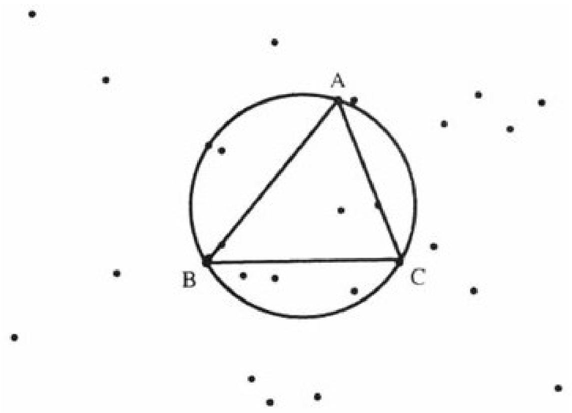

Figure 13.26. *After* 25 *rounds*

Exercises

13.6.1 For which triangles does the orthocenter lie (i) within the triangle (ii) on one side of the triangle (iii) one side of the triangle? Can the orthocenter ever lie in the interior of a side of the triangle?

13.6.2 Show that the altitudes of a triangle meet in a point.

13.6.3 In the iteration just considered, do the Ti's converge to any limiting shape?

13.6.4 Consider all possible triangles inscribed in a circle Γ, and let $\mathcal{H}$ denote the set of their orthocenters. Show that $\mathcal{H}$ occupies a circular region whose radius is three times that of Γ. You will need to use the following well known result due to Euler:

> *For any triangle, the circumcenter O centroid G and orthocenter H lie on a straight line the "Euler line" of the triangle, with H between O and G and moreover,* OH = 3OG.

13.6.5 It had been noted above that "for some choices of the starting triangle T0, a dust-like effect is *not* obtained; instead, we get a cycle." Investigate under what conditions this will happen.

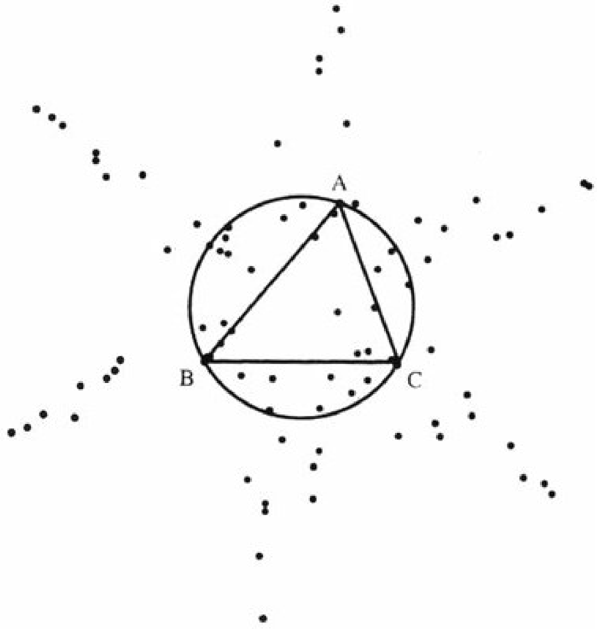

Figure 13.27. *After* 85 *rounds*

13.7 Pretty pictures

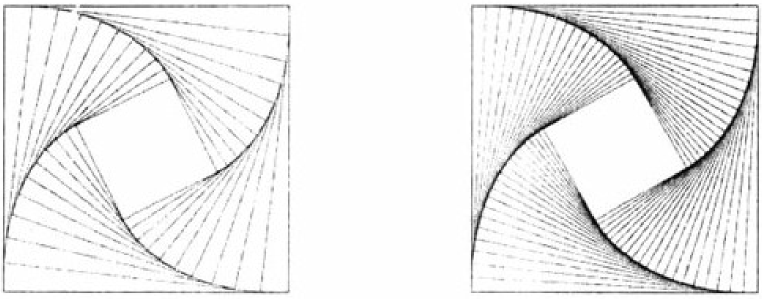
Next we show how simple iterative actions can give rise to very attractive pictures.

13.7.1 Nested Squares

Let k be a number lying between 0 and 1. Let S0 be a square, and let its vertices be labelled in cyclic order as A,B,C,D. Let points P,Q,R,S, respectively, be located on the sides *AB*, BC,CD,DA of S0, according to the following rule:

$$AP\ AB = BQ\ BC = CR\ CD = DS\ DA = k.$$

(If k = 0.5, then P,Q,R,S are the mid-points of the sides of S0.) The segments PQ,QR,RS,SP are drawn, giving another square, S1, which we take to be the output of a function with input S0. Observe that S1 is smaller than S0 and is wholly contained within it; it has the same center as its parent square, but has been turned through a small angle. To draw S2 we temporarily rename S1 as *ABCD* and locate points P,Q,R,S on its sides as per our rule; then S2 is the square *PQRS*; and so on. We thus obtain a sequence of squares



$k = 0.1$, 10 *iterations*

$k = 0.05$, 20 *iterations*

Figure 13.28. *Nested squares*

$$\langle S0,S1,S2,S3,\ldots\rangle,$$

in which each square lies inside all the preceding ones. It is easy to see that the squares converge to the center of symmetry of the square. The picture that results is a pretty one; two such pictures have been portrayed in Figure 13.28.

Exercises

13.7.1 Prove that Si is a square for each i.

13.7.2 What picture results when k = 0.5?

13.7.3 Which values of k generate the nicest pictures? (You will need to do some experimentation to find out!)

13.7.4 If you work with non-square quadrilaterals instead of squares, what do you find?

13.7.5 If you carefully study the pictures generated above, you will see many spiralling curves. This is actually an optical effect: even though we have not drawn any curve, it so happens that the lines that we have drawn are all tangent to a particular curve, and it is this curve that we “see. So in this sense the curve is not merely an illusion but has been created by the lines. (The lines are said to *envelope* the curve.)

List some daily life situations in which straight lines create the effect of a curve. (Hint. Think of the “tea-cup curve.”)

13.7.6 Four men (A,B,C,D) are stationed at the comers of a square, one at each vertex, and at a given instant they start walking towards one other: A towards B,B towards C,C towards D and D towards A, all at the same speed. As they are all in movement, each one must continuously alter his direction of movement. What paths do the men trace out? Where do they meet?

13.7.7 A dog spots a rabbit and starts to chase it; the rabbit heads straight for its burrow. What sort of path does the dog follow? (Experiment with different possibilities. If the dog and rabbit run in the same direction, then the path is simply a straight line. What happens if the rabbit initially starts in a direction which is perpendicular to the dog’s path?)

13.7.2 Nested Triangles

We do exactly the same thing with triangles. Let T0 be a equilateral triangle and let k be any number lying between 0 and 1. We label the vertices of T0 as A,B,C, then locate points P,Q,R on the sides of T0 using the following rule:

$$BP\ BC = CQ\ CA = AR\ AB = k;$$

then we declare T1 to be △PQR. We find that T1 is equilateral, but of smaller size that T0; it has the same center of symmetry as its parent triangle, and is wholly contained within it. We similarly generate T2 from T1,T3 from T2, and so on. The sequence

$$\langle \mathrm{T0},\mathrm{T1},\mathrm{T2},\mathrm{T3},\ldots \rangle$$

then consists of nested triangles, one within the other, converging to the center of symmetry of the triangle. Figure 13.29 shows two sample pictures.

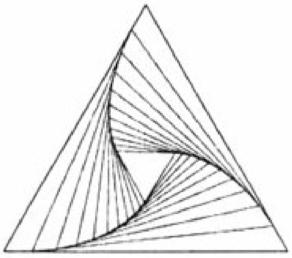
This example and the previous one ("nested squares") form the basis of,many pretty *Nail-and-thread* art pieces that can be found in the craft center of a school.

Exercises

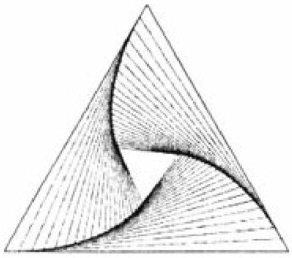
13.7.8 Suppose that T0 is not equilateral. What can be said about T1,T2,T3, … ? Are the triangles further down the sequence 'more equilateral' than the earlier ones?

13.8 Fractals

Fractals constitute a relatively modem discovery; they date to the latter half of the 20th century and may be said to have originated in the work of the French mathematician and geometer Benoit Mandelbrot. In the bargain a new class of mathematical objects has emerged, one that holds considerable relevance to the study of the natural world. The concept is a relatively simple one, but it is remarkable how far it takes us. We illustrate the idea with a simple example —that of the *snowflake curve*.



$k = 0.1$, 10 *iterations*



$k = 0.05$, 20 *iterations*

Figure 13.29. *Nested triangles*

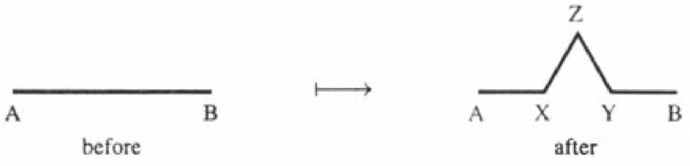


Figure 13.30. *Action of* f *on a line segment*

★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★

We first describe how the function f acts. Let a line segment ℓ = AB be given, and let f act on ℓ thus: we locate the points X,Y which trisect AB (with X nearer to A than to B, so the points occur on ℓ in the order A,X,Y,B), and then locate Z such that ΔXYZ is equilateral. The ambiguity regarding the side of ℓ on which Z is located is resolved thus: in ΔXYZ, the vertex order (X,Y,Z) is required to be *anticlockwise*. Following this, segment XY is deleted and replaced by segments XZ and Y Z (see Figure 13.30).

Now let a geometric figure G0 be given, composed only of line segments; for instance, G0 could be a polygon. We let f act on each edge of G0, and obtain a new geometric figure, say G1. The same treatment is given to G1, and so on, and we thus obtain a sequence of geometric figures,

$$\langle G0, G1, G2, G3, \ldots \rangle,$$

each of which is composed only of line segments, which get smaller and smaller as we go down the sequence. The following sequence of figures shows what happens when G0 is an equilateral triangle. Note the beauty of the figures! It is possible in the minds' eye to imagine what happens 'in the limit', but it is impossible to draw it. The limiting object is known as the *snowflake curve*— for obvious reasons, as this is what the object resembles it its broad outline and symmetry. (We have stopped at G5 because, as you will readily see, drawing even the next shape is going to be rather tedious.)

Is it not remarkable how such a simple rule can give rise to so pretty a shape?

13.9 Map-in-a-map

A USAMO problem Our last example of iterations in geometry will be based on the following elegant problem which appeared in the USA mathematical olympiad (USAMO) of 1978.

> *We are given two square maps of the same country, drawn to different scales. The smaller map is placed on and within the boundary of the larger one. Show that there is precisely one point on the small map which represents the same place of the country as the point of the large map that lies directly below it. Give a way of locating this point.*

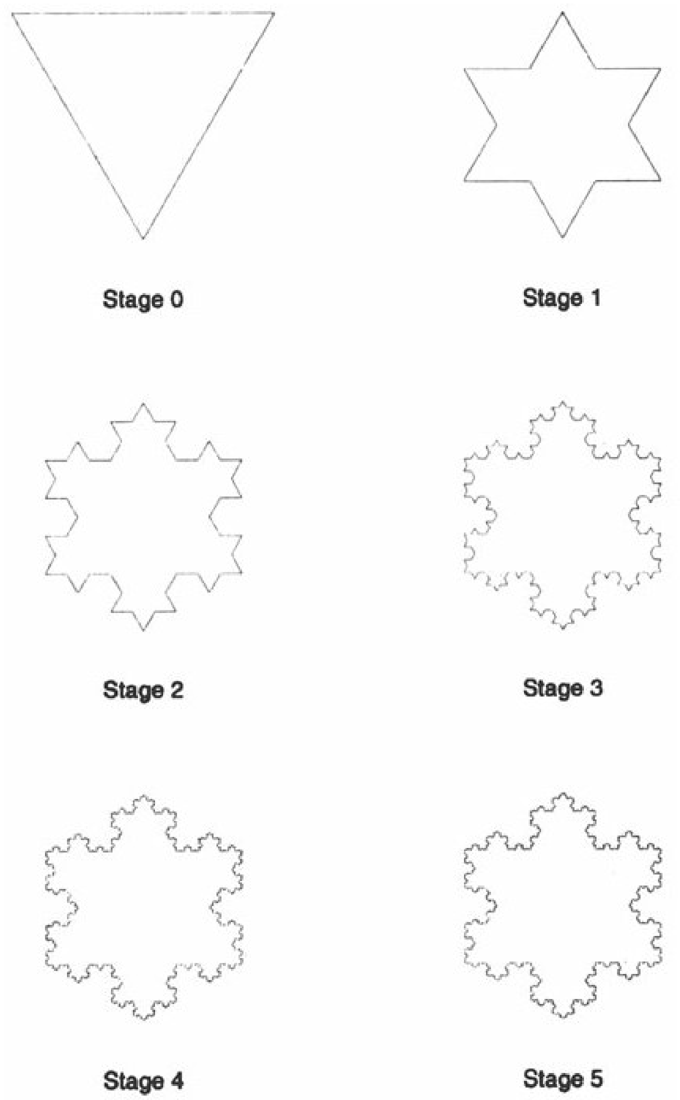
The use of the word "square" may suggest that the result holds only for maps which are square in shape, but this is clearly no restriction, for any map can be embedded in a larger map that is square in shape.

Notation

Let ABCD denote the larger map, and A′B′C′D′ the smaller one. We use the prime symbol (′) to show the correspondence between the maps: if X is any point on the large map, then the point on the small map corresponding to X will be denoted by X′. We also write $X' = f(X)$, where f is the function describing how the two maps correspond to one another (in Figure 13.32, $A' = f(A)$,$B' = f(B)$, and so on).

Next, we denote by r the scale factor of the small map relative to the large map ($0 < r < 1$). The scaling applies uniformly to all parts of the map, so if two distinct points P and Q of the large map correspond to (distinct) points P′ and Q′ of the small map, then $P'Q' = r \cdot PQ < PQ$. So if "dist" represents the distance function, with dist (P,Q) = the distance between the points P and Q, then the function f has the property that

$$\text{dist}\,(f(P),f(Q)) = r \cdot \text{dist}\,(P,Q) < \text{dist}\,(P,Q),$$



Stage 0
Stage 1
Stage 2
Stage 3
Stage 4
Stage 5

Figure 13.31. *Stages* 0 *to* 5 *of the snowflake curve*

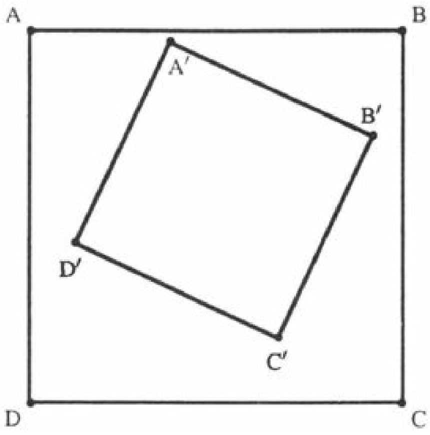


Figure 13.32. *Map-in-a-map*

for all points P≠Q of the large map. Note in particular that for all points P≠Q of the large map, the distance between f(P) and f(Q) is strictly less than the distance between P and Q.

The problem asks us to show that there is one and only one point O of the large map such that f(O) = O (i.e., f has one and only one fixed point), and to show how the point can be located geometrically.

Solution to the problem

Observe that the 'only one' pan is easy: there certainly cannot be *more than one* such point. For if P and Q were both fixed points (P≠Q), then we would have P = f(P) and Q = f(Q), i.e., P′ = P and Q′ = Q, implying that P′Q′ = PQ; but this contradicts the relation P′Q′ < PQ obtained above. So there can be at most one fixed point.

When f is applied to the entire square M = ABCD, we get the smaller square M′. What happens if we apply f to M′? We obviously get a square M″ which lies within M′ and bears exactly the same relation to M′ as M′ does to M. The scale of M″ is r times that of M′, and therefore r2 times that of M. If we are given only M and M′, we can easily construct M″ using Euclidean tools. For, point A″ must lie inside M′ and be located such that ΔA″A′B′~ΔA′AB. We can easily do this using the tools of Euclidean geometry.

This can clearly be continued indefinitely: we can apply f to M'' and get M''', and so on. The squares thus obtained shrink at a geometric rate, and each lies within the preceding square. So we get a "nested" sequence of squares (see Figure 13.33).

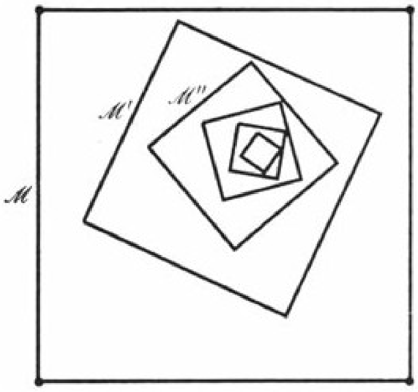

Figure 13.33. *Nested maps*

If we focus attention (see Figure 13.34) on the f-iterates of the vertex A alone, we see that the sequence of iterates

$$A, A', A'', A''', A'''', \ldots$$

quite visibly converges to a limiting point *O. This is the fixed point of* f.

Locating the fixed point geometrically

It is possible to find the fixed point O without too much work. Indeed, we need only two iterates, A' and A''. (If we are not given A'', then we first construct it as indicated above.) We give below a geometric procedure for locating O.

Observe firstly that for any three points P,Q and R, the image of $\triangle PQR$ under f, namely $\triangle P'Q'R'$, is similar to $\triangle PQR$. Since O is a fixed point ($O' = O$), we infer that $\triangle OAA'$ is similar to $\triangle OA'A''$, and $\angle OA'A'' = \angle OAA'$. Therefore $A'A''$ is tangent (at A') to the circumcircle of $\triangle OAA'$. This circle can readily be drawn, even though we do not know where 0 lies; for its center must lie on the line through A' perpendicular to $A'A''$, and it must also lie on the perpendicular bisector of segment AA'.

Next, we have ∠OA′A = ∠OA″A′, therefore AA′ is tangent (at A′) to the circumcircle of △OA″A′. This circle too can be drawn readily, even though we have not yet found O, by applying the same logic: its center must lie on the line through A′ perpendicular to AA′ and also on the perpendicular bisector of segment A′A″.

The two circles meet at A′ and O, therefore O is located; see Figure 13.35.

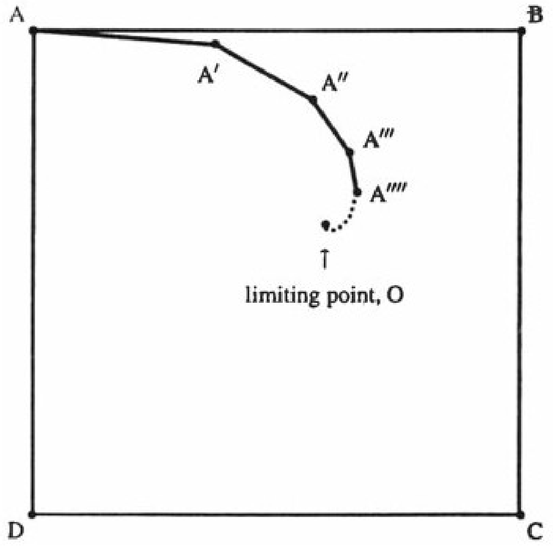

Figure 13.34. *Successive iterates of A*

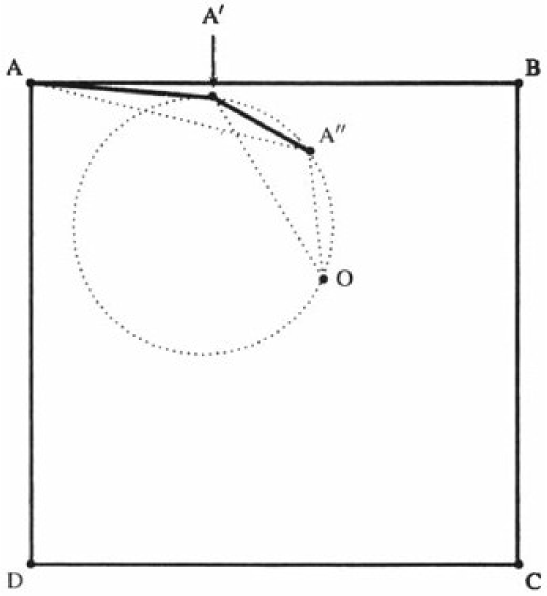

Figure 13.35. *Locating the fixed point* A

Closing remarks

The subject of this section is related to what is known as *fixed point theory*, a very active area of mathematics today—it has whole journals and websites devoted to it! Fixed point theory is part of a subject called *topology*.

The map-in-a-map result is a special case of an extremely important result in this field called Brouwer's *fixed point theorem*. The theorem has all kinds of nice applications in subjects that would seem very far removed from mathematics; for example, economics. The theorem was discovered by a Dutch mathematician, L E J Brouwer (1881–1966).

The "map" result is an application of Brouwer's theorem in *two* dimensions. Even the one dimensional case of the theorem is elegant:

> *Let* f *be a continuous map from a finite interval I into itself; then* f *has a fixed point.*

The two dimensional version of the theorem states the following:

> *Let* f *be a continuous function from a convex, bounded set* S *into itself;*

then fhos *a fixed point.*

The word “continuous” in these two statements here has a technical meaning which we will not go into. In the context of our “map” result, what it means is that while we are allowed to shrink the map as much as we wish, and place it inside the larger map at any orientation, even upside down, we are not permitted to *tear* it. Tearing the map would qualify as a “discontinuous” operation.

The theorem may be similar extended to cover the case of three dimensions.

Here is a pretty application of the theorem; it is called the *coffee cup theorem*. It says that if you take a cup of coffee and stir the coffee with a spoon, then at the end there is some coffee particle that is in exactly the same place that it was before the stirring. If you “push” this particle out of its position, then somewhere else in the cup a particle will end up in its original position!

Exercises

13.9.1 Consider the case when the sides of the small map are parallel respectively to the sides of the large map. Two subcases of interest are: (a) $A'B' \parallel AB$, $B'C' \parallel BC$; (b) $A'B' \perp AB$, $B'C' \perp BC$.

Find simpler ways of locating the fixed point O in these two subcases.

13.9.2 What happens if the small map juts outside the large map? Does a fixed point necessarily exist?

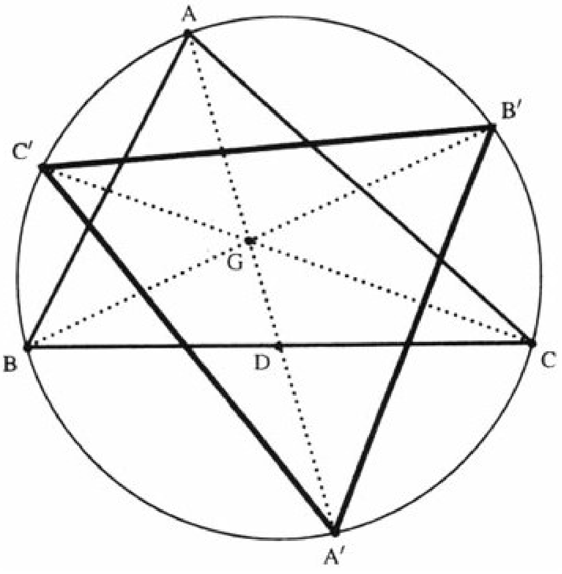

Figure 13.36.

13.9.3 I take a walk as follows: from my house I walk 1 km East, then 1/2 km North, then 1/4 km West, then 1/8 km South, then 1/16 km East, then 1/32 km North, and so on. Where do I find myself eventually? (Give a geometric argument for locating the limiting position.)

13.10 Appendix—analysis of the medians-iteration

We now take up the analysis of the medians iteration studied in Section 13.4. We had said then that the analysis was rather challenging. We now give the full details. Our approach will be.to translate the geometric iteration into an algebraic one, and then recast it into a geometric context using the idea of BARYCENTRIC COORDINATES. (For those who are unfamiliar with this term, a full definition is given below.)

★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★

In Figure 13.36, AD,BE,CF are the medians of triangle ABC, and their lengths are ma,mb,mc, respectively. The medians, when extended, meet the circumcircle Γ at points A′,B′,C′. Let the sides of triangle ABC be a,b,c, and let the lengths of the medians be ma,mb,mc, respectively. Then $a' : b' : c' =$

$ama : bmb : cmc$ (this was proved earlier). It follows that

$$a'2 : b'2 : c'2 = a2(2b2 + 2c2 - a2) : b2(2c2 + 2a2 - b2) : c2(2a2 + 2b2 - c2).$$

Let $x : y : z = a2 : b2 : c2$ and $x' : y' : z' = a'2 : b'2 : c'2$. Then, we have:

$$x' : y' : z' = x(2y + 2z - x) : y(2z + 2x - y) : z(2x + 2y - z).$$

Noting that the sum of the numbers in the triple on the right side is:

$$x(2y+2z-x)+y(2z+2x-y)+z(2x+2y-z) = 4(xy+yz+z\kappa)-(x2+y2+z2),$$

we define a mapping on triples of real numbers whose sum is 1, as follows. If (x,y,z) is such a triple, i.e., with $x + y + z = 1$, then its image is $(x',y',z') = f(x,y,z)$, where

$x' = x(2y + 2z - x)\ 4(xy + yz + zx) - (x2 + y2 + z2)$, $y' = x(2z + 2x - y)\ 4(xy + yz + zx) - (x2 + y2 + z2)$, $z' = x(2x + 2y - z)\ 4(xy + yz + zx) - (x2 + y2 + z2)$, (13.1)

We need to show that the iterates tend to the triple (1/3, 1/3, 1/3).

Transformation of problem, using barycentric coordinates

Let us regard (x,y,z) as the *barycentric coordinates* of a point P with reference to some fixed equilateral triangle T. Before going on, we define what this means.

Oriented area Given a polygon P with its boundary (usually denoted by ∂P) traversed in an anticlockwise or clockwise direction, its *oriented area* (denoted by [P]) is its ordinary area affixed with a *positive* sign if the direction is anticlockwise, and a *negative* sign if the direction is clockwise.

From the definition, it follows that [ABC] = -[ACB] for any triangle ABC, for the "sense" of the closed path A → B → C → A is opposite to that of the path A → C → B→ A.

Barycentric coordinates Given a fixed triangle T with vertices A,B,C (we shall call it as the *triangle of reference*), for any point P in the plane of the triangle, let

$$x : y : z = [PBC] : [PCA] : [PAB] .$$

We shall assume that the labelling of triangle ABC is done in an anticlockwise order (so [ABC] is positive). The location of P is uniquely determined once the ratios x : y : z are known (this follows from elementary geometry). We call the triple (x,y,z), or the ratios x : y : z, the *barycentric coordinates* of P. Examples: The barycentric coordinates of vertex A are (1,0,0), those of the mid-point of side BC are (1/2, 1/2, 0) , and those of the centroid of the triangle are (1/3, 1/3, 1/3). The only triple that does not correspond to any point in the plane is (0,0,0).

Note that the triple (kx,ky,kz) corresponds to the same point as (x,y,z). (So the centroid may also be described by the triple (1, 1, 1), and the mid-point of side BC by the triple (1, 1, 0) .) If x,y,z all have the same sign, then the point P lies inside the triangle, and if $x < 0, y > 0, z > 0$, then P lies within the angle determined by the rays $\overrightarrow{AB}$and $\overrightarrow{AC}$but on the opposite side of BC as compared with A.

★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★

Coming back to our iteration, we see that the image of a point P, determined by a triple (x,y,z), is a point P′, determined by the triple (x′,y′,z′), where x′,y′,z′ are computed using equation (13.1). We need to check whether the iterates of P under this mapping tend to the centroid G of the triangle of reference, T.

We assign the following coordinates to the vertices of T = △UV W:

$$U = (0,3), V = (-1,0), W = (1,0).$$

Then. the centroid of T is G = (0,1⁄3), and the coordinates of the point P corresponding to the triple (x,y,z) are

$$x \cdot U + y \cdot V + z \cdot W x + y + z = z - y x + y + z, x3 x + y + z$$

We first establish two preliminary results (“lemmas”).

Lemma 1. *The equation of the incircle of* T *is* x2 + y2 + z2 = 2(xy + yz + zx). *Points within the incircle have* x2 + y2 + z2 < 2(xy + yz + zx); *points outside the incircle have* x2 + y2 + z2 > 2(xy + yz + zx).

For, the square of the distance between P and G is

$$PG2 = z - y x + y + z2 + x3 x + y + z - 1 32$$

= 4(x2 + y2 + z2 - xy - yz - zx) 3(x + y + z)2 .

Since the radius of the incircle is 1⁄3, we compute the quantity PG2 - 1⁄3:

PG2 -1 3 = 4(x2 + y2 + z2 - xy - yz - zx) 3(x + y + z)2 -1 3

= x2 + y2 + z2 - 2(xy + yz + zx) (x + y + z)2 .

So x2 + P + z2 - 2(xy + yz + zx) is negative, zero or positive, according to whether P is within, on, or outside the incircle of the triangle. ❑

Lemma 2. *The equation of the circumcircle of* T *is* xy + yz + zx = 0. *Points within the circumcircle have* xy + yz + zx > 0, *and points outside the circumcircle have* xy + yz + zx < 0.

Since the radius of the circumcircle of the triangle is 2⁄3, we compute the quantity PG2 - 4⁄3, using the expression for PG2 from above. After simplification, we get:

PG2 -4 3 = 4(x2 + y2 + z2 - xy - yz - zx) 3(x + y + z)2 -4 3 = -4(xy + yz + zx) (x + y + z)2 .

Therefore, xy + yz + zx is positive, zero or negative, according to whether P is within, on, or outside the circumcircle. ❑

Theorem 13.1 *If P lies within the incircle, the image point P ′ lies closer to the center of the incircle than P, i. e ., GP′ < GP. If P lies on the incircle, then so does P′; i. e the distance from G stays fixed. If P lies outside the incircle, then P ′ too lies outside the incircle. If P lies on the circumcircle, then so does P′.*

Proof. The coordinates of the image point P ′, with x ′,y′,z′ given by equations (13.1), are

(y - z) · (2x - y - z) 4(xy + yz + zx) - (x2 + y2 + z2) , x · (x - 2y + 2z)3 4(xy + yz + zx) - (x2 + y2 + z2).

The square of the distance between P′ and G(i.e.,P′G2) is therefore given by

(y - z) · (2x - y - z) 4(xy + yz + zx) - (x2 + y2 + z2)2 + 1 3 · 2x2 - y2 - z2 - 2xy - 2xz + 4yz 4(xy + yz + zx) - (x2 + y2 + z2)2.

This simplifies (after some effort!) to

P′ G2 = 4 3 · (x2 + y2 + z2 - xy - yz - zx)2 [4(xy + yz + zx) - (x2 + y2 + z2)]2.

Therefore,

P′G2 -1 3 = (x + y + z)2 · (x2 + y2 + +z2 - 2xy - 2yz - 2zx) [4(xy + yz + zx) - (x2 + y2 + z2)]2 . (13.2)

Observe that if x;y : z = 1 : 1 : 1, then P′G = 0, i.e., P′ = G. Further , if P≠G, then

P′G2 PG2 - 1 = 9 · (x2 + y2 + z2 - 2xy - 2yz - 2zx) · (xy + yz + zx) [4(xy + yz + zx) - (x2 + y2 + z2)]2 . (13.3)

From equations (13.2) and (13.3), we see that the following possibilities can arise.

- If P lies within the incircle, then we have

  xy + yz + zx > 0,x2 + y2 + z2 < 2(xy + yz + zx),

  so P′G < PG. Therefore, points within the incircle are pulled *towards* the center of the triangle.

- If P lies on the incircle, then

  x2 + y2 + z2 = 2(xy + yz + zx),

  giving P′G2 - 1⁄3 = 0; therefore, P′ too lies on the incircle.

- If P lies outside the incircle, i.e.,

  x2 + y2 + z2 > 2(xy + yz + zx),

  then P′G2 - 1⁄3 > 0, which means that P′ too lies outside the incircle.

- If P lies outside the in circle but within the circumcircle, then

  xy + yz + zx > 0,x2 + y2 + z2 > 2(xy + yz + zx),

  so P′G > PG. Therefore, points in this region are pushed *away* from the center of the triangle.

- If P lies on the circumcircle, then P′G = PG, therefore, P′ too lies on the circumcircle.

- If P lies outside the circumcircle, then P′G < PG. So such points are once again pulled *towards* the center of the triangle.

Convergence of the iteration. Let the quantity t be defined by

$$t = x2 + y2 + z2\ xy + yz + zx. \qquad (13.4)$$

Note that we cannot have t < 1, as x,y,z are real. We now write the relation

$$P'G2\ PG2 = (x + y + z)2 \cdot (x2 + y2 + z2 - xy - yz - zx)\ [4(xy + yz + zx) - (x2 + y2 + z2)]2 \qquad (13.5)$$

in terms of t. Since

$$(x + y + z)2 = (xy + yz + zx) \cdot (t + 2),$$

$$x2 + y2 + z2 - xy - yz - zx = (xy + yz + zx) \cdot (t - 1),$$

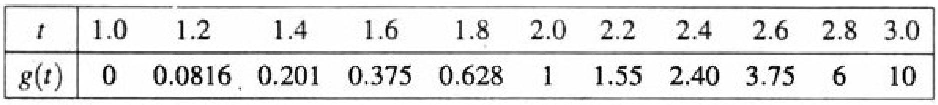
$$4(xy + yz + zx) - (x2 + y2 + z2) = (xy + yz + zx) \cdot (4 - t),$$

we get:

$$P'G2\ PG2 = (t + 2) \cdot (t - 1)\ (4 - t)2\ . \qquad (13.6)$$

Let $g(t) = (t + 2) \cdot (t - 1)/(4 - t)2$. Then $g(2) = 1$; this confirms what we already know: that points on the incircle stay on the incircle.

A table of values of g is of interest:



t	1.0	1.2	1.4	1.6	1.8	2.0	2.2	2.4	2.6	2.8	3.0
$g(t)$	0	0.0816	0.201	0.375	0.628	1	1.55	2.40	3.75	6	10

We see that as t drops from 2 to 1, g(t) decreases from 1 to 0; moreover, the slope of g(t) at t = 0 is 0. This explains why the iterates converge to the equilateral shape so rapidly.

Does the starting point always lie within the incircle? We must check that at the start of the iteration, the point P does lie inside the incircle. But this is easy. Recall that at the start we had

$$x : y : z = a2 : b2 : c2.$$

Therefore, to show that $x2 + y2 + z2 < 2(xy + yz + zx)$ we must show that

$$a4 + b4 + c4 < 2(a2b2 + b2c2 + c2a2).$$

In other words, we must show that

$$a4 + b4 + c4 - 2(a2b2 + b2c2 + c2a2) < 0.$$

Rather conveniently for us, the expression on the side factorizes exactly, as

$$-(a + b + c) \cdot (a + b - c) \cdot (b + c - a) \cdot (c + a - b).$$

In this factorization, the quantities $a + b - c, b + c - a$ and $c + a - b$ are all positive (strictly), by virtue of the triangle inequality ("any two sides of a triangle are together greater than the third side"); also, trivially, $a + b + c$ is positive. It follows that the quantity

$$a4 + b4 + c4 - 2(a2b2 + b2c2 + c2a2)$$

is negative, and therefore, the inequality $a4 + b4 + c4 < 2(a2b2 + b2c2 + c2a2)$ is true.

This means that the triple (x,y,z) with which we start the iteration satisfies the relation

$$x2 + y2 + z2 < 2(xy + yz + zx).$$

So, at the start of the iteration, the point P lies strictly within the incircle, and the iteration pulls if towards the center of the triangle, at an ever increasing rate. , ❑

★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★ ★

We may anticipate from the above that the triangles for which convergence is slow are those for which the ratio $(a2 + b2 + c2)/(ab + bc + ca)$ is close to 2; the closer the ratio is to 2, the slower the convergence. This will be the case for an isosceles triangle whose base is small in relation to the equal sides; for example, a triangle with sides $a = 100 = b$ and $c = 1$, with ratio $20001/10200 \approx 1.961$.

Let us try the iteration using this triangle. The initial values of x,y,z are given by:

$$X = 1002\ 1002 + 1002 + 12 \approx 0.499975, y \approx 0.499975, z \approx 0.00005.$$

Starting with this triple, the first few iterates are the following:

(0.49998, 0.49998, 0.00005), (0.49990, 0.49990, 0.00020),

(0.49960, 0.49960, 0.00080), (0.49841, 0.49841, 0.00317),
(0.49380, 0.49380, 0.01240), (0.47731, 0.47731, 0.04538),
(0.43254, 0.43254, 0.13492), (0.36922, 0.36922, 0.26157),
(0.33729, 0.337 29, 0.32542), (0. 33338, 0.33338,0.33324),
(0.33333, 0.33333, 0.33333), (0.33333, 0.33333 ,0.33333).

We see that even with such a skewed starting triple, convergence to the equilateral shape is very rapid.

Remark. As noted above, if the point P lies in the annular region between the incircle and the circumcircle of T, then $P'G > PG$; it is "pushed away" from the center of the triangle. And if P lies outside the circumcircle, then $P'G < PG$; it is "pulled back" towards the center of the triangle.

This has the following remarkable consequence: if the starting point lies out-side the incircle of T, then its iterates cannot converge to any position whatever. Instead, they are forced to "wander around" aimlessly outside the incircle; neither can they enter within the circle, nor can they recede very far from it—a strange situation, indeed !

4.4 MEASURE ZERO

There is measure in all things.—Horace

The measure theory approach to integration, *Lebesgue integration*, is discussed in Section 4.11. It is superior to Riemann integration from several points of view. It makes it possible to integrate otherwise nonintegrable functions, and it is better behaved than Riemann integration with respect to limits.

However, Lebesgue integrals are essentially impossible to compute, unless you treat the integral as a Riemann integral or a limit of such integrals.

We mentioned in Section 4.3 that the criterion for integrability given by Theorem 4.3.9 is not sharp. It is not necessary that a function (bounded and with bounded support) be continuous except on a set of volume 0 to be integrable: it is necessary and sufficient that it be continuous except on a set of *measure* 0.

Measure theory is a big topic, discussed in Appendix A21. Fortunately, the notion of *measure* 0 is much more accessible. It is a subtle notion with some bizarre consequences; it gives us a way, for example, of saying that the rational numbers "don't count". Thus it allows us to use Riemann integration to integrate some quite interesting functions, including one we explore in Example 4.4.7 as a reasonable model for space averages in statistical mechanics.

In Definition 4.4.1 of measure 0, a *box* B in $\mathbb{R}^n$ of sidelength $\delta > 0$ is a cube of the form

$$\{\, \mathbf{x} \in \mathbb{R}^n \mid a_i < x_i < a_i + \delta,\ i = 1, \dots, n \,\}. \qquad 4.4.1$$

There is no requirement that the a_i or δ be dyadic.

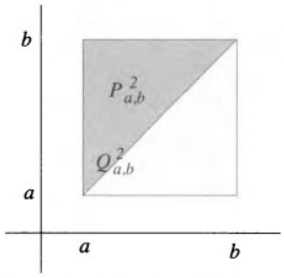

Figure for Exercise 4.3.4

Exercise 4.3.4, part a: Permutations are discussed in Section 4.8. Exercise 4.5.17 gives further applications of Exercise 4.3.4.

4.3.4 For any real numbers $a < b$, let

$$Q^n_{a,b} = \{\, \mathbf{x} \in \mathbb{R}^n \mid a \le x_i \le b \text{ for all } 1 \le i \le n \,\},$$

and let $P^n_{a,b} \subset Q^n_{a,b}$ be the subset where $a \le x_1 \le x_2 \le \cdots \le x_n \le b$. (The case where $n = 2$ is shown in the figure in the margin.)

a. Let $f : \mathbb{R}^n \to \mathbb{R}$ be an integrable function that is symmetric in the sense that

$$f\begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} = f\begin{pmatrix} x_{\sigma(1)} \\ \vdots \\ x_{\sigma(n)} \end{pmatrix} \quad \text{for any permutation } \sigma \text{ of the symbols } 1, 2, \dots, n.$$

Show that

$$\int_{Q^n_{a,b}} f(\mathbf{x})\, |d^n\mathbf{x}| = n! \int_{P^n_{a,b}} f(\mathbf{x})\, |d^n\mathbf{x}|.$$

b. Let $f : [a, b] \to \mathbb{R}$ be an integrable function. Show that

$$\int_{P^n_{a,b}} f(x_1) f(x_2) \cdots f(x_n) |d^n\mathbf{x}| = \frac{1}{n!}\left(\int_a^b f(x)|dx|\right)^n.$$

Exercise 4.3.5: You may either apply theorems or prove the result directly. If you use theorems, you must show that they apply.

4.3.5 Let P be the region $x^2 < y < 1$. Prove that $\int_P \sin(y^2)\, |dx\, dy|$ exists.

4.4 MEASURE ZERO

There is measure in all things.—Horace

The measure theory approach to integration, *Lebesgue integration*, is discussed in Section 4.11. It is superior to Riemann integration from several points of view. It makes it possible to integrate otherwise nonintegrable functions, and it is better behaved than Riemann integration with respect to limits.

However, Lebesgue integrals are essentially impossible to compute, unless you treat the integral as a Riemann integral or a limit of such integrals.

We mentioned in Section 4.3 that the criterion for integrability given by Theorem 4.3.9 is not sharp. It is not necessary that a function (bounded and with bounded support) be continuous except on a set of volume 0 to be integrable: it is necessary and sufficient that it be continuous except on a set of *measure* 0.

Measure theory is a big topic, discussed in Appendix A21. Fortunately, the notion of *measure* 0 is much more accessible. It is a subtle notion with some bizarre consequences; it gives us a way, for example, of saying that the rational numbers "don't count". Thus it allows us to use Riemann integration to integrate some quite interesting functions, including one we explore in Example 4.4.7 as a reasonable model for space averages in statistical mechanics.

In Definition 4.4.1 of measure 0, a *box* B in $\mathbb{R}^n$ of sidelength $\delta > 0$ is a cube of the form

$$\{\, \mathbf{x} \in \mathbb{R}^n \mid a_i < x_i < a_i + \delta,\ i = 1, \dots, n \,\}. \qquad 4.4.1$$

There is no requirement that the a_i or δ be dyadic.

Definition 4.4.1 (Measure 0). A set $X \subset \mathbb{R}^n$ has *measure* 0 if for every $\epsilon > 0$, there exists an infinite sequence of open boxes B_i such that

$$X \subset \cup B_i \quad \text{and} \quad \sum \mathrm{vol}_n(B_i) \leq \epsilon. \tag{4.4.2}$$

You may have noticed that while our dyadic cubes are semi-open, the boxes in Definition 4.4.1 are open. But the theory could be built just as well with closed cubes and boxes (see Exercise 4.4.1).

The theory also applies to boxes with other shapes: Definition 4.4.1 works with the B_i as arbitrary sets with well-defined volume. Exercise 4.4.2 asks you to show that you can use balls; Exercise 4.9 asks you to show that you can use arbitrary pavable sets.

Definition 4.4.2 (Almost everywhere, almost all). The term *almost everywhere*, abbreviated *a.e.*, means *except on a set of measure 0*. A property true of all **x** except for **x** on a set of measure 0 is said to be true for *almost all* **x**.

The crucial difference between measure and volume is the word "infinite" in Definition 4.4.1. A set with volume 0 can be contained in a *finite* sequence of cubes whose total volume is arbitrarily small. A set with volume 0 necessarily has measure 0, but it is possible for a set to have measure 0 but not to have a defined volume, as shown in Example 4.4.3. Note that when we speak of measure 0 of a subset $X \subset \mathbb{R}^n$, we mean n-dimensional measure 0.

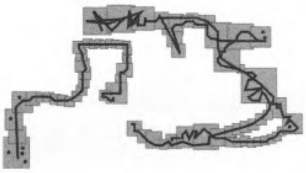

FIGURE 4.4.1.
The set X, shown as a black line, is covered by boxes that overlap.

Remark. We speak of boxes rather than cubes to avoid confusion with the cubes of our dyadic pavings. In dyadic pavings, we considered "families" of cubes all the same size: the cubes at a particular resolution N, and fitting the dyadic grid. The boxes B_i of Definition 4.4.1 get small as i increases, since their total volume is less than ϵ, but it is not necessarily the case that any particular box is smaller than the one immediately preceding it. The boxes can overlap, as illustrated in Figure 4.4.1, and they are not required to square with any particular grid. △

Exercise A21.1 in the appendix explores some of the bizarre properties of the set U_ϵ of Example 4.4.3. This set is a good one to keep in mind while trying to picture the boxes B_i, because it helps us to see that while the sequence $i \mapsto B_i$ is made of $B_1, B_2, \dots$, in order, these boxes may skip around: if B_1 is centered at 1/2, then B_2 is centered at 1/3, B_3 at 2/3, B_4 at 1/4, and so on. Some boxes may be contained in others: for example, depending on the choice of ϵ, the interval centered at 17/32 may be contained in the interval centered at 1/2.

Example 4.4.3 (A set with measure 0, undefined volume). The set of rational numbers in the interval $[0,1]$ has measure 0. You can list them in order, for instance, as 1, 1/2, 1/3, 2/3, 1/4, 2/4, 3/4, 1/5, ... (The list is infinite and includes some numbers more than once.) Center an open interval of length $\epsilon/2$ at 1, an open interval of length $\epsilon/4$ at 1/2, an open interval of length $\epsilon/8$ at 1/3, and so on. Call U_ϵ the union of these intervals. The sum of the lengths of these intervals is $\epsilon\,(1/2 + 1/4 + 1/8 + \cdots) = \epsilon$, and the length of the union is $< \epsilon$, since some of the intervals overlap.

You can place all the rationals in $[0,1]$ in intervals that are infinite in number but whose total length is arbitrarily small! The set U_ϵ thus has measure 0. But it does not have a defined volume because every interval that is not a single point contains both rational and irrational numbers. △

A similar argument proves a stronger result:

Theorem 4.4.4 (A countable union of sets of measure 0 has measure 0). *Let $i \mapsto X_i$ be a sequence of sets of measure 0. Then*

$$X_1 \cup X_2 \cup \dots \quad \textit{is a set of measure 0.}$$

Example 4.4.3 (and, more generally, any countable set) corresponds to the case of Theorem 4.4.4 where each X_i is a single point.

Theorem 4.4.4 is of course not true for arbitrary unions: any set is the union of its points, which all have measure 0. Thus measure theory depends on distinguishing between countable and uncountable infinities, and could only come after Cantor's work (see Section 0.6). Indeed Riemann integration, which doesn't depend on Cantor's work, came before, but Lebesgue integration, which does, comes after.

Proof of Theorem 4.4.4: We can turn the sequences

$$B_{1,i}, \dots, B_{j,i}, \dots$$

into a single sequence by listing the boxes in some order, just as we did for the rational numbers in Example 4.4.3.

For instance, one could list first the boxes where $i+j=2$, then those where $i+j=3$, and so on:

$$B_{1,1}, B_{1,2}, B_{2,1}, B_{1,3}, B_{2,2}, \dots.$$

Proof of Theorem 4.4.4. Since there exist infinite sequences $i \mapsto B_{j,i}$ of boxes (one sequence for each j) such that

$$\begin{aligned} X_1 &\subset B_{1,1} \cup B_{1,2} \cup \dots, \quad \text{and} \quad \sum \operatorname{vol} B_{1,i} \le \frac{\epsilon}{2} \\ X_2 &\subset B_{2,1} \cup B_{2,2} \cup \dots, \quad \text{and} \quad \sum \operatorname{vol} B_{2,i} \le \frac{\epsilon}{4} \\ &\vdots \\ X_j &\subset B_{j,1} \cup B_{j,2} \cup \dots, \quad \text{and} \quad \sum \operatorname{vol} B_{j,i} \le \frac{\epsilon}{2^j}, \end{aligned} \qquad 4.4.3$$

there exists an infinite sequence of open boxes $B_{j,i}$ such that

$$(X_1 \cup X_2 \cup \dots) \subset \bigcup_{j,i} B_{j,i} \quad \text{and} \quad \sum_{i,j} \operatorname{vol} B_{i,j} \le \epsilon. \qquad \square$$

Corollary 4.4.5. *Let $B_R(\mathbf{0})$ be the ball of radius R centered at $\mathbf{0}$. If for all $R \ge 0$ the subset $X \subset \mathbb{R}^n$ satisfies $\operatorname{vol}_n(X \cap B_R(\mathbf{0})) = 0$, then X has measure 0.*

Proof. Since $X = \cup_{m=1}^{\infty} (X \cap B_m(\mathbf{0}))$, it is a countable union of sets of volume 0, hence measure 0. $\square$

Proposition 4.4.6. *Let X be a subspace of $\mathbb{R}^n$ of dimension $k < n$. Then X has measure 0, and any translate of X has measure 0.*

We could also state Proposition 4.4.6 in terms of affine subspaces: an affine subspace $X \in \mathbb{R}^n$ of dimenion $k < n$ has measure 0.

Proof. The first statement follows from Proposition 4.3.5 and Corollary 4.4.5; the second from Proposition 4.1.22. $\square$

The set described in Example 4.4.3 was already encountered in Example 4.3.3, where we found that we could not integrate the function that is 1 at the rational numbers in $[0,1]$ and 0 elsewhere. This function is discontinuous everywhere; in every interval, no matter how small, it jumps from 0 to 1 and from 1 to 0. In Example 4.4.7 we see a function that looks similar but is very different. This function *is* continuous except over a set of measure 0 and thus *is* integrable. It arises in real life (statistical mechanics, at least).

Example 4.4.7: "In lowest terms" traditionally includes the requirement that the denominator be positive, so f is well defined for negative numbers: $-\frac{1}{2}$ can be written only as $\frac{-1}{2}$, not as $\frac{1}{-2}$.

Example 4.4.7 (An integrable function with discontinuities on a set not of volume 0). Consider the function

$$f(x) = \begin{cases} \frac{1}{q} & \text{if } x = \frac{p}{q} \text{ is rational, written in lowest terms with } q > 0 \text{ and } |x| \le 1 \\ 0 & \text{if } x \text{ is irrational or } |x| > 1. \end{cases}$$

This function is integrable although it is discontinuous at values of x for which $f(x) \ne 0$. For instance, $f(3/4) = 1/4$, but arbitrarily close to

3/4 we have irrational numbers, giving $f(x) = 0$. But such values form a set of measure 0. The function is continuous at the irrationals: arbitrarily close to any irrational number x you will find rational numbers p/q, but you can choose a neighborhood of x that includes only rational numbers with arbitrarily large denominators q, so that f will be arbitrarily small in such a neighborhood. $\triangle$

FIGURE 4.4.2.
Ludwig Boltzmann (1844–1906) is credited with the invention of statistical mechanics. A mathematical physicist, he also gave lectures in Vienna on philosophy so popular that no lecture hall large enough could be found.

"The most ordinary things are to philosophy a source of insoluble puzzles," he wrote. "With infinite ingenuity it constructs a concept of space or time and then finds it absolutely impossible that there be objects in this space or that processes occur during this time ... the source of this kind of logic lies in excessive confidence in the so-called laws of thought." In Hegel he found an "unclear thoughtless flow of words"; in Kant, "there were many things that I could grasp so little that ... I almost suspected that he was pulling the reader's leg or was even an imposter."

For the KAM theorem, see "A proof of Kolmogorov's theorem on the conservation of invariant tori," J. Hubbard and Y. Ilyashenko, *Discrete and Continuous Dynamical Systems*, vol. 10, N.1 & 2, Jan. and March 2004, pp. 367–385.

The function of Example 4.4.7 is important because it is a model for functions that show up in an essential way in statistical mechanics (unlike the function of Example 4.3.3, which, as far as we know, is only a pathological example, devised to test the limits of mathematical statements).

In statistical mechanics, one tries to describe a system, typically a gas enclosed in a box, made up of perhaps 10^{25} molecules. Quantities of interest might be temperature, pressure, concentrations of various chemical compounds, etc. A state of the system is a specification of the position and velocity of each molecule (and rotational velocity, vibrational energy, etc., if the molecules have inner structure); to encode this information, one might use a point in some gadzillion-dimensional space.

Mechanics tells us that at the beginning of our experiment, the system is in some state that evolves according to the laws of physics, "exploring" as time proceeds some part of the total state space (and exploring it quite fast relative to our time scale: particles in a gas at room temperature typically travel at several hundred meters per second and undergo millions of collisions per second). The guess underlying thermodynamics is that the quantity one measures, which is really a time average of the quantity as measured along the trajectory of the system, should be nearly equal in the long run to the average over all possible states, called the *space average*. (The "long run" is quite a short run by our clocks.)

This equality of time averages and space averages is called *Boltzmann's ergodic hypothesis*. It is the key hypothesis that connects statistical mechanics to thermodynamics, and physicists believe that it holds in great generality, although there aren't many mechanical systems where it is mathematically proved to be true, and the KAM theorem shows that in some cases where you might expect it to be true, it is not.[4]

What does this have to do with the function f of Example 4.4.7? Even if you believe that a generic time evolution will explore state space fairly evenly, there will always be some trajectories that don't. Consider the (considerably simplified) model of a single particle, moving without friction on a square billiard table, with ordinary bouncing when it hits an edge (the angle of incidence equal to the angle of reflection). Most trajectories (those that start with irrational slope) will evenly fill up the table. But those with rational slopes emphatically will not: they form closed trajectories, which go over and over the same closed path.

---

[4] The KAM theorem, due to Andrei Kolmogorov, Vladimir Arnold, and Jürgen Moser, applies to all frictionless systems of classical mechanics. It shows that under some conditions, these systems are inherently stable. The difference between stability and chaos can hinge on a delicate question in number theory: to what extent irrational numbers can be approximated by rational numbers.

Still, as shown in Figure 4.4.3, these closed paths visit more and more of the table as the denominator of the slope becomes large.

Suppose further that the quantity to be observed is some function f on the table with average 0, which is positive near the center and very negative near the corners, as indicated by the lack of shading near the corners in Figure 4.4.3. Suppose we start our particle at the center of the table but don't specify its direction.

Trajectories through the center of the table, and with slope 0, will have positive time averages, as will trajectories with slope ∞; the trajectories will miss the corners. Similarly, we believe that the average, over time, of each trajectory with rational slope will also be positive. But trajectories with irrational slope will have 0 time averages: given enough time, these trajectories will visit each part of the table equally. And trajectories with rational slopes with large denominators will have time averages close to 0.

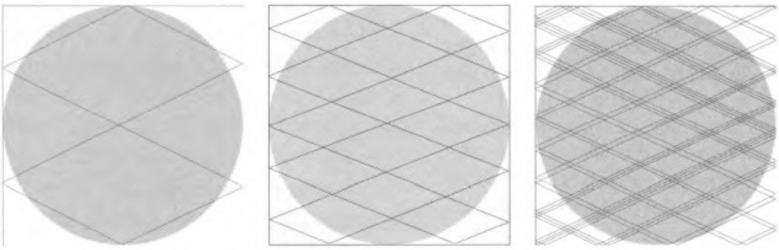

FIGURE 4.4.3. The trajectory with slope 2/5, at center, visits more of the square than the trajectory with slope 1/2, at left. The slope of the trajectory at right closely approximates an irrational number; if allowed to continue, this trajectory would visit nearly every part of the square. (The square would soon become black.)

Because the rational numbers have measure 0, their contribution to the average does not matter; in this case, at least, Boltzmann's ergodic hypothesis seems correct. △

This billiard table example is a caricature of the kind of thing we might run into in statistical mechanics, for instance, having one gas in half a box and another in another half, and removing the partition between them.

Statistical mechanics is an attempt to apply probability theory to large systems of particles, to estimate average quantities, like temperature, pressure, etc., from the laws of mechanics. Thermodynamics, on the other hand, is a completely macroscopic theory. It tries to relate the same macroscopic quantities (temperature, pressure, etc.) on a phenomenological level. Clearly, one hopes to explain thermodynamics by statistical mechanics.

Questions of rational versus irrational numbers are central to understanding the intricate interplay of chaotic and stable behavior exhibited, for example, by the *lakes of Wada*. For more on this topic, see J.H. Hubbard, "What it Means to Understand a Differential Equation," *The College Mathematics Journal*, Vol. 25 (Nov. 5, 1994), 372–384.

Integrability of "almost" continuous functions

We are now ready to state and prove Theorem 4.4.8. This theorem makes it clear that whether or not a function is integrable does not depend on where it is placed on some arbitrary grid.

Theorem 4.4.8 (What functions are integrable). *Let $f : \mathbb{R}^n \to \mathbb{R}$ be bounded with bounded support. Then f is integrable if and only if it is continuous except on a set of measure 0.*

Theorem 4.4.8 is stronger than Theorem 4.3.9, since any set of volume 0 also has measure 0, but not vice versa. It is also stronger than Theorem 4.3.6. It is not stronger than Theorem 4.3.1. Theorems 4.4.8 and 4.3.1 both give an "if and only if" condition for integrability; they are exactly equivalent. But it is often easier to verify that a function is integrable using Theorem 4.4.8.

Proof. We will start with the harder direction: if $f : \mathbb{R}^n \to \mathbb{R}$, bounded with bounded support, is continuous almost everywhere, then it is integrable. We will use the criterion for integrability given by Theorem 4.3.1; thus we want to prove that for all $\epsilon > 0$ there exists N such that the cubes $C \in \mathcal{D}_N$ over which $\text{osc}_C(f) > \epsilon$ have a combined volume less than ϵ. (Recall from Definition 4.1.4 that $\text{osc}_{B_i}(f)$ is the oscillation of f over B_i.)

Denote by Δ the set of points where f is not continuous, and choose $\epsilon > 0$ (which will remain fixed for the duration of the proof). By Definition 4.4.1 of measure 0, there exists an infinite sequence $i \mapsto B_i$ of open boxes such that

$$\Delta \subset \cup B_i \quad \text{and} \quad \sum \text{vol}_n B_i < \epsilon. \qquad 4.4.4$$

We will choose our boxes so that no box is contained in any other.

The proof is fairly involved. First, we want to get rid of infinity.

We prune the list of boxes by throwing away any box that is contained in an earlier one. We could prove our result without pruning the list, but it would make the argument more cumbersome.

Lemma 4.4.9. *Let $i \mapsto B_i$ be a sequence satisfying $\Delta \subset \cup B_i$ and $\sum \text{vol}_n B_i < \epsilon$. Then $\text{osc}_{B_i}(f) > \epsilon$ on only finitely many boxes B_i.*

Denote such boxes by B_{i_j}; denote the union of the B_{i_j} by L. (In Figure 4.4.4, the B_i are the lightly shaded boxes; the B_{i_j} are slightly darker.)

Proof of Lemma 4.4.9. Assume the lemma is false. Then there exist an infinite subsequence of boxes $j \mapsto B_{i_j}$ and two infinite sequences of points, $j \mapsto \mathbf{x}_j, j \mapsto \mathbf{y}_j$ in B_{i_j}, such that $|f(\mathbf{x}_j) - f(\mathbf{y}_j)| > \epsilon$.

The sequence $j \mapsto \mathbf{x}_j$ is bounded, since the support of f is bounded and $\mathbf{x}_j$ is in the support of f. So (by Theorem 1.6.3) it has a convergent subsequence $\mathbf{x}_{j_k}$ converging to some point $\mathbf{p}$. Since $|\mathbf{x}_j - \mathbf{y}_j| \to 0$ as $j \to \infty$, the subsequence $\mathbf{y}_{j_k}$ also converges to $\mathbf{p}$.

The function f is certainly not continuous at $\mathbf{p}$, so $\mathbf{p} \in \Delta$ and by formula 4.4.4, $\mathbf{p}$ has to be in a particular box; we will call it $B_\mathbf{p}$. (Since the boxes can overlap, it could be in more than one, but we just need one.) Since $\mathbf{x}_{j_k}$ and $\mathbf{y}_{j_k}$ converge to $\mathbf{p}$, and since the B_{i_j} get small as j gets big (their total volume being less than ϵ), then all $B_{i_{j_k}}$ after a certain point are contained in $B_\mathbf{p}$. But this contradicts our assumption that we had pruned our list of B_i so that no one box was contained in any other. Therefore, Lemma 4.4.9 is correct: there are only finitely many B_i on which $\text{osc}_{B_i} f > \epsilon$. $\square$ Lemma 4.4.9

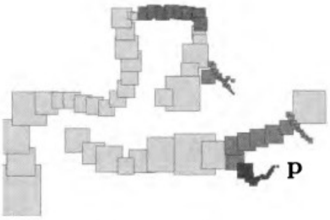

FIGURE 4.4.4.

The collection of boxes B_i covering Δ is lightly shaded. The boxes B_{i_j} with osc $> \epsilon$ are shaded slightly darker. A convergent subsequence of those is shaded darker yet. The key to Lemma 4.4.9 is that the point to which they converge must belong to some box B_i.

Lemma 4.4.10. *There exists N such that if $C \in \mathcal{D}_N(\mathbb{R}^n)$ and $\text{osc}_C f > \epsilon$, then $C \subset L$.*

If we prove this, we will be finished, because by Theorem 4.3.1, a bounded function with bounded support is integrable if there exists N at which the total volume of cubes with osc $> \epsilon$ is less than ϵ. We know that L is a finite set of B_i, and that the B_i have total volume $< \epsilon$.

Proof of Lemma 4.4.10. We will again argue by contradiction. Suppose the lemma is false. Then for every N, there exists a C_N not a subset of L such that $\text{osc}_{C_N} f > \epsilon$. In other words,

$$\exists \text{ points } \mathbf{x}_N, \mathbf{y}_N, \mathbf{z}_N \text{ in } C_N, \text{ with } \mathbf{z}_N \notin L \text{ and } |f(\mathbf{x}_N) - f(\mathbf{y}_N)| > \epsilon. \qquad 4.4.5$$

Since $\mathbf{x}_N, \mathbf{y}_N$, and $\mathbf{z}_N$ are infinite sequences (for $N = 1, 2, \dots$), there exist convergent subsequences $\mathbf{x}_{N_i}$, $\mathbf{y}_{N_i}$, and $\mathbf{z}_{N_i}$, all converging to the same point, which we will call $\mathbf{q}$.

What do we know about $\mathbf{q}$?

- $\mathbf{q} \in \Delta$: i.e., it is a discontinuity of f – no matter how close $\mathbf{x}_{N_i}$ and $\mathbf{y}_{N_i}$ get to $\mathbf{q}$, we have $|f(\mathbf{x}_{N_i}) - f(\mathbf{y}_{N_i})| > \epsilon$. Therefore (since all the discontinuities of f are contained in the B_i), it is in some box B_i, which we'll call $B_{\mathbf{q}}$.
- $\mathbf{q} \notin L$. (The set L is open, since it is a union of open sets; see Exercise 1.5.3. Therefore its complement is closed; since no point of the sequence $\mathbf{z}_{N_i}$ is in L, its limit, $\mathbf{q}$, is not in L either.)

Since $\mathbf{q} \in B_{\mathbf{q}}$, and $\mathbf{q} \notin L$, we know that $B_{\mathbf{q}}$ is not one of the boxes with osc $> \epsilon$. But $\mathbf{x}_{N_i}$ and $\mathbf{y}_{N_i}$ are in $B_{\mathbf{q}}$ for N_i large enough, so that $\text{osc}_{B_{\mathbf{q}}} f < \epsilon$ contradicts $|f(\mathbf{x}_{N_i}) - f(\mathbf{y}_{N_i})| > \epsilon$. □ Lemma 4.4.10

You may ask, how do we know they converge to the same point? Because $\mathbf{x}_{N_i}$, $\mathbf{y}_{N_i}$, and $\mathbf{z}_{N_i}$ are all in the same cube, which is shrinking to a point as $N \to \infty$.

Recall that Δ is the set of points where f is not continuous, and L is the finite union of the boxes B_i on which $\text{osc}_{B_i}(f) > \epsilon$.

The boxes B_i making up L are in $\mathbb{R}^n$, so the complement of L is $\mathbb{R}^n - L$. Recall (Definition 1.5.4) that a closed set $C \subset \mathbb{R}^n$ is a set whose complement $\mathbb{R}^n - C$ is open.

The proof of Lemma 4.4.10 means that we have proved Theorem 4.4.8 in one direction: if a bounded function with bounded support is continuous except on a set of measure 0, then it is integrable.

Now we need to prove the other direction: if a function $f : \mathbb{R}^n \to \mathbb{R}$, bounded and with bounded support, is integrable, then it is continuous almost everywhere. This is easier, but the fact that we chose our dyadic cubes half-open and our boxes open introduces a little complication.

Definition 4.4.1 specifies that the boxes B_i are open. Equation 4.1.12 defining dyadic cubes shows that they are half-open: x_i is greater than or equal to one amount, but strictly less than another:

$$\frac{k_i}{2^N} \le x_i < \frac{k_i + 1}{2^N}.$$

Choose $\delta > 0$. Since f is integrable, we know (Theorem 4.3.1) that for any $\epsilon > 0$, there exists N such that the finite union of cubes

$$\{\, C \in \mathcal{D}_N(\mathbb{R}^n) \mid \text{osc}_C(f) > \epsilon \,\} \qquad 4.4.6$$

has total volume less than ϵ. So we can choose N_1 such that if $\mathcal{C}_{N_1}$ denotes the finite collection of cubes $C \in \mathcal{D}_{N_1}(\mathbb{R}^n)$ with $\text{osc}_C f > \delta/4$, these cubes have total volume less than $\delta/4$.

Now let $\mathcal{C}_{N_2}$ be the finite collection of cubes with $\text{osc}_C f > \delta/8$; these cubes have total volume less than $\delta/8$. Continue with $\delta/16, \dots$. Finally, consider the infinite sequence of open boxes $B_1, B_2, \dots$ obtained by listing first the interiors of the cubes in $\mathcal{C}_{N_1}$, then those of the cubes in $\mathcal{C}_{N_2}$, etc.

This almost solves our problem: the sums of the volumes of the boxes in our sequence is at most $\delta/4 + \delta/8 + \cdots = \delta/2$. The problem is that discontinuities on the boundary of dyadic cubes may go undetected by oscillation on dyadic cubes: the value of the function over one cube could be 0, and the value over an adjacent cube could be 1; in each case the oscillation over the cube would be 0, but the function would be discontinuous at points on the border between the two cubes.

This is easily dealt with: the union of all the boundaries of all dyadic cubes (over all N) has measure 0. To see this, denote by $\delta\mathcal{D}_N(\mathbb{R}^n)$ the union of the boundaries of the dyadic cubes of $\mathcal{D}_N$. Then

1. For each N, the boundary $\delta\mathcal{D}_N(\mathbb{R}^n)$ is a countable union of translates of subspaces of dimension $n - 1$, hence has measure 0 by Theorem 4.4.4 and Corollary 4.4.5.

2. The set $\cup_{N=1}^{\infty} \delta \mathcal{D}_N(\mathbb{R}^n)$ has measure 0, since it is a countable union of sets of measure 0. □ Theorem 4.4.8.

Corollary 4.4.11. *Let f and g be integrable functions on $\mathbb{R}^n$ such that $f \geq g$ and $\int f(\mathbf{x})|d^n\mathbf{x}| = \int g(\mathbf{x})|d^n\mathbf{x}|$. Then*

$$\{\,\mathbf{x} \mid f(\mathbf{x}) \neq g(\mathbf{x})\,\} \text{ has measure 0.}$$

Proof. The function $f - g$ is integrable, hence continuous almost everywhere. Thus if $f > g$ on a set not of measure 0, there exists $\mathbf{x}_0$ such that $f(\mathbf{x}_0) > g(\mathbf{x}_0)$ and $f - g$ is continuous at $\mathbf{x}_0$. Then there exist $\epsilon > 0$ and $r > 0$ such that $f(\mathbf{x}) - g(\mathbf{x}) > \epsilon$ when $|\mathbf{x} - \mathbf{x}_0| \leq r$. We then have

$$\int_{\mathbb{R}^n} (f-g)(\mathbf{x})|d^n\mathbf{x}| \geq \int_{B_r(\mathbf{x}_0)} (f-g)(\mathbf{x})|d^n\mathbf{x}| \geq \epsilon \ \mathrm{vol}_n(B_r(\mathbf{x}_0)) > 0, \quad 4.4.7$$

contradicting our assumption that $\int f(\mathbf{x})|d^n\mathbf{x}| = \int g(\mathbf{x})|d^n\mathbf{x}|$. □

In Proposition 4.1.14 we saw that the sum of two integrable functions is integrable, and that the product of a real number and an integrable function is integrable. It is also true that if two functions $f, g : \mathbb{R}^n \to \mathbb{R}$ are both integrable, their product is integrable (although the integral of the product is in general *not* the product of the integrals).

Corollary 4.4.12: The integral of the product is usually *not* the product of the integrals. However (Proposition 4.1.16), if f and g are functions of *different* variables, then the integral of the product over the product of the domains *is* the product of the integrals.

Corollary 4.4.12 (Product of integrable functions is integrable). *If two functions $f, g : \mathbb{R}^n \to \mathbb{R}$ are both integrable, then fg is also integrable.*

Proof. If f is continuous except on a set X_f of measure 0, and g is continuous except on a set X_g of measure 0, then (Proposition 1.5.29) fg is continuous except on a subset of $X_f \cup X_g$. By Theorem 4.4.4, this subset has measure 0. Thus by Theorem 4.4.8, fg is integrable. □

Corollary 4.4.13 follows from Theorem 4.4.8.

Corollary 4.4.13 (Integration is translation invariant). *If a function $f : \mathbb{R}^n \to \mathbb{R}$ is integrable, then for any $\vec{\mathbf{v}} \in \mathbb{R}^n$, the function $\mathbf{x} \mapsto f(\mathbf{x} - \vec{\mathbf{v}})$ is integrable.*

EXERCISES FOR SECTION 4.4

4.4.1 Use Definition 4.1.17 of n-dimensional volume to show that the same sets have measure 0 whether you define measure 0 using open boxes or closed boxes.

4.4.2 Show that $X \subset \mathbb{R}^n$ has measure 0 if and only if for any $\epsilon > 0$ there exists an infinite sequence of balls

$$B_i = \{\,\mathbf{x} \in \mathbb{R}^n \mid |\mathbf{x} - \mathbf{a}_i| < r_i\,\} \text{ with } \sum_{i=1}^{\infty} r_i^n < \epsilon \text{ such that } X \subset \cup_{i=1}^{\infty} B_i.$$

4.4.3 Prove that any compact subset of $\mathbb{R}^n$ of measure 0 has volume 0.

Hint for Exercise 4.4.3: Use the Heine Borel theorem in Appendix A3.

****4.4.4** Consider the subset $U \subset [0,1]$ that is the union of the open intervals $\left(\frac{p}{q} - \frac{C}{q^3}, \frac{p}{q} + \frac{C}{q^3}\right)$ for all rational numbers $p/q \in [0,1]$. Show that for $C > 0$ sufficiently small, U is not pavable. What would happen if the 3 were replaced by 2? (This is really hard.)

4.4.5 Show that Corollary 4.4.11 is false if you replace "measure" by "volume".

4.4.6 Show that if the boundary of $A \subset \mathbb{R}^n$ has a well-defined n-dimensional volume, that volume is 0: $\text{vol}_n\, \partial A = 0$. *Hint*: Use Theorem 4.8.8.

4.4.7 Show that the set of numbers which in base 10 can be written using only the digits 1–6 has measure 0.

4.5 FUBINI'S THEOREM AND ITERATED INTEGRALS

FIGURE 4.5.1.

The Italian mathematician Guido Fubini (1879–1943) was forced to retire when the Manifesto of Fascist Racism made anti-Semitism official policy of Italy in 1938. He joined the Institute for Advanced Study in Princeton the following year.

We now know – in principle, at least – how to determine whether a function is integrable. Assuming it is, how do we integrate it? Fubini's theorem allows us to compute multiple integrals by hand, or at least reduce them to the computation of one-dimensional integrals. It asserts that if $f : \mathbb{R}^n \to \mathbb{R}$ is integrable, then

$$\int_{\mathbb{R}^n} f(\mathbf{x})\, |d^n\mathbf{x}| = \int_{-\infty}^{\infty} \left(\dots \left(\int_{-\infty}^{\infty} f \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} dx_1 \right) \dots \right) dx_n. \qquad 4.5.1$$

That is, first we hold the variables $x_2, \dots, x_n$ constant and integrate with respect to x_1; then we integrate the resulting (no doubt complicated) function with respect to x_2, and so on. Note that the expression on the left side of equation 4.5.1 doesn't specify the order in which the variables are taken, so the iterated integral on the right can be written in any order: we could integrate first with respect to x_n, or any other variable. This is important for both theoretical and computational uses of Fubini's theorem. Note also that in one dimension, equation 4.5.1 becomes equation 4.1.30.

Remark. Equation 4.5.1 is not quite correct, because some of the functions in parentheses on the right side of equation 4.5.1 may not be integrable; this problem is discussed in Appendix A17. We state Fubini's theorem correctly at the end of this section. For now, assume that we are in the (common) situation where equation 4.5.1 works. △

In practice, the main difficulty in setting up a multiple integral as an iterated one-dimensional integral is dealing with the "boundary" of the region over which we wish to integrate the function. We tried to sweep difficulties like the fractal coastline of Britain under the rug by choosing to integrate over all of $\mathbb{R}^n$, but of course those difficulties are still there. This is where we have to come to terms with them: we have to figure out the upper and lower limits of the integrals.

If the domain of integration looks like the coastline of Britain, it is not obvious how to go about this. For domains of integration bounded by smooth curves and surfaces, formulas exist in many cases that are of interest (particularly during calculus exams), but this is still the part that gives students the most trouble. So before computing any multiple integrals, let's see how to set them up. While a multiple integral is *computed* from inside out – first with respect to the variable in the inner parentheses – we recommend *setting up* the problem from outside in, as shown in Examples 4.5.1 and 4.5.2.

By "integrate over the triangle" we mean that we imagine that the function f is defined by some formula inside the triangle, and by $f = 0$ outside the triangle.

Example 4.5.1 (Setting up multiple integrals: an easy example). Suppose we want to integrate a function $f : \mathbb{R}^2 \to \mathbb{R}$ over the triangle

$$T = \left\{ \begin{pmatrix} x \\ y \end{pmatrix} \in \mathbb{R}^2 \,\middle|\, 0 \le 2x \le y \le 2 \right\} \qquad 4.5.2$$

shown in Figure 4.5.2. This triangle is the intersection of the three regions (here, halfplanes) defined by the inequalities $0 \le x,\ 2x \le y,$ and $y \le 2$.

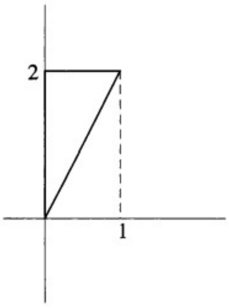

FIGURE 4.5.2.
The triangle defined by equation 4.5.2.

Say we want to integrate first with respect to y. We set up the integral as follows, temporarily omitting the limits of integration:

$$\int_{\mathbb{R}^2} f \begin{pmatrix} x \\ y \end{pmatrix} |dx\, dy| = \int \left(\int f\, dy \right) dx. \qquad 4.5.3$$

(We just write f for the function, as we don't want to complicate issues by specifying a particular function.) Starting with the outer integral – thinking first about x – we hold a pencil parallel to the y-axis and roll it over the triangle from left to right. We see that the triangle (the domain of integration) starts at $x = 0$ and ends at $x = 1$, so we write in those limits:

$$\int_0^1 \left(\int f\, dy \right) dx. \qquad 4.5.4$$

Now think about what happened as you rolled the pencil from $x = 0$ to $x = 1$: for each value of x, what values of y were in the triangle? In this simple case, for every value of x, the pencil intersects the triangle in an interval going from the hypotenuse to $y = 2$. So the upper value is $y = 2$, and the lower value is $y = 2x$, the line on which the hypotenuse lies. Thus we have

$$\int_0^1 \left(\int_{2x}^2 f\, dy \right) dx. \qquad 4.5.5$$

If we want to start by integrating f with respect to x, we write

$$\int_{\mathbb{R}^2} f \begin{pmatrix} x \\ y \end{pmatrix} |dx\, dy| = \int \left(\int f\, dx \right) dy; \qquad 4.5.6$$

starting with the outer integral, we hold our pencil parallel to the x-axis and roll it from the bottom of the triangle to the top, from $y = 0$ to $y = 2$. As we roll the pencil, we ask what are the lower and upper values of x for each value of y. The lower value is always $x = 0$, and the upper value is set by the hypotenuse, but we express it as $x = y/2$. This gives

$$\int_0^2 \left(\int_0^{\frac{y}{2}} f\,dx \right) dy. \qquad 4.5.7$$

Now suppose we are integrating over only part of the triangle, as shown in Figure 4.5.3. What limits do we put in the expression $\int(\int f\,dy)\,dx$? Try it yourself before checking the answer in the footnote.[5] △

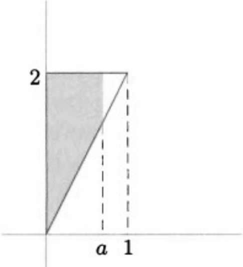

FIGURE 4.5.3.

The shaded area represents a truncated part of the triangle of Figure 4.5.2.

Example 4.5.2 (Setting up multiple integrals: a somewhat harder example). Now let's integrate an unspecified function $f:\mathbb{R}^2 \to \mathbb{R}$ over the area bordered on the top by the parabolas $y = x^2$ and $y = (x-2)^2$ and on the bottom by the straight lines $y = -x$ and $y = x - 2$, as shown in Figure 4.5.4.

Let's start again by sweeping our pencil from left to right, which corresponds to the outer integral being with respect to x. The limits for the outer integral are clearly $x = 0$ and $x = 2$, giving

$$\int_0^2 \left(\int f\,dy \right) dx. \qquad 4.5.8$$

As we sweep our pencil from left to right, we see that the lower limit for y is set by the straight line $y = -x$, and the upper limit by the parabola $y = x^2$, so we are tempted to write $\int_0^2 \left(\int_{-x}^{x^2} f\,dy \right) dx$, but at $x = 1$, we have a problem. The lower limit is now set by the straight line $y = x - 2$, and the upper limit by the parabola $y = (x-2)^2$. How can we express this? Try it yourself before looking at the answer in the footnote.[6] △

Exercise 4.5.3 asks you to set up the multiple integral for Example 4.5.2 when the outer integral is with respect to y. The answer will be a sum of integrals.

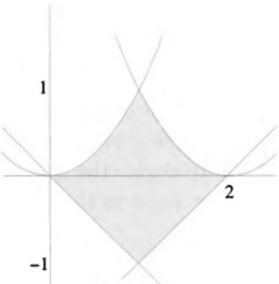

FIGURE 4.5.4.

The region of integration for Example 4.5.2.

Example 4.5.3 (Setting up a multiple integral in $\mathbb{R}^3$). Already in $\mathbb{R}^3$ this kind of visualization becomes much harder. Suppose we want to integrate a function over the pyramid P shown in Figure 4.5.5 and given by the formula

$$P = \left\{ \begin{pmatrix} x \\ y \\ z \end{pmatrix} \in \mathbb{R}^3 \mid 0 \le x;\ 0 \le y;\ 0 \le z;\ x + y + z \le 1 \right\}. \qquad 4.5.9$$

---

[5] When the domain of integration is the truncated triangle in Figure 4.5.3, the integral is written

$$\int_0^a \left(\int_{2x}^2 f\,dy \right) dx.$$

The other direction is harder; we will return to it in Exercise 4.5.2.

[6] We need to break up this integral into a sum of integrals:

$$\int_0^1 \left(\int_{-x}^{x^2} f\,dy \right) dx + \int_1^2 \left(\int_{x-2}^{(x-2)^2} f\,dy \right) dx.$$

Exercise 4.5.1 asks you to justify ignoring that we have counted the line $x = 1$ twice.

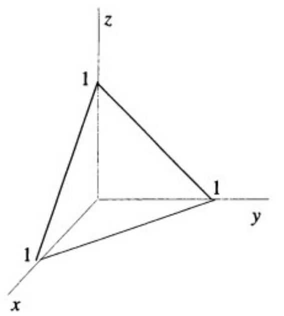

FIGURE 4.5.5.
Pyramid for Example 4.5.3.

We want to figure out the limits of integration for the multiple integral

$$\int_P f\begin{pmatrix}x\\y\\z\end{pmatrix}|dx\,dy\,dz| = \int\left(\int\left(\int f\,dx\right)dy\right)dz. \qquad 4.5.10$$

There are six ways to apply Fubini's theorem, which in this case because of symmetries will result in the same expressions with the variables permuted. Let us vary z first. For instance, we can lift a piece of paper and see how it intersects the pyramid at various heights. Clearly the paper will only intersect the pyramid when its height is between 0 and 1. This gives $\int_0^1 (\quad)dz$, where the space needs be filled in by the double integral of f over the part of the pyramid P at height z, pictured at left in Figure 4.5.6, and again at right, this time drawn flat.

Note that when setting up a multiple integral, the upper and lower limits for the outer integral are just numbers. Then (going from outer to inner) the limits for the next integral may depend on the variable of the outer integral. See, for instance the upper limit $y/2$ in integral 4.5.7, and the upper limit $1 - z$ in integral 4.5.11. The limits for the next integral may depend on the variables of the two outer integrals; see the upper limit $1 - y - z$ in formula 4.5.12.

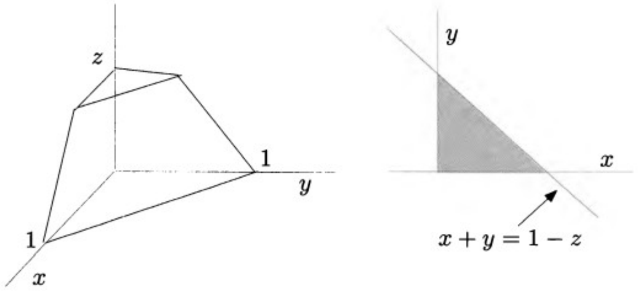

FIGURE 4.5.6. LEFT: The pyramid of Figure 4.5.5, truncated at height z. RIGHT: The plane at height z, put flat.

This time we are integrating over a triangle (which depends on z); see the right side of Figure 4.5.6. So we are in the situation of Example 4.5.1. Let's vary y first. Holding a pencil parallel to the x-axis and rolling it over the triangle from bottom to top, we see that the relevant y-values are between 0 and $1 - z$ (the upper value is the largest value of y on the part of the line $y = 1 - z - x$ that is in the triangle). So we write

$$\int_0^1\left(\int_0^{1-z}(\qquad\qquad)dy\right)dz, \qquad 4.5.11$$

where now the blank represents the integral over part of the horizontal line segment at height z and "depth" y. These x-values are between 0 and $1 - z - y$, so finally the integral is

$$\int_0^1\left(\int_0^{1-z}\left(\int_0^{1-y-z} f\begin{pmatrix}x\\y\\z\end{pmatrix}dx\right)dy\right)dz. \quad \triangle \qquad 4.5.12$$

Formula 4.5.12: When we integrate with regard to x, why is the upper value $1-y-z$, when the upper value with regard to y is $1-z$, not $1-z-x$? Since the inner integral, first to be computed, is with regard to x, we must consider all values of y and z. But when we integrate with regard to y, we have already integrated with regard to x. Clearly the value of x for which $y = 1 - z - x$ is largest is $x = 0$, giving upper value $y = 1 - z$.

Example 4.5.4 (A less visual example). In the preceding examples, we could deduce the upper and lower limits from pictures of the region over which we want to integrate. Here is a case where the picture doesn't give the answer. Let us set up a multiple integral over the ellipse E defined by

$$E = \left\{ \begin{pmatrix} x \\ y \end{pmatrix} \mid x^2 + xy + y^2 \le 1 \right\}. \qquad 4.5.13$$

The boundary of E is defined by $y^2 + xy + x^2 - 1 = 0$, so on the boundary,

$$y = \frac{-x \pm \sqrt{x^2 - 4(x^2-1)}}{2} = \frac{-x \pm \sqrt{4 - 3x^2}}{2}. \qquad 4.5.14$$

Such values exist only if $4 - 3x^2 \ge 0$, i.e., $|x| \le 2\sqrt{3}/3$. So to set up the integral of a function f over E we write

Here, x and y play symmetric roles, so to integrate first with respect to x, we would just replace every y by x and vice versa.

$$\int_{-2\sqrt{3}/3}^{2\sqrt{3}/3} \left(\int_{\frac{-x-\sqrt{4-3x^2}}{2}}^{\frac{-x+\sqrt{4-3x^2}}{2}} f\begin{pmatrix} x \\ y \end{pmatrix} dy \right) dx. \quad \triangle \qquad 4.5.15$$

Now let's actually compute a few multiple integrals.

Example 4.5.5 (Computing a multiple integral). Let $f:\mathbb{R}^2 \to \mathbb{R}$ be the function $f\begin{pmatrix} x \\ y \end{pmatrix} = xy\,\mathbf{1}_S\begin{pmatrix} x \\ y \end{pmatrix}$, where S is the unit square, as shown in Figure 4.5.7. Then

$$\begin{aligned} \int_{\mathbb{R}^2} f\begin{pmatrix} x \\ y \end{pmatrix} |dx\,dy| &= \int_0^1 \left(\int_0^1 xy\,dx \right) dy \\ &= \int_0^1 \left[\frac{x^2y}{2} \right]_{x=0}^{x=1} dy = \int_0^1 \frac{y}{2}\,dy = \frac{1}{4}. \quad \triangle \end{aligned} \qquad 4.5.16$$

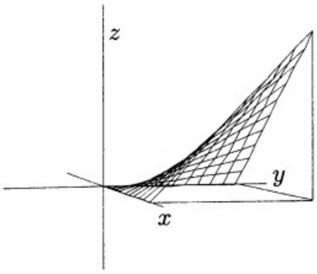

FIGURE 4.5.7.

The integral in equation 4.5.16 is 1/4: the volume under the surface defined by $f\begin{pmatrix} x \\ y \end{pmatrix} = xy$ and above the unit square is 1/4.

In Example 4.5.5 it is clear that we could have taken the integral in the opposite order and found the same result, since our function is $f\begin{pmatrix} x \\ y \end{pmatrix} = xy$. Fubini's theorem says that this is always true as long as the functions involved are integrable. This fact is useful; sometimes a multiple integral can be computed in elementary terms when written in one direction, but not in the other, as you will see in Example 4.5.6. It may also be easier to determine the limits of integration if the problem is set up in one direction rather than another, as we saw in the case of the truncated triangle shown in Figure 4.5.3.

Example 4.5.6 (Choose the easy direction). Let us integrate the function e^{-y^2} over the triangle shown in Figure 4.5.8:

$$T = \left\{ \begin{pmatrix} x \\ y \end{pmatrix} \in \mathbb{R}^2 \mid 0 \le x \le y \le 1 \right\}. \qquad 4.5.17$$

Fubini's theorem gives us two ways to write this integral as an iterated one-dimensional integral:

$$\int_0^1 \left(\int_x^1 e^{-y^2} dy \right) dx \qquad \text{and} \qquad \int_0^1 \left(\int_0^y e^{-y^2} dx \right) dy. \qquad 4.5.18$$

The first cannot be computed in elementary terms, since e^{-y^2} does not have an elementary antiderivative. But the second can:

$$\int_0^1 \left(\int_0^y e^{-y^2} dx \right) dy = \int_0^1 ye^{-y^2}\, dy = -\frac{1}{2}\left[e^{-y^2}\right]_0^1 = \frac{1}{2}\left(1 - \frac{1}{e}\right). \qquad 4.5.19$$

(The y in ye^{-y^2} makes it possible to integrate in elementary terms.) △

Older textbooks contain many examples of such computational miracles. We believe it is sounder to take a serious interest in the numerical theory and go lightly over computational tricks, which do not work in any great generality in any case.

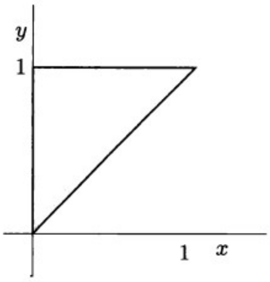

FIGURE 4.5.8.
The triangle

$$\left\{ \begin{pmatrix} x \\ y \end{pmatrix} \in \mathbb{R}^2 \mid 0 \le x \le y \le 1 \right\}$$

of Example 4.5.6.

Example 4.5.7: The ball $B_1^n(\mathbf{0})$ is the ball of radius 1 in $\mathbb{R}^n$, centered at the origin; the ball

$$B^{n-1}_{\sqrt{1-x_n^2}}(\mathbf{0})$$

is the ball of radius $\sqrt{1-x_n^2}$ in $\mathbb{R}^{n-1}$, still centered at the origin.

In the first line of equation 4.5.20 we imagine slicing the n-dimensional ball horizontally and computing the $(n-1)$-dimensional volume of each slice.

Example 4.5.7 (Volume of a ball in $\mathbb{R}^n$). Let $B_R^n(\mathbf{0})$ be the ball of radius R in $\mathbb{R}^n$, centered at $\mathbf{0}$, and let $b_n(R)$ be its volume. By Proposition 4.1.24, $b_n(R) = R^n b_n(1)$. We will denote by $\beta_n = b_n(1)$ the volume of the unit ball. By Fubini's theorem,

$$\begin{aligned}
\underbrace{\beta_n}_{\substack{\text{vol. of}\\ \text{unit ball in } \mathbb{R}^n}} &= \int_{B_1^n(\mathbf{0})} |d^n\mathbf{x}| = \int_{-1}^{1} \overbrace{\left(\int_{B^{n-1}_{\sqrt{1-x_n^2}}(\mathbf{0})} |d^{n-1}\mathbf{x}| \right)}^{\substack{(n-1)\text{-dimensional vol.}\\ \text{of one slice of } B_1^n(\mathbf{0})}} dx_n \\
&= \int_{-1}^{1} \underbrace{b_{n-1}\left(\sqrt{1-x_n^2}\right)}_{\substack{\text{vol. ball of radius}\\ r=\sqrt{1-x_n^2} \text{ in } \mathbb{R}^{n-1}}} dx_n = \int_{-1}^{1} \underbrace{(1-x_n^2)^{\frac{n-1}{2}}}_{r^{n-1}} \underbrace{\beta_{n-1}}_{\substack{\text{vol. ball of}\\ \text{radius 1}\\ \text{in } \mathbb{R}^{n-1}}} dx_n \\
&= \underbrace{\beta_{n-1}}_{\substack{\text{vol. of unit}\\ \text{ball in } \mathbb{R}^{n-1}}} \int_{-1}^{1} (1-x_n^2)^{\frac{n-1}{2}}\, dx_n. \qquad 4.5.20
\end{aligned}$$

This reduces the computation of β_n to computing the integral

$$c_n = \int_{-1}^{1} (1-t^2)^{\frac{n-1}{2}}\, dt. \qquad 4.5.21$$

This is a standard tricky problem from one-variable calculus: Exercise 4.5.4 asks you to show that $c_0 = \pi$ and $c_1 = 2$ and that for $n \ge 2$,

$$c_n = \frac{n-1}{n} c_{n-2}. \qquad 4.5.22$$

This allows us to make Table 4.5.9. It is easy to continue the table. (What is β_6? Check below.[7]) △

If you enjoy inductive proofs, you might try Exercise 4.5.5, which asks you to find a formula for β_i for all i. Exercise 4.5.6 asks you to show that as n increases, the volume of the n-dimensional unit ball becomes a smaller and smaller proportion of the smallest n-dimensional cube that contains it.

---

[7] $c_6 = \frac{5}{6}c_4 = \frac{15\pi}{48}$, so $\beta_6 = c_6\beta_5 = \frac{\pi^3}{6}$.

n	$c_n = \frac{n-1}{n} c_{n-2}$	Volume of ball $\beta_n = c_n \beta_{n-1}$
0	π	
1	2	2
2	$\frac{\pi}{2}$	π
3	$\frac{4}{3}$	$\frac{4\pi}{3}$
4	$\frac{3\pi}{8}$	$\frac{\pi^2}{2}$
5	$\frac{16}{15}$	$\frac{8\pi^2}{15}$

TABLE 4.5.9. Computing the volume of the unit ball in $\mathbb{R}^1$ through $\mathbb{R}^5$.

Computing probabilities using integrals

We saw in Section 4.2 that integrals are useful in computing probabilities.

Example 4.5.8 (Using Fubini to compute probabilities). Recall (equation 4.2.12) that the expectation (expected value) of a random variable f is given by $E(f) = \int_S f(s)\mu(s)\,|ds|$, where the function μ weights outcomes according to how likely they are, and S is the sample space. If we choose two points x, y in the interval $[0, 1]$, without privileging any part of that interval, what is the expected value of the function $f\begin{pmatrix} x \\ y \end{pmatrix} = (x-y)^2$?

"Without privileging any part of that interval" means that $\mu = 1$. Thus

$$\begin{aligned} E\big((x-y)^2\big) &= \int_0^1 \int_0^1 (x-y)^2 dx\,dy = \int_0^1 \left(\int_0^1 x^2 - 2xy + y^2\,dx \right) dy \\ &= \int_0^1 \left[\frac{x^3}{3} - x^2 y + y^2 x \right]_0^1 dy = \int_0^1 \frac{1}{3} - y + y^2\,dy \\ &= \left[\frac{y}{3} - \frac{y^2}{2} + \frac{y^3}{3} \right]_0^1 = \frac{1}{6}. \end{aligned} \qquad 4.5.23$$

Given x, y in the same interval, what is the expected value of the function $f\begin{pmatrix} x \\ y \end{pmatrix} = |x-y|$? Now we want to include positive values of $x - y$ and positive values of $y - x$. To do this, let's assume that $x > y$ (so the integral for y goes from 0 to x) and double the integral to account for the cases where $y > x$:

$$\begin{aligned} E\big(|x-y|\big) &= 2\int_0^1 \left(\int_0^x x - y\,dy \right) dx = 2\int_0^1 \left[xy - \frac{y^2}{2} \right]_0^x dx \\ &= 2\int_0^1 x^2 - \frac{x^2}{2}\,dx = 2\left[\frac{x^3}{3} - \frac{x^3}{6} \right]_0^1 = \frac{1}{3}. \quad \triangle \end{aligned} \qquad 4.5.24$$

Exercise 4.5.10 asks you to show that if two points $\mathbf{x}, \mathbf{y}$ are chosen in the unit square, without privileging any part of the square, then $E\Big(|\mathbf{x} - \mathbf{y}|^2\Big) = 1/3$.

Note that the expected value of $|x - y|$ is more complicated to compute than the expected value of $(x-y)^2$. Asked to give the expected distance between x and y, a probabilist would most likely compute $E((x-y)^2)$ and take the square root, getting $1/\sqrt{6}$, which is not the actual expected distance of $1/3$. Computing $E((x-y)^2)$ and taking the square root is analogous to computing the standard deviation; computing $E(|x-y|)$ is analogous to computing the mean absolute deviation.

Abstract

The circle and the square are among the most common shapes used by mankind. Consequently, it is worthwhile to study the mathematical correspondence between the two. This chapter discusses three different ways of mapping a circular region to a square region and vice versa. Each of these mappings has nice closed-form invertible equations and different interesting properties. In addition, this chapter will present artistic applications of these mappings such as

Introduction

In topology, a *homeomorphism* is equivalence relation between two geometric objects that can be continuously deformed into one another. Two objects are homeomorphic if there is a continuous invertible mapping between them. An opt-repeated humorous example of this is the homeomorphism between the donut and the coffee cup. Joking aside, a coffee cup is not at all easy to define mathematically. Instead, this chapter will focus on two objects that are simple and well-defined mathematically – namely, the circular disc and the square. We shall study ways to map the circular disc to a square region and vice versa (Fig. 1).

Needless to say, there are infinitely many ways to map a circular disc to a square. Of particular interest to us are mappings with nice closed-form invertible equations. This chapter will discuss three such mappings. In addition, this chapter will also introduce and discuss different curious properties of these mappings. These properties include concepts such as uniform grids, radial constraints, and conformality. But before we proceed, this is an important lingering issue that needs to be addressed. This mathematical problem sounds all too familiar. Are we dealing with a classic problem in mathematics? Is this problem just "squaring the circle" under a modern guise?

Indeed, there is a famous classic problem in mathematics called "squaring the circle." This well-known geometric construction problem involves using a straight-

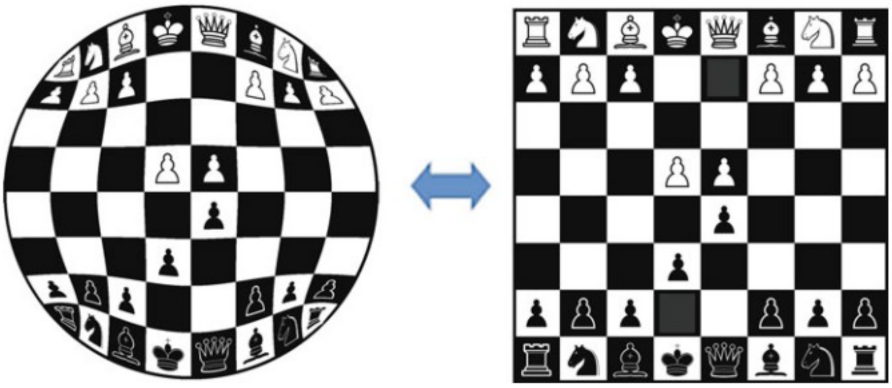

Fig. 1 A chessboard mapped to a circular disc

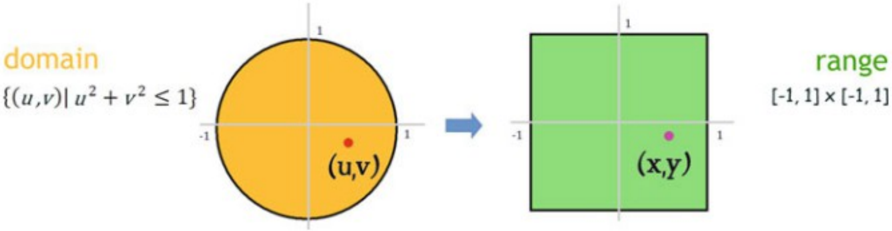

Fig. 2 Canonical mapping space for the circular disc and the square

edge and a compass to produce a circle and square with equal area. At first glance, our mapping problem seems similar to "squaring the circle." However, the two problems are only superficially alike and ultimately quite different. Our mapping problem involves finding two-dimensional mapping equations that a computer can calculate, whereas the classic problem has to do with geometric construction using a draftsman's tools.

Canonical Mapping Space

In order to mathematically describe the mappings, we need to first cover notation and introduce some variables in the canonical mapping space. For the mappings, the domain is the unit disc centered at the origin, and the range is the square with corners at $(\pm 1, \pm 1)$. This is shown in Fig. 2. We shall denote (u, v) as a point contained in the unit disc and (x, y) as the corresponding point contained in the square after the mapping.

Mathematically speaking, we want to find functions f that maps every point (u, v) in the circular disc to a point (x, y) in the square region and vice versa. In others word, we want to derive equations for f such that $(u, v) = f(x, y)$ and $(x, y) = f^{-1}(u, v)$.

Mapping Diagram with Equations

Figure 3 shows the three mappings that are at the core of this chapter. These are the *Tapered2 Squircular*, *Elliptical Grid*, and the *Conformal Square mapping*. In order to illustrate the visual properties of these mappings, there are diagrams for a disc with a radial grid converted to a square. These appear on the left side of Fig. 3. Similarly, on the right side, there are diagrams for a rectilinear square grid converted to a circular disc. Each of these mappings has corresponding forward and inverse equations accompanying the diagrams. From here, one can observe that these equations come in varying degrees of mathematical sophistication.

For the Tapered2 Squircular mapping, it is convenient to use vector notation. In contrast, for the Conformal Square mapping, it is most appropriate to use complex

numbers to come up with relatively compact equations. On the other hand, the Elliptical Grid mapping can be expressed simply by using plain algebraic equations. Each of these mappings will be discussed in more detail in the next section.

It is important to review the signum function at this point. This function is abbreviated as $sgn(x)$ and is defined as

$$sgn(x) = \begin{cases} -1 & if \;\; x < 0 \\ 0 & if \;\; x = 0 \\ 1 & if \;\; x > 0 \end{cases}$$

Some Mathematical Details

Fernandez-Guasti Squircle

In 1992, Manuel Fernandez-Guasti discovered a plane algebraic curve that is an intermediate shape between the circle and the square (Fernandez-Guasti, 1992). His curve is represented by a quartic equation.

$$x^2 + y^2 - \frac{s^2}{r^2} x^2 y^2 = r^2 \tag{1}$$

His equation includes a parameter s that can be used to blend between the circle and the square smoothly. Figure 4 illustrates the Fernandez-Guasti squircle at varying values of s.

The squareness parameter s can have any value between 0 and 1. When $s = 0$, the equation produces a circle with radius r. When $s = 1$, the equation produces a square with side length $2r$. In between, the equation produces a smooth curve that is a geometric hybrid of the circle and the square.

Tapered2 Squircular Mapping

The Fernandez-Guasti squircle can be used as groundwork for creating mappings between the circular disc and the square. The key idea is to match circular contours inside the circular disc to squircular contours inside the square. This is shown in Fig. 5.

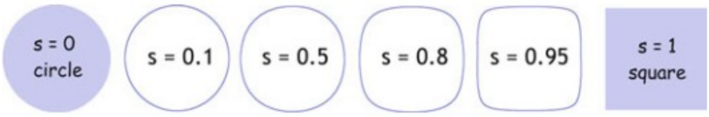

Fig. 4 The Fernandez-Guasti squircle at varying squareness

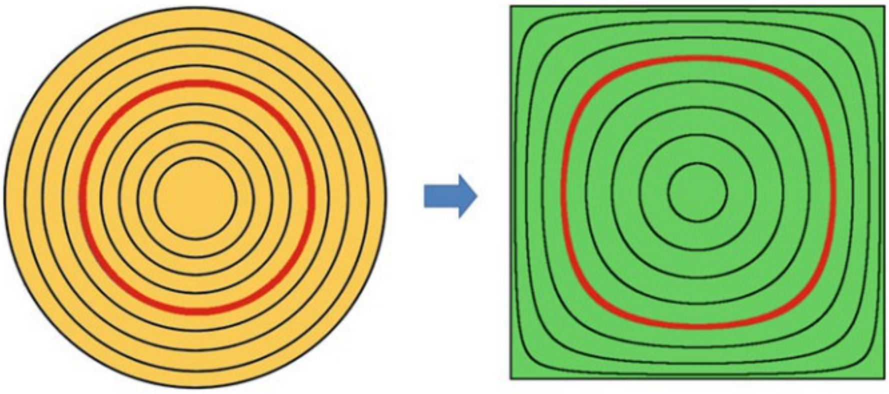

Fig. 5 Mapping based on the squircular continuum

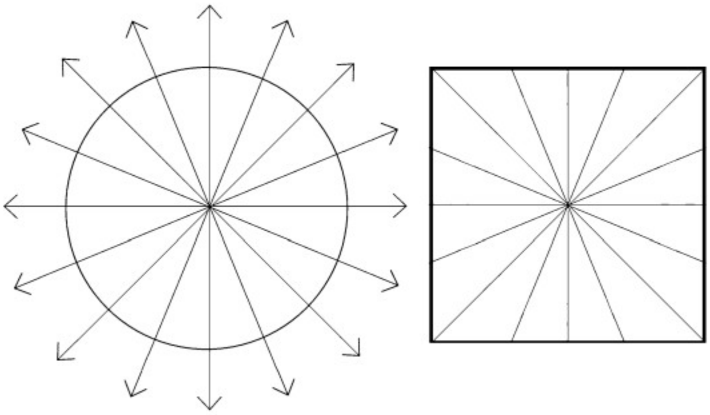

Fig. 6 Radial constraint on the mapping

A circular disc can be considered as a continuum of concentric circles. Likewise, a square region can be considered as a continuum of concentric squircles with increasing squareness. These concentric squircles become increasingly square-like as they approach the bounding rim. We shall denote this phenomena as the *squircular continuum* of the square.

In addition to matching contours inside the circular disc and the square, the Tapered2 Squircular mapping has a restriction called the *radial constraint*. In a nutshell, this means that points are only allowed to move radially during the mapping process. This is illustrated in Fig. 6.

By coupling the radial constraint with a nonlinear squircular continuum, it is possible to derive a set of equations for mapping the circular disc to a square. This is a geometric overview of how the Tapered2 Squircular mapping was derived. For more details, see Fong (2019).

The mapping equations provided in Fig. 3 are not exactly precise. In the interest of brevity, some important details were intentionally left out. For example, in the square-to-disc mapping equation, there are degenerate points that cause a division by zero. These degenerate points are located at the center and the four corners of the square. At these locations, the mapping equation results in the indeterminate form $\frac{0}{0}$. However, the limiting value of the mapping for these points is well-defined.

In view of these and other missing details, here are the amended mapping equations for the Tapered2 Squircular mapping.

$$\begin{bmatrix} x \\ y \end{bmatrix} = \begin{cases} sgn(uv)\sqrt{\frac{-u^2-v^2+\sqrt{(u^2+v^2)[u^2+v^2+4u^2v^2(u^2+v^2-2)]}}{2(u^2+v^2-2)}} \begin{bmatrix} \frac{1}{u} \\ \frac{1}{v} \end{bmatrix} & if \quad \begin{matrix} u \neq 0 \\ v \neq 0 \end{matrix} \\ \begin{bmatrix} u \\ v \end{bmatrix} & otherwise \end{cases}$$

$$\begin{bmatrix} u \\ v \end{bmatrix} = \begin{cases} \sqrt{\frac{x^2+y^2-2x^2y^2}{(x^2+y^2)(1-x^2y^2)}} \begin{bmatrix} x \\ y \end{bmatrix} & if \quad \begin{matrix} (x, y) \neq (0, 0) \\ (x, y) \neq (\pm 1, \pm 1) \end{matrix} \\ \begin{bmatrix} sgn(x)\ \frac{1}{2}\sqrt{2} \\ sgn(y)\ \frac{1}{2}\sqrt{2} \end{bmatrix} & if \quad (x, y) = (\pm 1, \pm 1) \\ \begin{bmatrix} 0 \\ 0 \end{bmatrix} & if \quad (x, y) = (0, 0) \end{cases}$$

Lamé Squircle

The Fernandez-Guasti squircle is by no means the only shape that is a parameterized hybrid of the circle and square. In fact, there is a much more famous curve known as the superellipse that also has this property. The Lamé squircle is a special case of the superellipse with no eccentricity. This plane algebraic curve was originally studied by Gabriel Lamé in 1818. Qualitatively, the curve appears very similar to the Fernandez-Guasti squircle, but there are several important differences which will be discussed later. The Lamé squircle has the equation

$$|x|^p + |y|^p = r^p \tag{2}$$

There are two parameters in this equation: p and r. The power parameter p allows the shape to interpolate between the circle and the square. When $p = 2$, the equation produces a circle with radius r. As $p \to \infty$, the equation produces a square with a side length of $2r$. In between, the equation produces a smooth planar curve that resembles both the circle and the square. Figure 7 shows the Lamé curve at increasing powers.

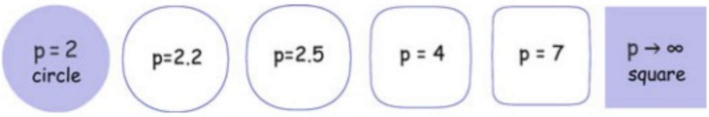

Fig. 7 Lamé squircle at varying polynomial powers

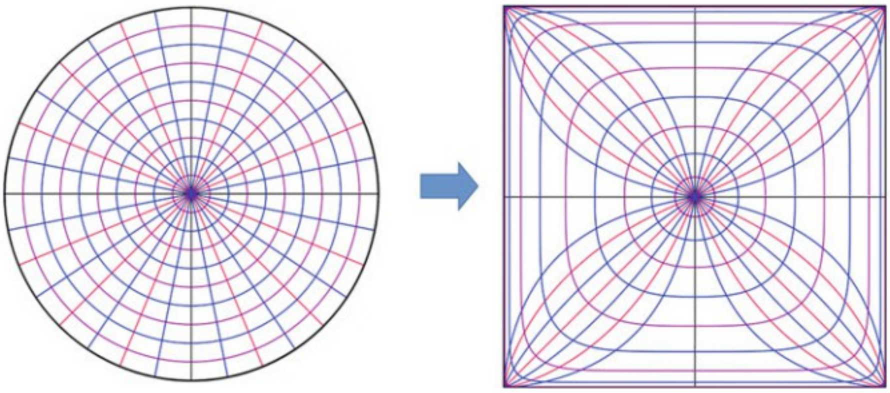

Fig. 8 Disc-to-square mapping based on the Lamé squircle

Although the Lamé squircle exhibits qualitative similarities with the Fernandez-Guasti squircle, there is a major difference between the two. The Lamé squircle can only approximate the square. It requires an infinite exponent in order to fully realize the square. Moreover, since the polynomial equation for the Lamé curve has unbounded exponents, it is unwieldy and difficult to manipulate algebraically. Nevertheless, the Lamé squircle can be used as groundwork for devising another disc-to-square mapping.

The Lamé squircle has a parametric form in which x and y coordinates of points on the curve can be specified in terms of parameter t. The parametric equations are

$$\begin{aligned} x(t) &= sgn(\cos t)\ |\cos t|^{\frac{2}{p}} \\ y(t) &= sgn(\sin t)\ |\sin t|^{\frac{2}{p}} \end{aligned} \tag{3}$$

Using these parametric equations of the Lamé squircle, it is possible to devise another disc-to-square mapping. The key idea is to make the substitutions $\mathbf{u} = \cos \mathbf{t}$ and $\mathbf{v} = \sin \mathbf{t}$ to represent points in the circular disc. This mapping is shown in Fig. 8 with corresponding equations as

$$\begin{aligned} x &= sgn(u)\ |u|^{1-u^2-v^2} \\ y &= sgn(v)\ |v|^{1-u^2-v^2} \end{aligned} \tag{4}$$

This mapping based on the Lamé squircle has several undesirable properties that make it less useful than the other mappings shown in Fig. 3. For one thing, explicit inverse equations are not provided. It is quite likely that there are no closed-form equations for expressing the inverse mapping. This means that the inverse mapping can only be computed using iterative root-solving techniques in numerical analysis.

Another egregious property of this mapping is that it only works on the open circular disc and the open square region. This means that mapping does not include the circular boundary of the disc or the rim of the square region. Mathematically, the domain of the mapping is the open circular disc $\{(u, v) | u^2 + v^2 < 1\}$, and the range of the mapping is the $(-1, 1) \times (-1, 1)$ open square region.

Elliptical Grid Mapping

The square can easily be subdivided into a grid of smaller squares. In stark contrast, there is no easy way to subdivide the circle into a grid of smaller nonoverlapping circles. Nevertheless, the circular disc can be subdivided into a uniform grid based on elliptical arcs. This is shown on the right of Fig. 9. Using this observation, it is possible to devise a square-to-disc mapping. The key idea is to match cells inside the square grid with cells inside the circular grid.

In 2005, Philip Nowell (2005) came up with very simple equations for mapping a square to a circular disc. The derivation basically boils down to two mathematical constraints needed to match square cells with elliptical grid cells. The first constraint comes from matching vertical line segments inside the square to vertically oriented elliptical arcs inside the circular disc. This is illustrated in Fig. 10 where a vertical line and its corresponding elliptical arc are shown in red. This mapping relationship can be summarized by the equation:

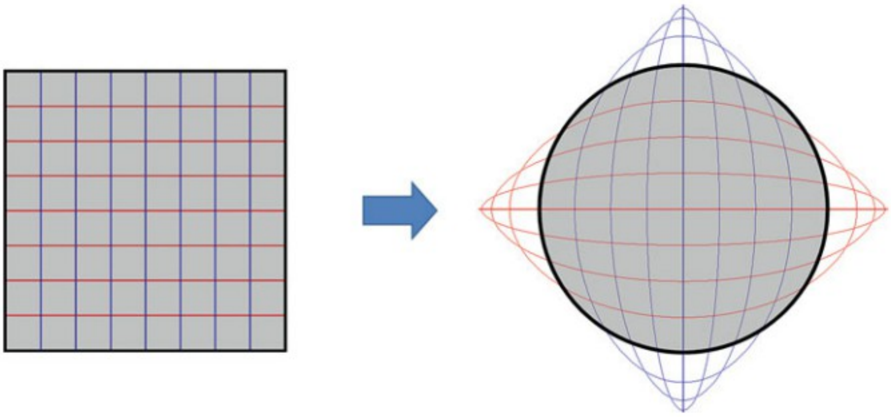

Fig. 9 Overview of the Elliptical Grid mapping

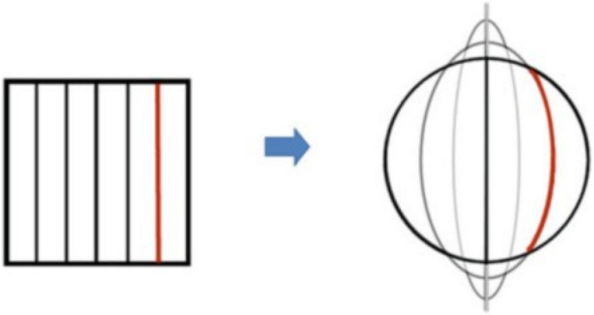

Fig. 10 Vertical constraint of the Elliptical Grid mapping

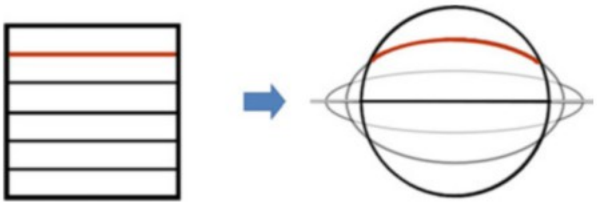

Fig. 11 Horizontal constraint of the Elliptical Grid mapping

$$1 = \frac{u^2}{x^2} + \frac{v^2}{2 - x^2} \tag{5}$$

Essentially, for each vertical line segment of constant x inside the square, there is a corresponding equation of an ellipse centered in the circle. The bounds, eccentricity, and semi-major and semi-minor axial lengths of this ellipse vary depending on the value of x. Specifically, the left and right vertex tips of the ellipse follow the value of x. Meanwhile, the top and bottom vertex tips vary as $\pm\sqrt{2 - x^2}$.

The second constraint of the mapping comes from matching horizontal line segments inside the square to sideway-oriented elliptical arcs inside the circular disc. This is illustrated in Fig. 11 where a horizontal line and its corresponding elliptical arc are shown in red. This mapping relationship can also be summarized by the equation:

$$1 = \frac{u^2}{2 - y^2} + \frac{v^2}{y^2} \tag{6}$$

Essentially, for each horizontal line segment of constant y in the square, there is a corresponding equation of an ellipse centered in the circle. The bounds, eccentricity, and semi-major and semi-minor axial lengths of this ellipse vary depending on the value of y. Specifically, the top and bottom vertex tips of the ellipse follow the value of y. Meanwhile, the left and right vertex tips vary as $\pm\sqrt{2 - y^2}$.

Basically, the mapping assigns the grid of perpendicular vertical and horizontal lines inside the square to a grid of elliptical arcs inside the circular disc. As shown in Fig. 9, this is essentially matching square grid cells with elliptical grid cells . A curvilinear grid of elliptical arcs can be formed by superimposing the vertically

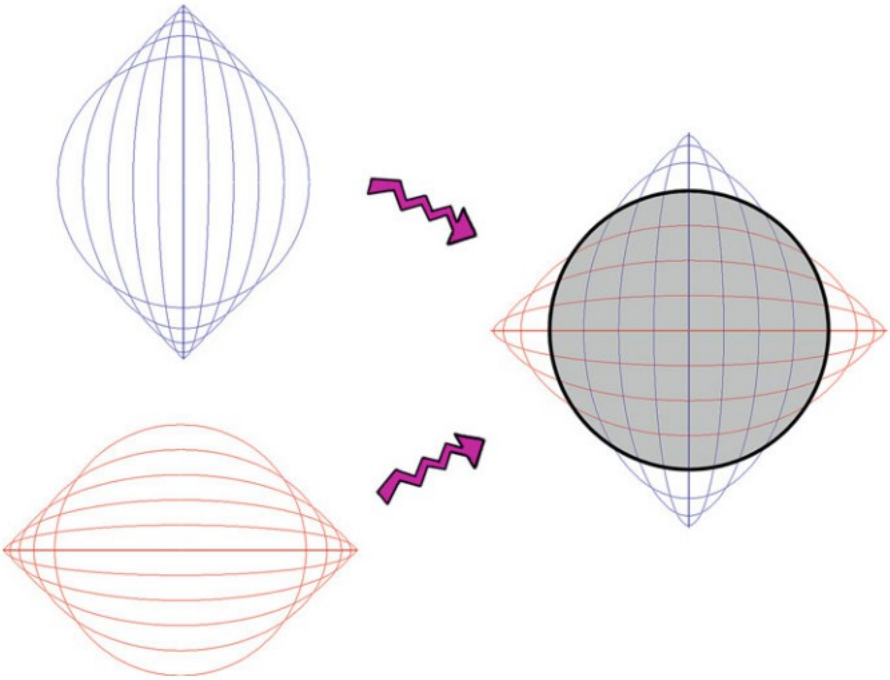

Fig. 12 Superimposing the vertical and horizontal arcs to create a curvilinear elliptical grid

oriented and horizontally oriented elliptical arcs inside the circular disc. Figure 12 shows the resulting curvilinear grid resulting from the superimposition.

Note that the ellipses get more and more eccentric as x or y approach zero. Also, the ellipses get more circular as x or y approach ± 1.

Mathematically, we can mix the vertical constraint equation with the horizontal constraint equation to get algebraic expressions for u and v in terms of x and y. This can be done by starting with the vertical constraint equation and doing some algebraic manipulations to isolate u^2.

$$1 = \frac{u^2}{x^2} + \frac{v^2}{2 - x^2} \quad \Longrightarrow \quad 1 - \frac{v^2}{2 - x^2} = \frac{u^2}{x^2} \quad \Longrightarrow \quad u^2 = x^2 \left(1 - \frac{v^2}{2 - x^2} \right)$$

We can then plug this u^2 value into the horizontal constraint equation

$$1 = \frac{u^2}{2 - y^2} + \frac{v^2}{y^2} \quad \Longrightarrow \quad 1 = \frac{x^2 \left(1 - \frac{v^2}{2 - x^2} \right)}{2 - y^2} + \frac{v^2}{y^2}$$

Multiply both sides of the equation by $(2 - x^2)(2 - y^2)y^2$ to remove fractions and get

$$(2-x^2)(2-y^2)y^2 = x^2y^2(2-x^2-v^2) + v^2(2-x^2)(2-y^2)$$

After which, one can isolate v^2 into one side of the equation

$$\begin{aligned}
(2-x^2)(2-y^2)y^2 - x^2y^2(2-x^2) = -x^2y^2v^2 + (2-x^2)(2-y^2)v^2 &\implies \\
v^2(2-x^2)(2-y^2-x^2y^2) = (2-x^2)y^2(2-y^2-x^2) &\implies \\
v^2 = y^2\frac{(2-x^2)(2-y^2-x^2)}{(2-x^2)(2-y^2)-x^2y^2} &\implies \\
v^2 = y^2\frac{(2-x^2)(2-y^2-x^2)}{4-2x^2-2y^2} = y^2\frac{2-x^2}{2} &\implies \\
v = y\sqrt{\frac{2-x^2}{2}} \implies \mathbf{v} = \mathbf{y}\sqrt{\mathbf{1}-\frac{\mathbf{x}^2}{\mathbf{2}}}
\end{aligned}$$

Similarly, in a symmetric fashion, one can solve for u as

$$\mathbf{u} = \mathbf{x}\sqrt{\mathbf{1}-\frac{\mathbf{y}^2}{\mathbf{2}}}$$

It is also possible to derive the inverse equations for this mapping, but the algebraic manipulation needed is much more elaborate. Instead, we refer the reader to Fong (2014) for a lengthy derivation of denested inverse equations.

Conformal Square Mapping via Schwarz-Christoffel

A conformal map is a mapping that preserves angles between geometric features after the mapping operation is performed. In other words, a conformal mapping does not distort angles. This section will discuss a disc-to-square mapping that is conformal. However, in order to do this, we need to take a small detour through the complex plane beforehand and discuss some theory first.

One of the most celebrated results in nineteenth-century complex analysis is the Riemann mapping theorem (Frederick and Schwarz, 1990). It states that there exists a conformal map between the open unit disc and every simply connected subset of the complex plane. Moreover, it states that this conformal map is unique if we fix a point and the orientation of the mapping. In theory, the Riemann mapping theorem is nice, but it is only an existence theorem. It does not specify how to find the conformal mapping. The next important breakthrough came with the works of Hermann Schwarz and Elwin Christoffel. In the 1860s, Schwarz and Christoffel independently developed a formula for a conformal mapping between the unit disc and simple polygonal regions in the complex plane. The formula is complicated and involves an integral in the complex plane.

In order to show how complicated this formula is, it is listed below in its full glory. We will not bother explaining what each of the variables mean in the complex integral. It is suffice to say that the general Schwarz-Christoffel formula is quite complicated.

$$f(z) = \int^{z} \prod_{k=1}^{n} \left(1 - \frac{\zeta}{z_k}\right)^{\alpha_k - 1} d\zeta \tag{7}$$

Furthermore, for most polygons, the integral can only be approximated numerically. Fortunately, for the special case of the square, the Schwarz-Christoffel formula can be reduced to an explicit analytical expression involving complex-valued elliptic integrals and elliptic functions (Langer and Singer, 2011).

Legendre Elliptic Integrals

It is appropriate to make a segue here and briefly discuss elliptic integrals and elliptic functions. Of particular interest to us are Legendre elliptic integrals and Jacobi elliptic functions. Specifically, we are interested in the incomplete Legendre elliptic integral of the first kind called F and its closely related inverse function, the Jacobi elliptic function cn.

Mathematically, the incomplete Legendre elliptic integral of the first kind is a two-parameter function defined as

$$F(\phi, k) = \int_{0}^{\phi} \frac{1}{\sqrt{1 - k^2 sin^2(t)}}\, dt \tag{8}$$

Note that this integral cannot be simplified using any of the standard techniques covered in freshman calculus classes. This integral was originally studied in the context of measuring the arc length of an ellipse. That is the reason why it is called an elliptic integral (Rice and Brown, 2012).

The two arguments provided with this function are also intimately tied to the ellipse. The first parameter ϕ is some sort of angular parameter. It originates from the angle subtended by an arc of the ellipse. The second parameter k is closely related to the eccentricity of the ellipse.

Meanwhile, the Jacobi elliptic function cn can be considered as some sort of inverse to F. Mathematically, it is related to F by the following equation:

$$cn(\eta, k) = \cos(F^{-1}(\eta, k)) \tag{9}$$

A Fundamental Conformal Map

Without getting into the nitty-gritty details of the Schwarz-Christoffel mapping, Fig. 13 shows a fundamental conformal map between the circular disc and the square in the complex plane. This mapping can be derived by simplifying the Schwarz-Christoffel integral for the square and using the doubly periodic nature of the Jacobi elliptic function cn on the complex plane. In essence, one could map every point

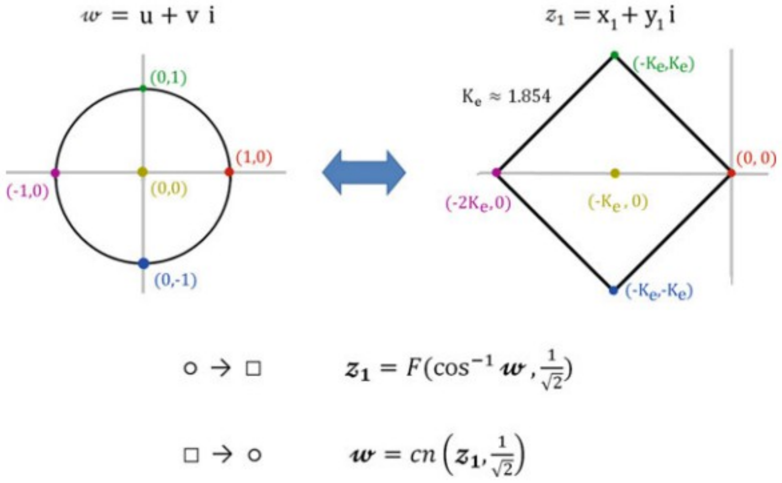

Fig. 13 A conformal map between the disc and square in the complex plane

inside the unit disc to a square region conformally by just an evaluation of the complex-valued Jacobi elliptic function *cn*. Furthermore, the inverse of the mapping can be calculated using the incomplete Legendre elliptic integral of the first kind F.

Canonical Alignment

The main drawback of the diagram on the complex plane is that the x and y coordinates are not in the canonical mapping space. Figure 13 shows a square with corner coordinates in terms of a constant K_e instead of the ±1 that is desired. Moreover, the square is tilted by 45° and off-center from the origin. In order to get this mapping into the canonical mapping space, one needs to perform a series of affine transformations on the square. These include centering the square to the origin and scaling it down to have a side length value of 2. In order to do this, one has to introduce a rotational factor for the 45° tilt as well as K_e offsets and scale factors. This is exactly what happens in the explicit equations for the Conformal Square mapping. Basically, this is the canonized mapping equation in the complex plane

$$\mathbf{z} = 1 - i - \frac{\sqrt{-2i}}{K_e} \;\; F(cos^{-1}\mathbf{w}\sqrt{i},\;\; \tfrac{1}{\sqrt{2}}) \tag{10}$$

and its inverse is

$$\mathbf{w} = \sqrt{-i} \;\; cn(K_e\mathbf{z}\sqrt{\tfrac{i}{2}} - K_e,\;\; \tfrac{1}{\sqrt{2}}) \tag{11}$$

where $\boldsymbol{z}$ is the complex number $x + y\,\boldsymbol{i}$
and $\boldsymbol{w}$ is the complex number $u + v\,\boldsymbol{i}$.

It is probably appropriate to explain the $\sqrt{\pm i}$ factors that appear throughout the equations. These multiplicative constants are just a compact way of representing the ±45° rotational adjustments needed to align the equations to the canonical mapping space in Fig. 2.

In the complex plane, rotation can be done simply by multiplication with the complex number $e^{i\theta}$. For 45° rotation, the multiplicative factor is

$$e^{i\frac{\pi}{4}} \;=\; \cos\frac{\pi}{4} + i\;\sin\frac{\pi}{4} \;=\; \frac{1}{\sqrt{2}}(1+i) \;=\; \sqrt{i} \tag{12}$$

For −45° rotation, the multiplicative factor is

$$e^{-i\frac{\pi}{4}} \;=\; \cos\frac{\pi}{4} - i\;\sin\frac{\pi}{4} \;=\; \frac{1}{\sqrt{2}}(1-i) \;=\; \sqrt{-i} \tag{13}$$

Software Implementation

In order to implement this mapping on a computer, one needs to be able to calculate special functions such as cn and F. Source code for numerical computation of these functions is readily available in open-source libraries such as Boost and the GNU Scientific Library. Also, there is a reference implementation appearing in the popular Numerical Recipes book (Press et al., 1992).

One possible pitfall in software implementation is that the mapping requires complex-valued versions of the special functions. These complex variants are typically not included in open-source libraries. Nonetheless, these complex variants are well-defined mathematically. The formulas for computing complex-valued cn and F are given by L.M. Milne-Thomson in the classic AMS-55 reference book (Abramowitz and Stegun, 1972).

It is worth mentioning here that there are well-established fast and robust algorithms for computing the F and cn special functions (Carlson, 1977). As a matter of fact, Gauss has shown that elliptic integrals can be calculated quickly using the arithmetic-geometric mean (Hancock, 1958). It is suffice to say that these special functions can be calculated about as fast as standard trigonometric functions.

A Complex Class of Squircles

The Fernandez-Guasti squircle was used as groundwork in the development of the Tapered2 Squircular mapping. This section will discuss using a similar idea but acting in reverse to derive another type of squircle. Specifically, one can start with the Conformal Square mapping and come up with a different type of squircle called the *complex squircle*.

Let us revisit the squircular continuum in Fig. 5 which was originally discussed in the derivation of the Tapered2 Squircular mapping. By working backward this time and starting from the Conformal Square mapping, it is possible to derive equations for a curve that is an intermediate shape between the circle and the square.

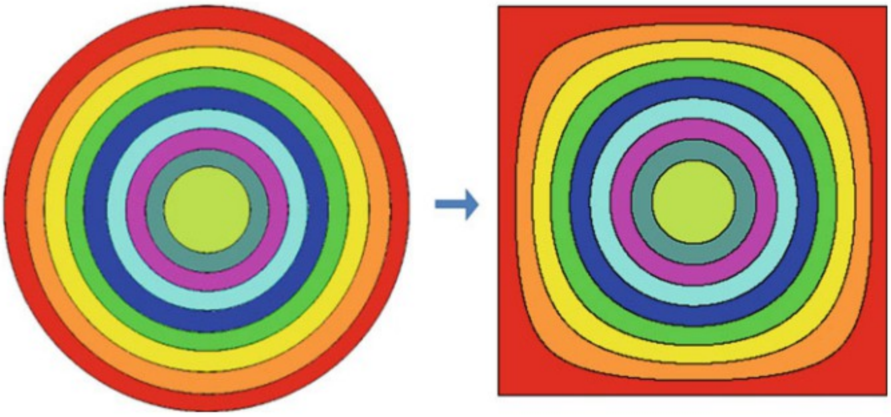

Fig. 14 The squircular continuum revisited

Figure 14 shows a circular disc subdivided into concentric rings of different colors. This circular disc is then mapped to a square via the Conformal Square mapping. The resulting square is still subdivided by concentric rings, but the enclosing shapes are not quite circular. Consequently, it is logical to ask what sort of shape encompasses the boundaries of the concentric rings inside the square.

One can then intuitively surmise from Fig. 14 that the concentric shapes inside the square are some sort of squircular curve. Indeed, these concentric shapes exhibit all of the defining characteristics of a hybrid curve between the circle and the square. Therefore, it makes sense to classify them as yet another type of squircle – the *complex squircle*.

The complex squircle can be written in parametric form by applying Conformal Square mapping to the parametric equation of the circle. In the complex plane, the parametric form of the unit circle is e^{it}, with $0 \leq t \leq 2\pi$. By applying the Conformal Square mapping on the circle, one can come up with a complex-valued function ψ that serves as an auxiliary representation of the complex squircle.

$$\psi(t,q) \;=\; 1 - i - \frac{\sqrt{-2i}}{K_e} F\left(\cos^{-1}(q e^{it}\sqrt{i}),\, \tfrac{1}{\sqrt{2}}\right) \tag{14}$$

ψ is a two-parameter complex function that is based on the disc-to-square equation of the Conformal Square mapping. The first argument t is used for curve parametrization. The second argument q is just a squareness parameter analogous to the s parameter of the Fernandez-Guasti squircle.

Using this ψ function, the complex squircle can be defined as the curve arising from these parametric equations:

$$\begin{aligned} x(t) \;&=\; \Re[\psi(t,q)]\, \tfrac{r}{\psi(0,q)} \\ y(t) \;&=\; \Im[\psi(t,q)]\, \tfrac{r}{\psi(0,q)} \end{aligned} \tag{15}$$

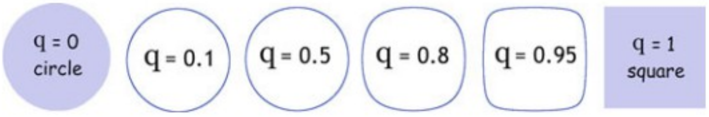

Fig. 15 The complex squircle at varying squareness values

Table 1 Three different types of squircles discussed in this chapter

Name	Squareness	Equation	Key property
Fernandez-Guasti squircle	$s \in [0, 1]$	$x^2 + y^2 - \frac{s^2}{r^2}x^2y^2 = r^2$	Quartic polynomial equation
Lamé squircle	$p \in [2, \infty)$	$\lvert x\rvert^p + \lvert y\rvert^p = r^p$	Unbounded polynomial power
Complex squircle	$q \in [0, 1]$	$\psi(t,q) = 1 - i - \frac{\sqrt{-2i}}{K_e} F(cos^{-1}(qe^{it}\sqrt{i}), \frac{1}{\sqrt{2}})$ $x(t) = \Re[\psi(t, q)]\ \frac{r}{\psi(0,q)}$ $y(t) = \Im[\psi(t, q)]\ \frac{r}{\psi(0,q)}$	Complex parametric equations with parameter $t \in [0, 2\pi]$

As with the other types of squircles previously discussed, there are two parameters for the complex squircle: q and r. The squareness parameter q allows this shape to interpolate between the circle and the square. When $q = 0$, the equation produces a circle with radius r. When $q = 1$, the equation produces a square with a side length of $2r$. In between, the equation produces a smooth planar curve that resembles both the circle and the square. This is shown in Fig. 15.

In summary, mathematical shapes known as squircles play an important role in the development of disc-to-square mappings. This chapter discussed three different types of squircles along with associated mappings. These squircles are summarized in Table 1.

Application: Squaring the Poincaré Disk

This section will discuss how to convert circular Escheresque artwork into squares. Figure 16 shows an example of a circular tiling with interlocking angels and devils. The pattern on the right was inspired from M.C. Escher's famous *Circle Limit IV* (1960). The pattern on the left is its conversion to a square.

In order to delve more into Escheresque artworks (Dunham, 2009), some mathematical background in non-Euclidean geometry is necessary. In particular, we need to discuss a type of non-Euclidean geometry called hyperbolic geometry. To make things simple, we shall restrict ourselves to a two-dimensional construct of hyperbolic geometry called the hyperbolic plane. One can intuitively think of the hyperbolic plane as a surface with negative curvature everywhere (Taimina, 2009). In contrast, the Euclidean plane is a flat surface with zero curvature everywhere.

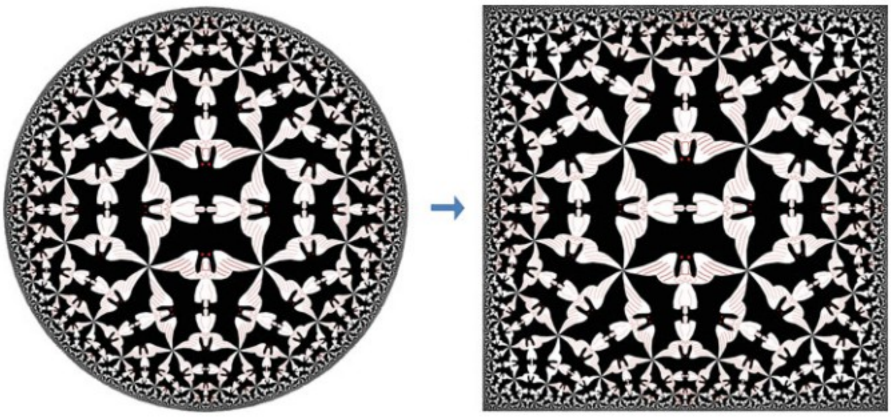

Fig. 16 A circular angels & devils pattern converted to a square

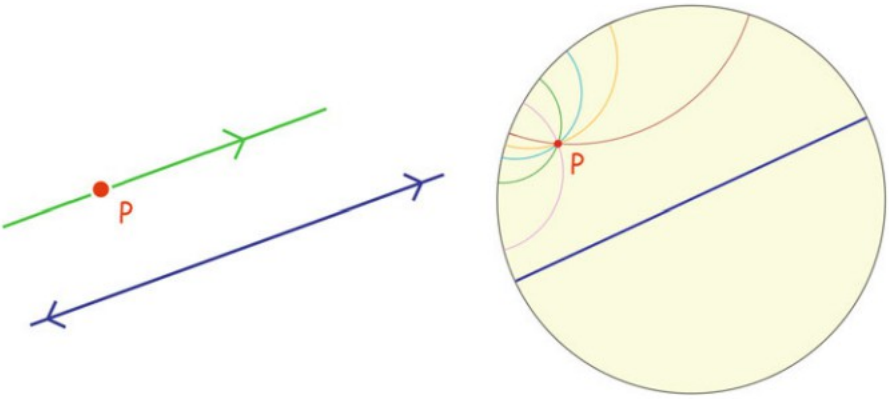

Fig. 17 Playfair's axiom on the Euclidean plane (left) and the hyperbolic plane (right)

There is a long and storied history of non-Euclidean geometry that this chapter will only gloss over. Non-Euclidean geometry arises from the negation of Euclid's fifth postulate – also known as the parallel postulate. A modern formulation of this postulate states that

> In a plane, given a line and a point not on it, at most one line parallel to the given line can be drawn through the point.

This formulation is known as Playfair's axiom. It is illustrated in the left diagram of Fig. 17. Meanwhile, hyperbolic geometry arises when Playfair's axiom is overturned with the following statement:

> In a hyperbolic plane, given a line and a point not on it, there are several lines parallel to the given line than can be drawn through the point.

In order to qualify this statement in hyperbolic geometry, one needs to have well-defined and consistent notions of points, lines, and parallelism in the hyperbolic plane. First, let us introduce the Poincaré disk.

Mathematicians have come up with many different models of the hyperbolic plane in order to study hyperbolic geometry. The most popular model is probably the Poincaré disk. The Poincaré disk can be considered as some sort of projection of the hyperbolic plane onto a unit circular disc in the Euclidean plane. It has several interesting properties that make it desirable for representing the hyperbolic plane.

One important property of the Poincaré disk is that it presents the entire hyperbolic plane within the confines of a finite circular disc in IR^2. Every point in the hyperbolic plane is represented by a unique point inside the Poincaré disk. This makes it easy to visualize the entire hyperbolic plane within the model.

Another important property of the Poincaré disk is conformality. In a conformal model, the hyperbolic measure of angle is the same as the Euclidean measure of angle. In other words, this hyperbolic model does not distort angles. One can measure hyperbolic angles between geometric entities inside the Poincaré disk by simply making Euclidean angular measurements. Unfortunately, the same does not hold true for hyperbolic distance. Hyperbolic distances are greatly distorted in the Poincaré disk.

In the Poincaré disk model, the origin at $(0, 0)$ lies at the center of the circular disc. The bounding circle at the rim of disc is infinitely far away from the origin. The hyperbolic distance of a point away from the origin gets larger and larger as the point gets closer to the bounding circle. As a consequence of this, geometric entities appear smaller as they approach the bounding circle.

One can think of the Poincaré disk in analogy to the Cartesian coordinate system. Just like the Cartesian coordinate system faithfully models the Euclidean plane, the Poincaré disk is a meaningful representation of the hyperbolic plane. The Cartesian coordinate system allows one to convert geometric statements about the Euclidean plane into algebraic equations. In a similar manner, the Poincaré disk allows one to do the same for the hyperbolic plane.

Table 2 lists various hyperbolic entities along with their Euclidean counterparts from within the Poincaré disk model. Using this table, one can make sense of Playfair's axiom in the hyperbolic plane.

Table 2 Hyperbolic entities in the Poincaré disk

Geometric entity	Corresponding feature inside the Poincaré disk
Hyperbolic point	This corresponds to a Euclidean point in the interior of the bounding circle of the Poincaré disk model
Hyperbolic line	This corresponds to a circular arc orthogonal to the bounding circle. Circular arcs can be part of circles of arbitrary radius
Hyperbolic angle	The angle between two hyperbolic lines is the same as the Euclidean angle between their corresponding circular arcs inside the Poincaré disk model
Hyperbolic parallelism	Hyperbolic lines are parallel if and only if they do not intersect in the interior of the Poincaré disk model

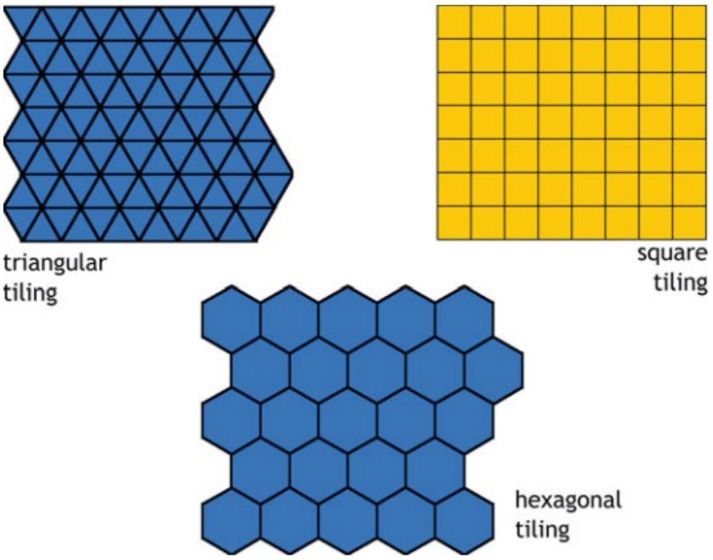

Fig. 18 The three regular Euclidean tilings

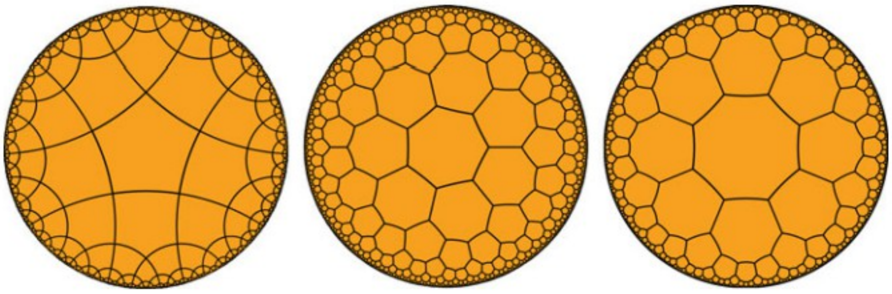

Fig. 19 Possible pentagonal, heptagonal, and octagonal tilings of the Poincaré disk

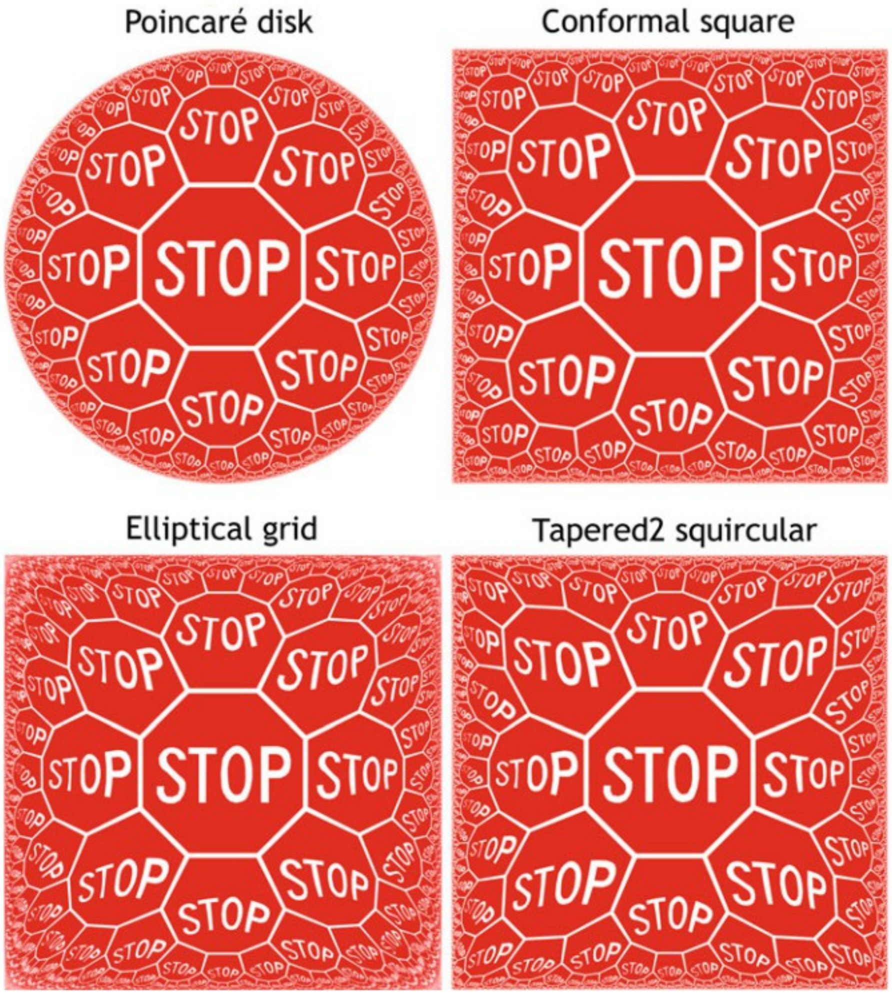
Hyperbolic Tilings

It is well-known that only three types of regular polygons can tile the Euclidean plane – namely, the triangle, the square, and the hexagon. These tilings are shown in Fig. 18. It is lesser known that all regular polygons can tile the hyperbolic plane! To illustrate this, Fig. 19 shows the Poincaré disk tiled with hyperbolic pentagons, heptagons, and octagons.

The stop sign is probably the most common octagonal shape that people encounter in their daily lives. It was ratified as an international standard by the United Nations in 1968. Being a regular octagon, the stop sign can tile the entire hyperbolic plane. This is shown in Fig. 20 as a Poincaré disk pattern. Furthermore,



Poincaré disk

Conformal square

Elliptical grid

Tapered2 squircular

Fig. 20 Hyperbolic stop signs

it is possible to convert this pattern into squares by using any of the three mappings discussed in this chapter.

The most relevant and appropriate way to convert the Poincaré disk to a square is via Conformal Square mapping. There is a very simple reason for this – conformality. Recall that the Poincaré disc model is a conformal model of the hyperbolic plane. It follows that the conformal square is a natural extension of the Poincaré disc to a square region. In essence, undistorted Euclidean angles in the Poincaré disk remain intact in the conformal square.

The two other mappings can also be used to convert the Poincaré disk to a square, but the results are less than stellar. For the Elliptical Grid mapping, the corners

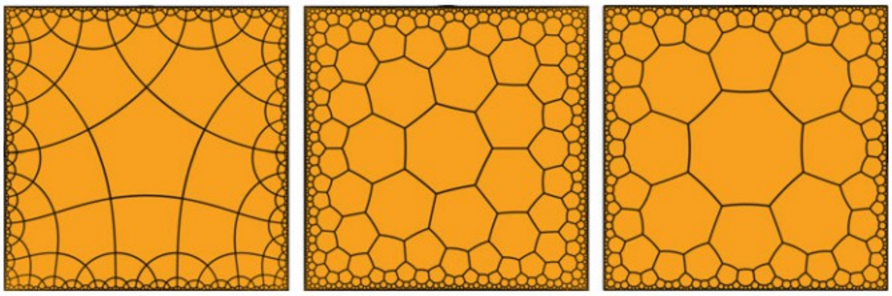


Fig. 21 Hyperbolic tilings mapped to the conformal square

of the square appear as a muddled mess. Meanwhile, the Tapered2 Squircular mapping produces fairly decent results, but there is significant shape distortion of the octagons.

To summarize, the conformal square is the natural extension of the Poincaré disk to a square. In order to further illustrate this, Fig. 21 shows the conformal square versions of the hyperbolic tilings from Fig. 19.

Application: Elliptification of Rectangular Imagery

Most of the world's photographs are rectangular. However, one might want to convert them into circular or elliptical images for artistic reasons. This section will extend the previously discussed square-to-disc mappings to handle ellipses and rectangles. After which, one can apply these mappings to rectangular artworks to produce elliptical ones. Henceforth, this process of molding a rectangle into an ellipse will be referred to as *elliptification*.

Elliptification is very simple if one already has a square-to-disc mapping. Elliptification can be done by simply removing the eccentricity and then reintroducing it back after the square-to-disc mapping is performed. This procedure is shown in the top diagram in Fig. 22 along with an illustrative example showing the elliptification of the United States flag at the bottom.

The artistic process of elliptification is not new. For centuries, artists would paint on oval-shaped canvases, and photographers would cut their pictures into oval regions. Creating oval-shaped artworks is an important form of artistic expression and stylization. This has traditionally been done by just cropping or cutting out the corner regions of the artwork.

This chapter promotes the idea of using explicit mathematical mappings to create oval-shaped artworks. This is possible using any of the square-to-disc mappings covered in this chapter and related papers (Fong, 2014, 2019; Shirley and Chiu, 1997). To demonstrate this effect, Figs. 23 and 24 show Edouard Manet's last major work *"A Bar at the Folies-Bergere"* (1882) converted into an oval region using

Schwarz-
Christoffel

Fig. 24 Elliptification of Manet's famous impressionist painting

the different mappings discussed in this chapter. The traditional process of simply cropping the picture to produce an oval region is quite unacceptable because it removes many noteworthy features near the corners of the painting. For example, observe that in Manet's cropped painting, the bar patron with the top hat is gone. Also, the dangling legs of the trapeze artist at the top left corner of the painting are nowhere to be found. In contrast, the mathematically mapped paintings keep all these features intact, albeit distorted.

Size Versus Shape Distortions

In differential geometry, two-dimensional distortion is generally categorized into two major types: size and shape distortions (Floater and Hormann, 2005). The elliptification of Manet's painting highlights the difference between these two types of distortion. The stretched Schwarz-Christoffel based on the Conformal Square mapping has significant size distortions near the corner. This is quite evident by observing the dangling legs of the trapeze artist, which has shrunk to the point of being barely visible. In contrast, the Elliptical Grid mapping has significant shape distortions near the corner. Specifically, the gentleman with a top hat appears considerably deformed. On the other hand, the Tapered2 Squircular mapping offers a good compromise between size and shape distortions. It provides the best result among the three mappings for Manet's painting. In fact, the circularized chessboard shown in Fig. 1 also uses the Tapered2 Squircular mapping. One can observe that the size and shape fidelity of the corner rooks is reasonably intact.

Conclusion

This chapter discussed three explicit methods for mapping the circular disc to a square and vice versa. In addition, some artistic applications of these mappings were provided. For hyperbolic art, the Conformal Square mapping gives the best results. However, for other artistic applications such as elliptification, this is not necessarily the case because the mapping has sizeable distortions near the four corners.

Hyperbolic Geometry

One strategy used to prove the parallel postulate was to replace it by its negation and then to search for a contradiction. Carl Friedrich Gauss first realized that this search would be in vain and that, in fact, there is a geometry that satisfies all Euclidean axioms but with the fifth postulate negated. Although he had developed a fairly advanced *non-Euclidean geometry* in the year 1816, Gauss did not publish it and confined himself to occasional remarks in private letters (see Stäckel 1933 for details). The first publications about what is now called *hyperbolic geometry* are by Nikolai Ivanovich Lobachevsky (1829) and János Bolyai (1832). Yet, even later, whether or not this new and counterintuitive geometry might contain a contradiction remained an open question. These doubts could be dispelled by providing a Euclidean model for hyperbolic geometry; that is, as discussed in the introduction, the terms line and point, among others, are associated with certain objects from Euclidean geometry that are then shown to satisfy the axioms. It follows that non-Euclidean geometry is consistent if Euclidean geometry is.

The first model described by Eugenio Beltrami in 1868 was the *pseudosphere model* that represents only a portion of the hyperbolic plane and will therefore not be discussed further. That same year Beltrami first described the Poincaré and Klein models, even in n dimensions (see Milnor 1982). In two dimensions these models can be introduced most conveniently using projections from a sphere, as is visualized in Fig. 15.

(1) The points of the *hemisphere model* are the points lying strictly in the upper half of a unit sphere in $\mathbb{R}^3$; the lines are half-circles orthogonal to the equator. In Fig. 15, one such line is depicted in yellow. It can be verified easily that each pair of distinct points determines exactly one line that meets them both. Moreover, to a given line L and a point P not on L, there exist an infinite number of lines through P that do not intersect L, so that this geometry does not satisfy Playfair's axiom.

(2) The *Poincaré disk model* is obtained from the hemisphere model by stereographic projection from the south pole to the equator plane. Here points are identified with points in the open unit disk $\mathbb{D}$, and lines are either open arcs orthogonal to the unit circle or open diameters. In Fig. 15, points and lines in the Poincaré model are depicted in red.

Figure 16 on the left shows a few hyperbolic lines in the Poincaré model. Again, through two distinct points in $\mathbb{D}$, there is exactly one (hyperbolic) line. The endpoints on the unit circle, which are not part of the line, are referred to as *ideal points*. Hence, two different lines terminating at the same ideal point are

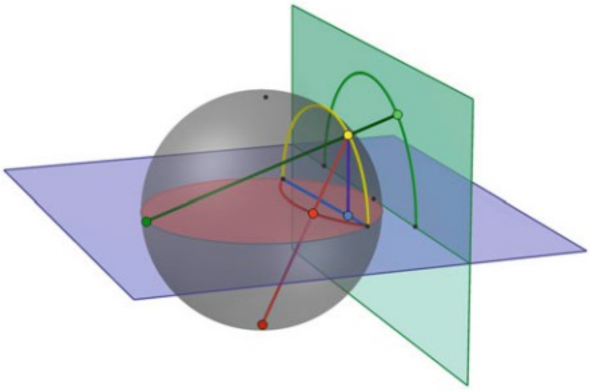

Fig. 15 Isomorphisms between the hemisphere model, the Klein model, and the Poincaré models

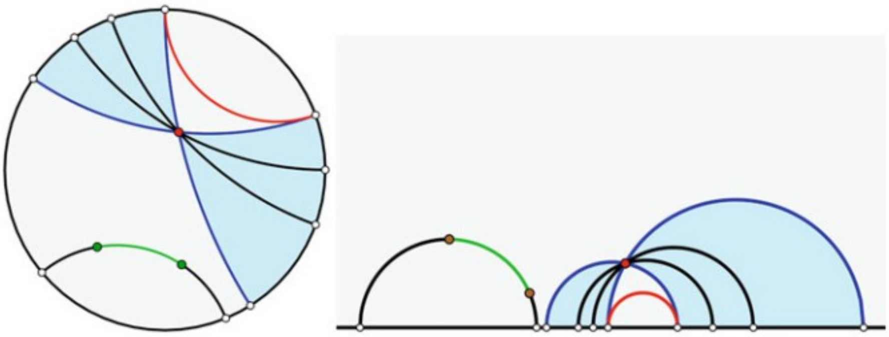

Fig. 16 Lines in the Poincaré disk model and the half-plane model

parallel because they have no common point in $\mathbb{D}$. This distinguishes them from *ultraparallel lines*, which do not even tend to common ideal points. Figure 16 also illustrates the fact that Playfair's axiom is violated.

(3) Projecting the hemisphere orthogonally onto the equator plane yields the *Klein model*, *Cayley-Klein model*, or *Beltrami-Klein model*. Its points are the points in the open unit disk, and its lines are open line segments connecting ideal points on the boundary of the unit disk. A (hyperbolic) line is depicted in blue in Fig. 15. Composing the two mappings just introduced yields an isomorphism between the Poincaré and the Klein model. Its explicit form in complex coordinates is

$$F(z) = \frac{2z}{1 + |z|^2}. \tag{1}$$

For more details about the Klein model, the reader is referred to Baldus (1944) and Greenberg (2007).

(4) If, as in Fig. 15, the projection is performed from a point on the equator of the Riemann sphere onto a plane tangent to the sphere at an opposite point, the model that lives in a half plane, usually identified with the upper half plane $\mathbb{H} := \{x + iy : y > 0\}$ of the complex plane, is obtained. This model is the *Poincaré half-plane model* in which lines are either open semicircles or open half-lines orthogonal to the real line; see Fig. 16, right. Elementary considerations also show a mapping that directly relates both Poincaré models. Such a mapping turns out to be the *Cayley transform*, a special Möbius transformation that maps $\mathbb{D}$ onto $\mathbb{H}$:

$$F(z) = \mathrm{i}\frac{1 - z}{1 + z}. \tag{2}$$

See, for example, the exposition in Anderson (2005), which is based on the Poincaré half-plane model.

Hilbert's axioms for plane geometry introduce only five undefined or *primitive terms* by the properties they are supposed to possess. These are "point," "line," "incidence," "betweenness," and "congruence." So, in the description of the models, all these terms must be addressed, not only points and lines. Incidence and betweenness have their usual Euclidean meaning. It is therefore possible to define a *line segment* $\overline{AB}$ as the collection of all points on the line through A and B that are located between A and B or coincide with one of the points. Such a line segment is colored in green in the two Poincaré models shown in Fig. 16.

It is also possible to define (hyperbolic) convexity: A set is *hyperbolically convex* if it contains all line segments between any two of its points. As in Euclidean geometry, the intersection of all convex sets containing a set M is again convex and will be called the *hyperbolic convex hull* of M.

The notion of congruence and length of line segments in the Poincaré model is more subtle, since it must be compatible with Hilbert's axioms. To this end, we define the *hyperbolic distance* between z and w in $\mathbb{D}$ by

$$d(z, w) = \log \frac{1 + \rho(z, w)}{1 - \rho(z, w)}, \quad \text{where } \rho(z, w) = \left| \frac{z - w}{1 - \overline{w}z} \right|. \tag{3}$$

The function ρ is called the *pseudo-hyperbolic distance*.

This formula has interesting consequences: If z is fixed and w tends to the boundary of the unit disk, their distance will go to infinity. In other words, the Poincaré disk is unbounded and ideal points have infinite distance from points inside the disk. If both z and w tend to $\partial\mathbb{D}$ while their Euclidean distance remains fixed, their hyperbolic distance will go to infinity. The other way around also works: An object of fixed size in the hyperbolic world that moves toward the boundary of the unit disk, (which is not a boundary of the hyperbolic disk) becomes tiny for an observer in the Euclidean plane.

The conformality of the Poincaré disk model and the Möbius map (2) imply that the Poincaré half-plane model is also conformal. On the other hand, the transition map (1) is not conformal. Therefore, the hyperbolic size of an angle between two lines in the Klein model is not equal to its Euclidean size.

The final relevant notion is that of *isometries*, that is, self-mappings of the hyperbolic plane that leave the length of line segments and, therefore, angles invariant. Isometries form a group under composition that acts on the hyperbolic plane. In the Poincaré disk model, there are two types of isometries: conformal self-maps of the unit disk, which are the special Möbius transformations that can be written in the form

$$b(z) = c \frac{z - z_0}{1 - \overline{z}_0 z} \tag{4}$$

with $|c| = 1$ and $z_0 \in \mathbb{D}$, and anti-conformal self-maps of $\mathbb{D}$, which can be written as the composition $b(\overline{z})$. Recall that $z \mapsto \overline{z}$ is the reflection in the real axis and it reverses orientation. A function of the form (4) is called a *Blaschke factor*.

When considered in the complex plane, b has a pole at $1/\overline{z_0}$, as can be seen on the left of Fig. 17. The image in the middle of the figure shows a Blaschke factor.

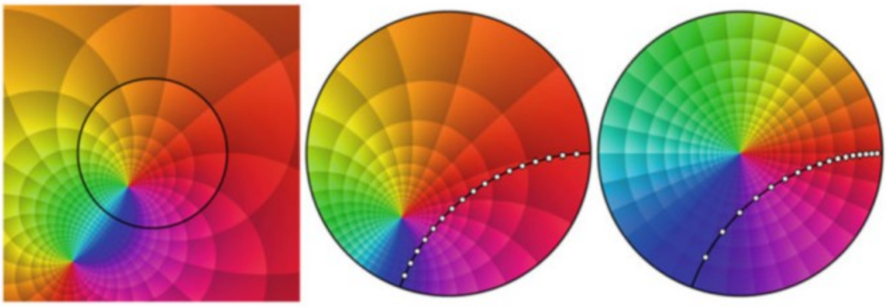

Fig. 17 A conformal self-map of the disk (domain on the left and in the middle, image at right)

This self-map of $\mathbb{D}$ is a *hyperbolic translation*; that is, there is a line that is invariant under b (which is the black line with the white dots in the middle and right images of the figure).

Blaschke Products

A *complex polynomial* p of *degree* n has the form $p(z) = a_n z^n + \cdots + a_1 z + a_0$ with complex coefficients $a_0, \ldots, a_n$, where $a_n \neq 0$ is assumed. It follows from the fundamental theorem of algebra that, for any $w \in \mathbb{C}$, the equation $p(z) = w$ has exactly n solutions, if they are counted according to multiplicities. Since p is also holomorphic, we can say that a polynomial is a self-map of $\mathbb{C}$ that maps $\mathbb{C}$ onto an n-fold covering of itself. In view of the fact that $\lim_{|z|\to\infty} |p(z)| = \infty$, polynomials have a continuous extension onto the Riemann sphere by defining $p(\infty) := \infty$. Recalling that $z \mapsto 1/z$ interchanges 0 and ∞, it is even possible to speak of the *multiplicity of* ∞, which is then defined to be the multiplicity of the zero of the analytic function $z \mapsto 1/p(1/z)$, and this multiplicity is easily seen to be equal to n. Hence, polynomials are also self-maps of the Riemann sphere of valency n. (It should be noted that they are not the only ones.)

What are the self-maps of the unit disk of valency n? The answer is that these are exactly the functions

$$B(z) = c \prod_{k=1}^{n} \frac{z - z_k}{1 - \overline{z}_k z} \tag{5}$$

with $|c| = 1$ and $z_1, \ldots, z_n \in \mathbb{D}$. These functions are called *Blaschke products* or *hyperbolic polynomials* of degree n. Blaschke products share many properties with polynomials. Again by the fundamental theorem of algebra, a polynomial of degree n can be factored as

$$p(z) = c\,(z - z_1) \cdots (z - z_n)$$

where $z_1, \dots, z_n \in \mathbb{C}$ are its zeros, each repeated according to its multiplicity. Recalling that conformal self-maps of $\mathbb{C}$ are of the form $z \mapsto az + b$, it follows that polynomials of degree n are exactly those functions that can be written as a product of n conformal self-maps of $\mathbb{C}$. Comparing the conformal self-maps of $\mathbb{D}$ appearing in (4) with the general form of a Blaschke product of degree n as in (5), it follows that Blaschke products are exactly those functions that can be written as a product of n conformal self-maps of $\mathbb{D}$.

The derivative of a polynomial p of degree n is a polynomial of degree $n - 1$ and therefore has $n - 1$ zeros, called *critical points* of p. The derivative of a Blaschke product B of degree n is not a Blaschke product, but it has $n - 1$ critical points in $\mathbb{D}$ (counting, of course, possible multiplicities). If the points $\zeta_1, \dots, \zeta_{n-1} \in \mathbb{C}$ are prescribed, and a polynomial p with these points as critical points is to be constructed, it is apparent that $p'(z) = a(z - \zeta_1) \cdots (z - \zeta_{n-1})$ with $a \neq 0$ arbitrary, and thus

$$p(z) = \int p'(z)\, dz = a \int (z - \zeta_1) \cdots (z - \zeta_{n-1})\, dz + b;$$

that is, p exists and is uniquely determined up to post-composition with a conformal self-map $z \mapsto az + b$ of the plane $\mathbb{C}$. The analogous property for hyperbolic polynomials is a nontrivial result that was first proved by Heins: Given $n - 1$ points in $\mathbb{D}$, there is a Blaschke product B of degree n with these points as critical points, Heins (1962, 1986). The function B is unique up to post-composition with conformal self-maps of $\mathbb{D}$. Semmler and Wegert (2019) gave a simple proof using equilibriums of charge configurations. For further references on this topic, see Kraus and Roth (2008, 2013) and Garcia et al. (2018, Chapter 6).

Blaschke products live most naturally in the Poincaré disk model because of their conformal character. This is demonstrated by the following theorem due to Walsh, which is the hyperbolic counterpart of the well-known Gauss-Lucas theorem, Walsh (1950, 1952). The Gauss-Lucas theorem states that the critical points of any complex polynomial lie in the convex hull of its zeros. Walsh's theorem says that the critical points (in $\mathbb{D}$) of a hyperbolic polynomial (i.e., a Blaschke product) lie in the hyperbolic convex hull of its zeros (for an alternative proof, see Wegert 2011).

In the picture on the left of Fig. 18, the 10 zeros of a Blaschke product are given (black points), along with their hyperbolic convex hull and the critical points in $\mathbb{D}$ of the Blaschke product (gray points).

In fact, from Formula (5) it is possible to define the Blaschke product B not only in the unit disk but also on the Riemann sphere. In this case, B is a rational function that maps the Riemann sphere onto itself. More precisely, each of the upper hemisphere, the lower hemisphere, and the equator is mapped onto an n-fold covering of itself, respectively. In particular, a Blaschke product of degree n maps $\mathbb{D}$ onto itself n times, and it wraps the unit circle around itself n times with strictly monotone argument.

The Blaschke product B also shows some nice symmetry: The value $B(1/\overline{z})$ at a point $1/\overline{z}$, which is the reflection of z in the unit circle, is the reflection of $B(z)$ in

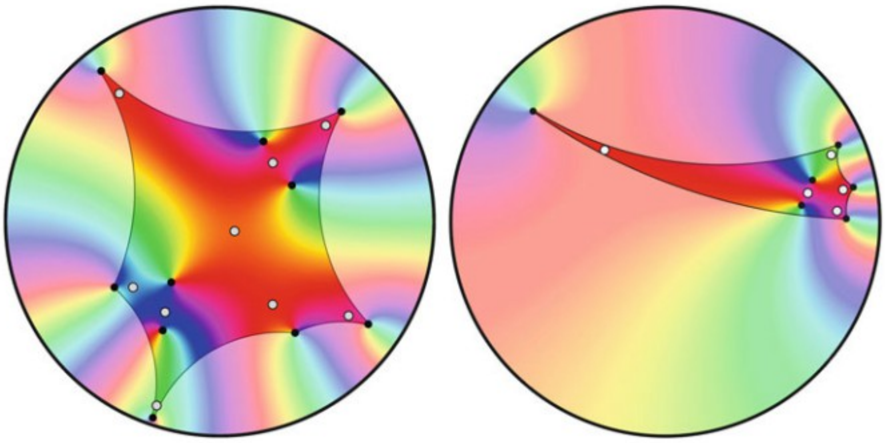

Fig. 18 Walsh's theorem on the location of critical points of a Blaschke product

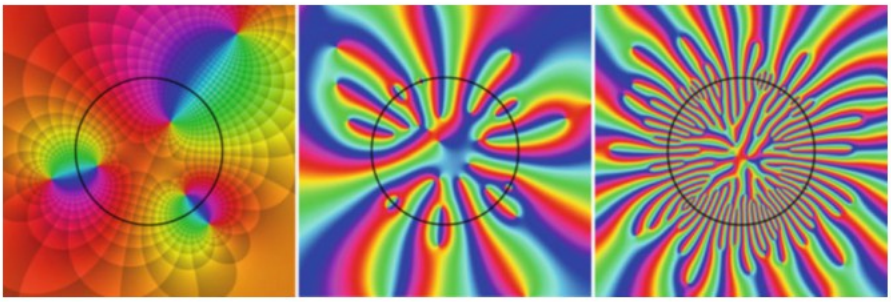

Fig. 19 Blaschke products of degrees 3, 20, and 70 in the square $|\operatorname{Re} z| \leq 2$, $|\operatorname{Im} z| \leq 2$

the unit circle,

$$B(1/\overline{z}) = 1/\overline{B(z)}, \qquad z \in \mathbb{C}. \tag{6}$$

This has the consequence that the zeros z_k of B inside the unit circle correspond to poles of B at the reflected points $1/\overline{z_k}$ outside the unit disk. This is illustrated in Fig. 19. (Not all poles can be seen because z is restricted to the square $|\operatorname{Re} z| \leq 2$, $|\operatorname{Im} z| \leq 2$.)

The perfect symmetry induced by relation (6) can be seen more readily by viewing the Blaschke product on the Riemann sphere, as shown in Fig. 20. Since reflection reverses orientation, the orientation of the color spectrum in the upper and lower hemisphere is reversed, and the zeros in the upper hemisphere appear as poles in the lower hemisphere.

This brief discussion demonstrates the surprising analogy between Blaschke products and polynomials, justifying the name hyperbolic polynomials. More substantial results in this direction can be found in Ng and Tsang (2013).

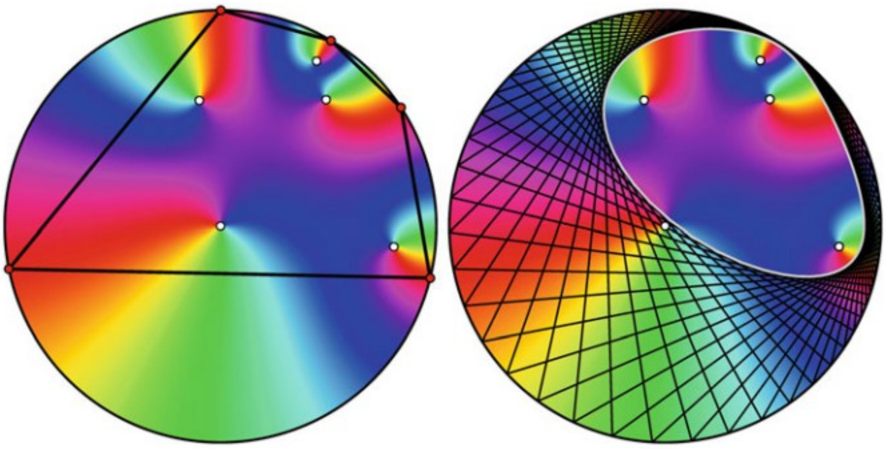

Fig. 21 A Blaschke product of degree 5 with some inscribed polygons

Blaschke Products and Ellipses in the Euclidean Plane

Recall from the previous section that a Blaschke product of degree n wraps the unit circle, $\partial\mathbb{D}$, around itself n times. Therefore, given any color, there will be exactly n points on the unit circle in the phase plot that have this color; in other words, these points are mapped to the same $\lambda \in \partial\mathbb{D}$. Now draw the convex n-gon with these points as vertices. In Fig. 21, this process is applied once in the figure on the left and then repeated on the right, moving λ around the unit circle. As this happens, the envelope of the n-gons obtained produces a closed curve in the unit disk. The phase portrait of the Blaschke product appears to have no obvious symmetries, but what about the curve? Can the curve be described in a nice way? Does it possess symmetries? And, if so, do these symmetries say anything about the Blaschke product?

To form a *Blaschke curve*, points of the same color on the unit circle are joined to their nearest neighbors using line segments. The envelope of these line segments yields the curve. The curve appearing in Fig. 21 is obtained from a Blaschke product of degree 5, and, perhaps as expected, it does not have any obvious symmetry. Here it is assumed that $B(0) = 0$. If this is not the case, it is possible to choose a Blaschke factor M mapping $B(0)$ to 0 and then to consider the Blaschke product defined by $B_1 := M \circ B$. Now B_1 and B are of the same degree, $B_1(0) = 0$, and the curve obtained from B_1 is the same as the one obtained from B. One thing is surprising though: The four nonzero zeros of the Blaschke product (the white dots not in the center) lie inside the curve. It is not difficult to show that if $B(0) = B(a) = 0$ and $a \neq 0$, then for each $\lambda \in \partial\mathbb{D}$ the point a lies in the convex hull of the points z for which $B(z) = \lambda$, Gorkin et al. (1994, Proposition 4.8).

Consider the Blaschke product $B(z) = \mathrm{i}\, z\,(z - 1/2)\,/\,(1 - z/2)$. In the picture of Fig. 22, there are two red points on the unit circle and these are the two points z_1 and z_2 for which $B(z_1) = B(z_2) = 1$. The result of connecting these two points is the picture on the left.

Continue connecting the two points on the circle of the same color and drawing the line segments; something unexpected happens as a result of this process. Looking at the picture on the right in Fig. 22, all line segments seem to intersect in one point, namely, the point $1/2$, the nonzero zero of B.

This is always true: Let B be a Blaschke product of degree 2 with one zero at 0 and one zero at a point a in $\mathbb{D}$, and consider the line segment joining the two points $z_{1,\lambda}$ and $z_{2,\lambda}$ for which $B(z_{1,\lambda}) = B(z_{2,\lambda}) = \lambda$. Then for all λ on the unit circle, these line segments will pass through the point a. In this simplest case, the enveloping curve will degenerate to a point. While this might be considered a symmetric object, it is not a very interesting one. The obvious question now is: What happens if B has zeros 0, a, and b and the points B identifies on the unit circle are connected?

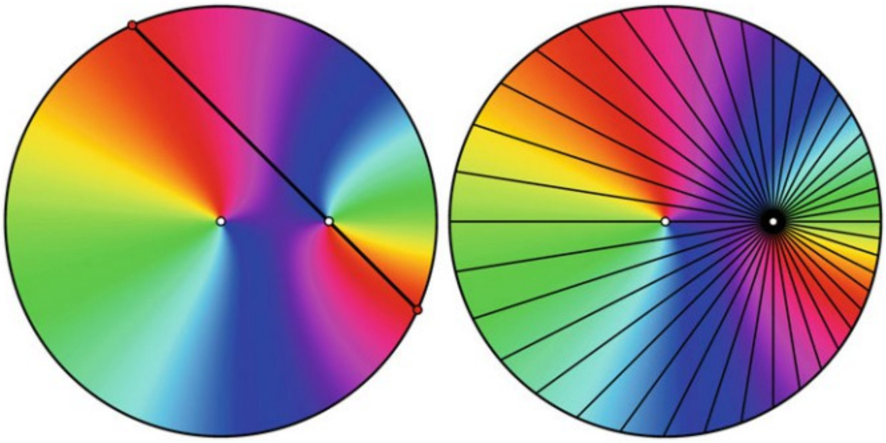

Fig. 22 Line segments with points on the unit circle identified by a Blaschke product of degree 2

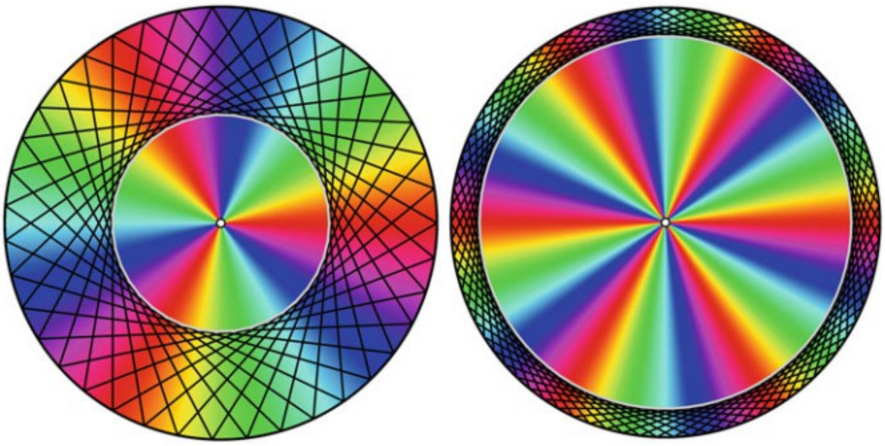

Fig. 23 The circles associated to $B_1(z) = z^3$ and $B_2(z) = z^6$

Start with the simplest degree-3 Blaschke product, namely, $B(z) = z^3$. As in Fig. 23, the points B identifies are equally spaced on the unit circle, and it follows from this that the curve obtained from this process is a circle, a perfectly symmetric curve. In fact, any Blaschke product of the form cz^n for $|c| = 1$ and a positive integer $n \geq 3$ will be associated with a circle centered at the origin. The bigger the n is, the larger the radius of the circle. This is illustrated by the picture on the right of Fig. 23.

Now consider the case in which the degree-3 Blaschke product has a nonzero zero. For example, suppose the two zeros are $a = 0.8 - 0.1\mathrm{i}$ and $b = 0.5 + 0.5\mathrm{i}$.

In Fig. 24, the three points B maps to the point 1 are connected to obtain the single triangle appearing in the picture on the left. For the picture on the right, 20 such triangles are formed. As before, a and b lie inside all the triangles. But more seems to be true here.

In fact, it seems that every triangle circumscribes an ellipse and that the foci of the ellipse are located at these two zeros of B. A classical theorem explains why such a result might be expected: Siebeck's theorem says that given three noncollinear points z_1, z_2, and z_3, the zeros of the function

$$F(z) = \frac{m_1}{z - z_1} + \frac{m_2}{z - z_2} + \frac{m_3}{z - z_3}, \text{ where } m_1, m_2, m_3 > 0$$

are the foci of the ellipse inscribed in the triangle formed by z_1, z_2, z_3. Applying Siebeck's theorem to the function

$$F_\lambda(z) = \frac{B(z)/z}{B(z) - \lambda}, \text{ for } \lambda \in \partial\mathbb{D},$$

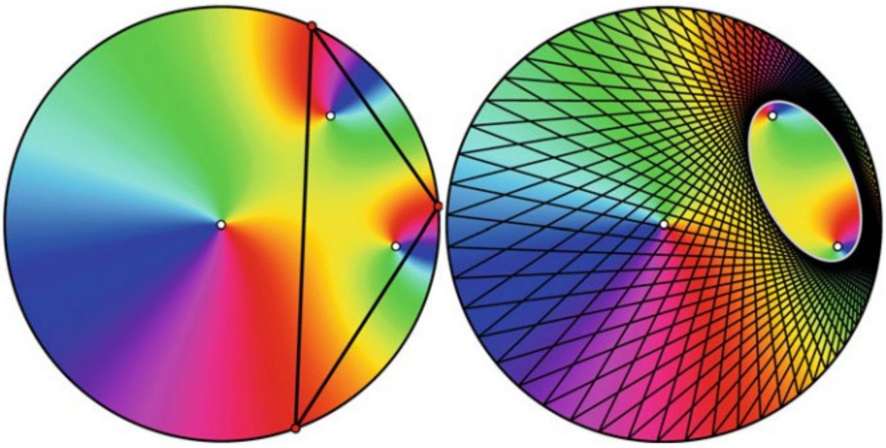

Fig. 24 A Blaschke product of degree 3

one sees that for each $\lambda \in \partial\mathbb{D}$, the triangle with vertices at the three points B maps to λ circumscribes an ellipse with foci at the zeros of $B(z)/z$. But these ellipses may change as λ changes. So the question is: Why do these triangles always circumscribe the same ellipse? For the answer, see Daepp et al. (2002, 2018). For Blaschke products of degree 3, then, the result is a well-known curve with two axes of symmetry, and the two foci of the curve are the zeros of $B(z)/z$.

The next case to consider is, of course, degree 4. Here, when the convex quadrilaterals with vertices at the points the Blaschke product identifies are formed, the result is a curve – but not a familiar one, in general. However, there is a very special case in which some symmetry appears: By a theorem of Fujimura, the associated curve of a degree-4 Blaschke product is an ellipse if and only if the Blaschke product is the composition of two degree-2 Blaschke products, Fujimura (2013) (see also Gorkin and Wagner 2017). For example, the picture on the left of Fig. 25 is associated with a Blaschke product that is a composition, $B = D \circ C$, where

$$C(z) = z\frac{z - (0.2 - 0.5\mathrm{i})}{1 - (0.2 + 0.5\mathrm{i})z} \quad \text{and} \quad D(z) = z\frac{z - (0.5 + 0.3\mathrm{i})}{1 - (0.5 - 0.3\mathrm{i})z}.$$

On the right, an asymmetrical picture associated with a degree-4 Blaschke product outlining a clearly non-elliptical form appears, and Fujimura's result says that the Blaschke product cannot be written as a composition of two nontrivial Blaschke products.

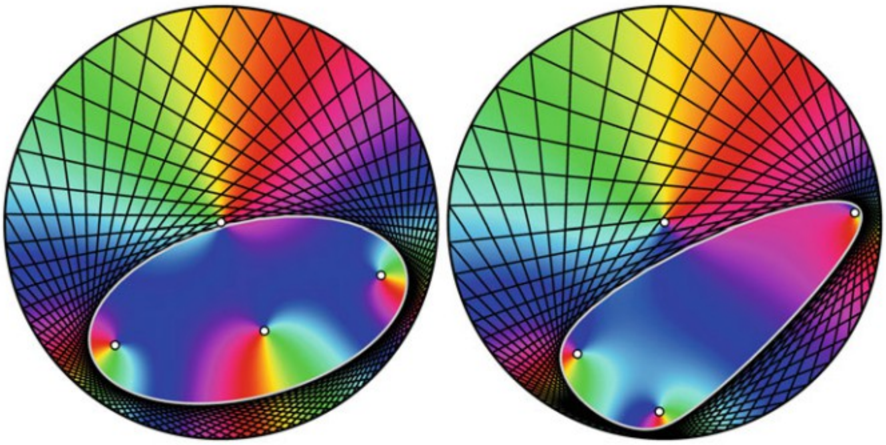

Fig. 25 Curves associated to degree-4 Blaschke products

Blaschke Products and Ellipses in the Poincaré Disk Model

So far, the focus has been on the envelope of the line segments joining the points that the Blaschke product B identifies. But Blaschke products are hyperbolic polynomials, so it is natural to view this in terms of hyperbolic geometry. In particular, what happens when the Euclidean lines of the previous section are replaced with hyperbolic lines in the Poincaré disk model?

We again start with the simplest case, a Blaschke product B of degree 2. The ideal points on the unit circle that are identified by B are now joined by the hyperbolic line of the Poincaré disk model. These lines all intersect in one point, but this time they intersect at the critical point of B; see Fig. 26. In the Euclidean model, when $B(0) \neq 0$, a Blaschke factor could be used to move points so that zero mapped to zero. In the hyperbolic case, there is no need to require that $B(0) = 0$, because the critical points are invariant under post-composition by a Blaschke factor.

Formula (3) for distance in the Poincaré disk model was introduced in the section entitled *Hyperbolic Geometry.* In view of this formula, it is reasonable to ask what a *hyperbolic circle* with center $a \in \mathbb{D}$ is. The answer is that it is the set of points z for which $d(z, a) = r$, for a constant r with $r > 0$ – the same as in the Euclidean setting, but using a different distance function. Since $d(z, a) = r$ if and only if $\rho(z, a) = s$ for some s with $0 < s < 1$, a hyperbolic circle with center a and ρ-radius s is

$$D_\rho(a, s) := \{z : \rho(z, a) = s\}.$$

If $a = 0$, then (as the reader should check) the hyperbolic circle centered at zero and of radius r is also a Euclidean circle with center zero and Euclidean radius s, where $s = (e^r - 1)/(e^r + 1)$. Something like this is true in general: Consider $D_\rho(a, s)$ and the Blaschke factor defined by

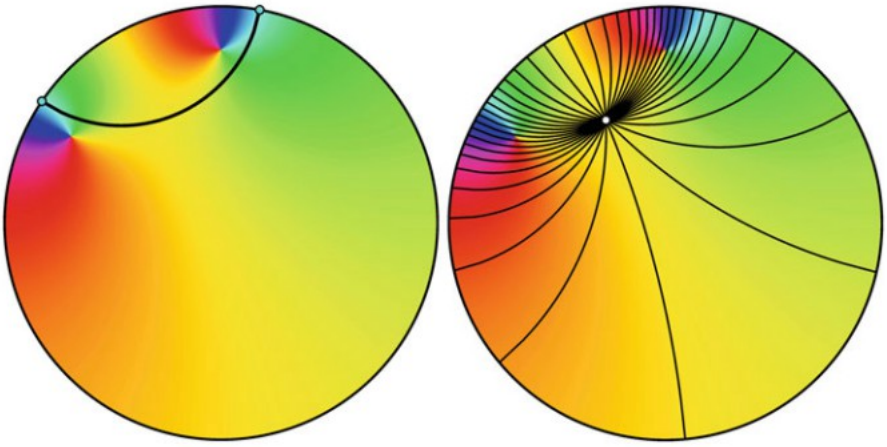

Fig. 26 Hyperbolic lines with ideal points identified by a degree-2 Blaschke product

$$M_a(z) = \frac{z-a}{1-\overline{a}z}$$

that maps a to 0. Since M_a preserves hyperbolic circles and distances, M_a maps the circle $C_\rho(a, s)$ to the circle $C_\rho(0, s)$. But M_a also preserves Euclidean circles and so does M_a^{-1}. Therefore $C_\rho(a, s) = M_a^{-1}(C_\rho(0, s))$ is also a Euclidean circle. Thus, a hyperbolic circle is also a Euclidean circle (and conversely), though the center and radius are not usually the same. Formulas for the center and the radius can be found in Garnett (1981). The Poincaré disk model bounded by the black unit circle with five blue circles of hyperbolic radius 1 appears in Fig. 27. The blue hyperbolic centers are located at five distinct points, namely

$$\left(1-\frac{1}{2^n}\right)\mathrm{e}^{(2n-1)\pi\,\mathrm{i}/4} \qquad \text{for } n = 0, \dots, 4.$$

The black dots are the Euclidean centers of the circles, and it should be noted that the Euclidean and hyperbolic centers of the circle centered at the origin coincide. The curve in the figure on the right is also a hyperbolic circle produced by the Blaschke product

$$B(z) = \left(\frac{z-(1+\mathrm{i})/5}{1-z(1-\mathrm{i})/5}\right)^3.$$

In the previous section, the focus was on ellipses (Euclidean ellipses). It is time to consider ellipses again, but this time in the hyperbolic setting. A *hyperbolic ellipse* is the set of points such that the sum of the distances to two fixed points a_1 and a_2

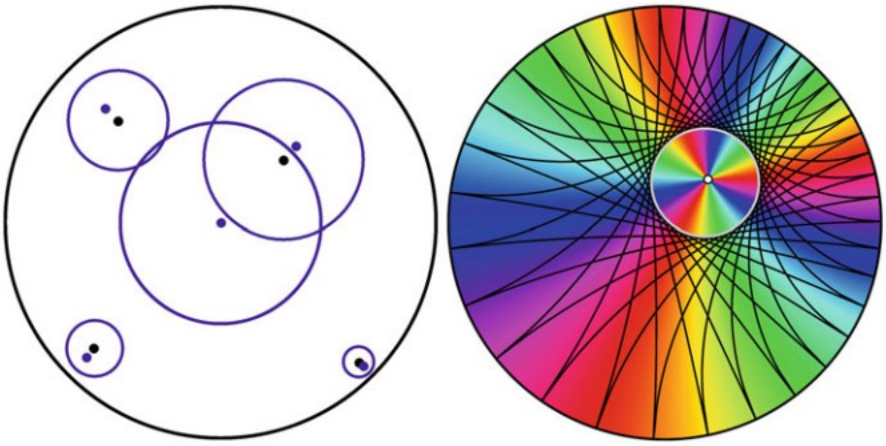

Fig. 27 Circles in the Poincaré disk model

is a constant. While this may sound familiar, the point is that the distance is now the hyperbolic distance.

Recall that lines in this model (the Poincaré disk model) are represented by circular arcs (geodesics) inside the unit circle that are orthogonal to the circle at their points of intersection. In the Euclidean model, starting with a Blaschke product of degree 3 with a zero at zero and connecting the points it identified, the resulting triangle circumscribed an ellipse. Consider now the hyperbolic version of this: Connect the three points a Blaschke product of degree 3 (not necessarily with a zero at 0) identifies with geodesics, forming three parallel lines. Is the result interesting? Indeed it is. On the left of Fig. 28, the ideal points that are identified by a Blaschke product of degree 3 are connected by three parallel lines. On the right, these lines envelope a curve when the procedure is repeated with other points on the unit circle.

In fact, Singer showed that if γ denotes the curve in $\mathbb{D}$ that is the envelope of the non-Euclidean geodesics joining points a Blaschke product B of degree n identifies, then γ is part of an algebraic curve for which the real foci in $\mathbb{D}$ are the critical points of B in $\mathbb{D}$ (together with their inverses with respect to $\mathbb{D}$), Singer (2006). If the Blaschke product is of degree 3, then the curve γ is a non-Euclidean ellipse, and the geometric foci are the two algebraic foci in $\mathbb{D}$, which are the two critical points of B in $\mathbb{D}$.

The curve on the right in Fig. 28 is thus a hyperbolic ellipse with foci marked in the figure. Our eye, trained by Euclidean geometry, is no longer able to recognize the symmetry of this curve because the distance function seems “distorted”; thus, to understand this, it is necessary to expand the traditional vision (i.e., Euclidean vision) of an ellipse.

We now also have a better understanding of the circle on the right of Fig. 27. The curve associated with this Blaschke product is a hyperbolic ellipse, but the two critical points coincide, and thus the ellipse becomes a hyperbolic circle. This, however, is also a Euclidean circle, as discussed above. It may be difficult to see in the picture, but the zero of the Blaschke product, which is also the critical point, is not in the Euclidean center of this circle. It is the circle's center with respect to the Poincaré disk model.

Figure 29 shows curves that correspond to Blaschke products of degrees 4 and 7, respectively. These are no longer ellipses, but the critical points of the Blaschke products that lie in the Poincaré disk are real foci of these curves. There is another piece of the curve and other critical points outside the disk; the relation between the points is that those outside are the symmetric points, with respect to the unit circle, of those inside.

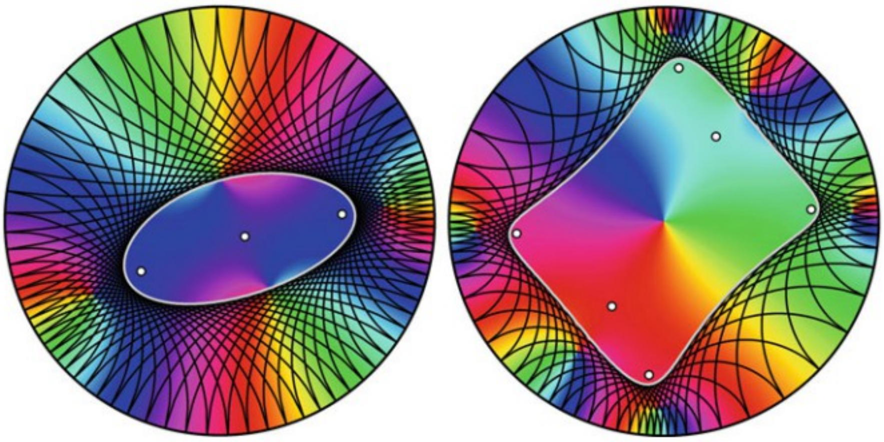

Fig. 29 Curves associated to Blaschke products of degree 4 and 7 in the Poincaré model

Compositions of Blaschke Products

This section demonstrates how visualization can provide new insight into the algebraic structure of mathematical objects. Such structures arise, for instance, from the factorization of natural numbers, which is the source of the rich field of number theory. In contrast to this, factorization of Blaschke products in the usual sense is trivial. However, there is another algebraic operation that gives rise to a number of challenging questions – this is the *composition* $g \circ f$ of two functions f and g, defined by $(g \circ f)(z) := g(f(z))$. It can easily be verified that the composition $B = g \circ f$ of Blaschke products f and g of degree m and n, respectively, is a Blaschke product of degree mn, so composition is an operation on the class of (finite) Blaschke products.

In analogy to multiplication of integers, it is easy to build a composition – but to decide whether or not a given function is composite, and to decompose it into its "factors," is a nontrivial task. There has been a great deal of interest in this problem: For polynomials a breakthrough appears in Ritt (1922). For a brief account of the history of the composition problem for Blaschke products, the reader, is referred to Cowen (2012). One approach to the problem will be described in detail below. For a different, but related, approach, see Chalendar et al. (2018).

Figure 30 shows enhanced phase plots of two Blaschke products. Knowing that one is a composition and the other one is not, it is not too difficult to guess which is which: A composition should have more structure than an arbitrary function – and looking at the phase plots with some patience, one finds that the candidate on the left is the better choice.

In fact, the relevant structure is encoded in the exceptional tiles that have more than 4 corners (see the section *Seeing Complex Functions*). The reason for this is

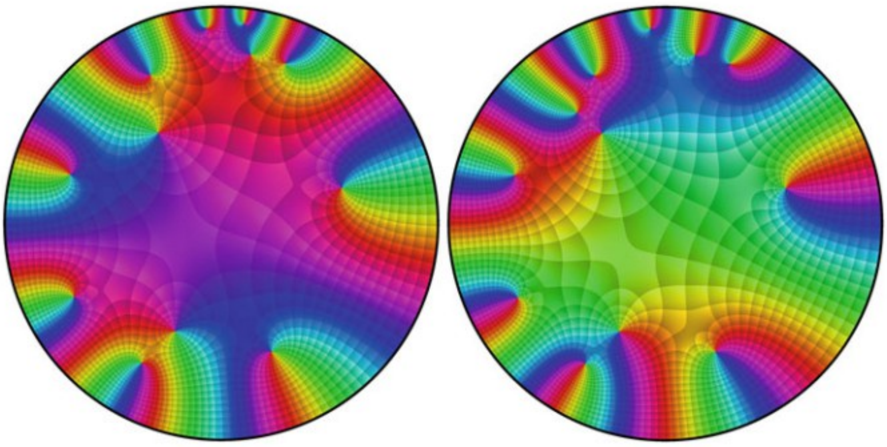

Fig. 30 Which of these phase plots represents a composition of Blaschke products?

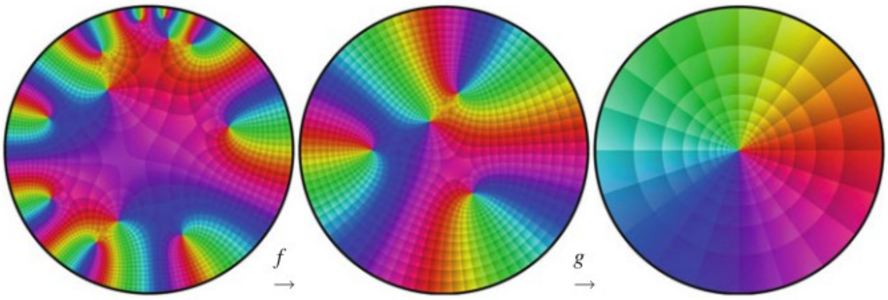

Fig. 31 Construction of the phase plot of a composition $g \circ f$, to be read from right to left

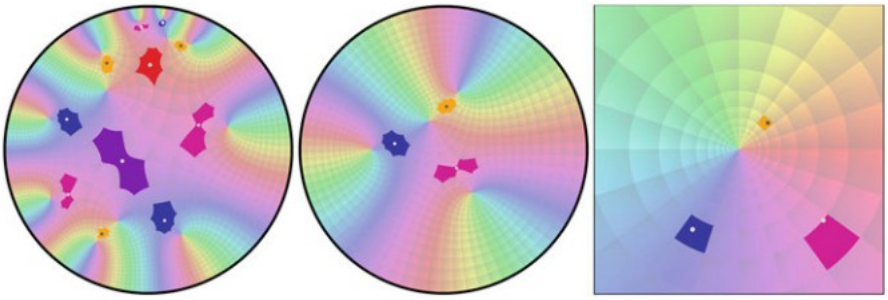

Fig. 32 Generation of critical tiles in the phase plots of $g \circ f$ and g from tiles in the z plane

explained in Fig. 31, which illustrates the composition of two Blaschke products. Starting with a standard polar pattern on the right-hand side, the phase plot of g in the middle is its pullback via the mapping g. The $n-1$ critical points of g are located in the exceptional tiles. The phase plot of $g \circ f$ on the left is the pullback of the image in the middle via f. Its exceptional tiles are of different origin: Tiles of the first type contain the critical points of f – they are pre-images of regular tiles of the plot in the middle – while tiles of the second type are generated as pullback of exceptional tiles in the phase plot of g. Since the image of f is an m-fold covering of the disk, each of the latter tiles is replicated m times.

As a consequence, the exceptional tiles in the phase plot of $g \circ f$ form $n-1$ groups, each consisting of m conformally equivalent tiles, and the remaining $m-1$ tiles contain the critical points of f (see Fig. 32). The arithmetic background of this observation is the chain rule

$$(g \circ f)' = (g' \circ f) \cdot f'.$$

The explanations above are somewhat simplified and have to be modified if f or g have multiple critical points or if their critical points and critical values are in special positions. Working out the details yields the following decomposition result.

A finite Blaschke product B is decomposable as $B = g \circ f$ with Blaschke products f and g of degree $m \geq 2$ and $n \geq 2$, respectively, if and only if the critical points of B can be partitioned into multisets[1] $A_0, A_1, \dots, A_{n-1}$ such that:

(i) The set A_0 contains $m - 1$ elements, and each set $A_1, \dots, A_{n-1}$ contains m elements.
(ii) Two critical points of B have the same multiplicity whenever they belong to the same set A_k for some $k = 1, \dots, n - 1$,
(iii) Let f_0 be (one and then any) Blaschke product of degree m with A_0 as set of critical points. Then f_0 is constant on each A_k for $k = 1, \dots, n - 1$.

If these conditions are satisfied, then B can be decomposed as $B = g_0 \circ f_0$, and the general form of such decompositions is

$$B = (g_0 \circ h^{-1}) \circ (h \circ f_0)$$

with a conformal disk automorphism h, Daepp et al. (2015).

In many cases the determination of candidates for the sets $A_1, \dots, A_{n-1}$ is rather easy: If $B = g_0 \circ f_0$ with f_0 satisfying condition (iii), then B must also be constant on each set, say $B(z) = c_k$ for all $z \in A_k$. Typically, these $n - 1$ critical values c_k of B are distinct, and they are also different from the critical values of B attained at the critical points of f_0. Thus, the splitting of critical points into the sets A_k corresponds to the values of B at these points. However, one should be aware that the existence of such a partitioning is a necessary condition that does not by itself guarantee that B is decomposable. Moreover, there are (exceptional) cases in which B also attains the critical value c_k at critical points not belonging to A_k, for instance, at points in $A_j \neq A_k$ or at critical points of f_0. This happens, for example, if g is itself a composition.

Verification of the crucial third condition relies on Heins' theorem on the existence and uniqueness of a Blaschke product f_0 of degree m with prescribed set A_0 of $m - 1$ (not necessarily distinct) critical points in $\mathbb{D}$ (see the section *Blaschke products*). The algorithmic aspects of this result are quite challenging, but in the case at hand, this can be circumvented in the following way: Since the set of Blaschke products (of any fixed degree) is invariant with respect to pre- and post-composition with conformal automorphisms h of the disk, one can assume that $B(0) = 0$ and then replace a (possible) composition $B = g \circ f$ by $B = (g \circ h^{-1}) \circ (h \circ f) = g_0 \circ f_0$, such that also $f_0(0) = 0$. This implies $g_0(0) = 0$. Hence, if $f_0(z_0) = 0$ at a point $z_0 \in \mathbb{D}$, then $B(z_0) = 0$. Consequently f_0 must be a sub-product of B, and it is only necessary to test the third criterion (iii) against all such f_0.

---

[1] In contrast to sets, multisets may contain elements repeatedly.

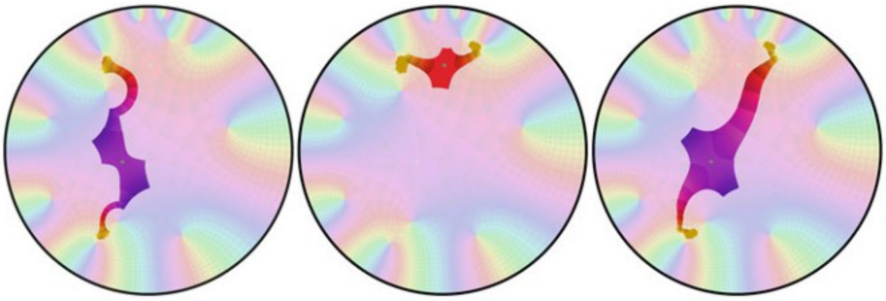

Fig. 33 Some hidden symmetries in the phase plot of a composition

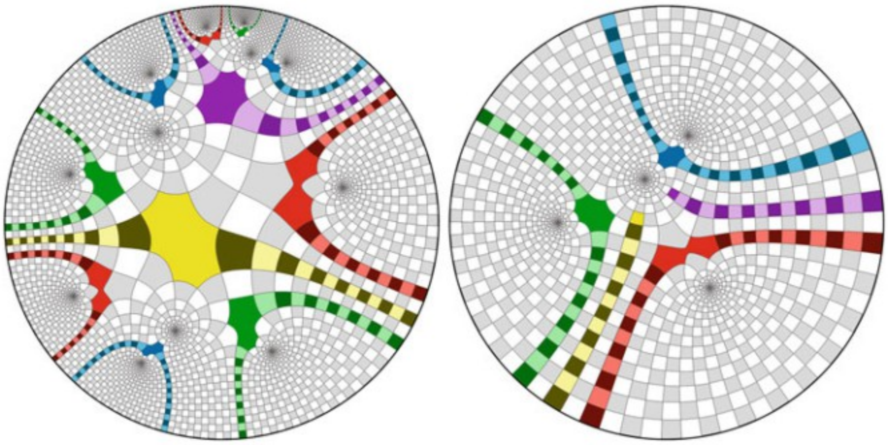

Fig. 34 Discrete conformal analysis of Blaschke products revealing symmetries

The governing principle behind these observations is a kind of hidden symmetry that is inherent in the compositions of Blaschke products and can be read off from their enhanced phase plots. Such symmetries are visualized in Fig. 33, which illustrates the fact that the critical points of $B = g \circ f$ belonging to the same set A_k (see the decomposition result) are, in a sense, symmetric with respect to the critical points of f. The reason for the appearance of these symmetries becomes plausible in Fig. 34, which shows "polar chessboard plots" of $g \circ f$ (left) and g (right). The yellow and the violet exceptional tiles contain the $m - 1 = 2$ critical points of f. Each of these belongs to a colored chain that connects opposite edges of that tile with the boundary of the disk. These two chains split the disk into $m = 3$ subdomains S_1, S_2, S_3, and f maps each subdomain onto (a copy of) $\mathbb{D}$ (shown on the right). These mappings are injective, except for the (colored) tiles of the bounding chains, in which two symmetric tiles have the same image. The exceptional (yellow and violet) tiles are mapped onto (double coverings) of the corresponding terminal tiles of the (yellow and violet) chains in the image on the right.

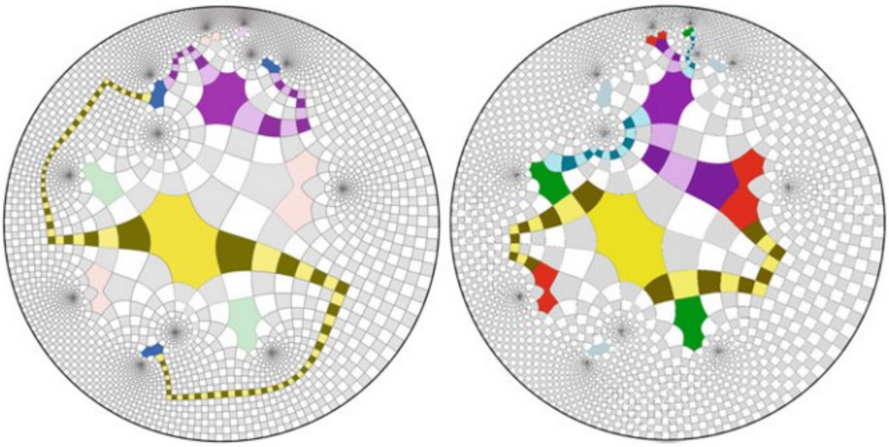

Fig. 35 Symmetric paths connecting tiles associated with the sets A_1 (left) and A_2 (right)

Each of the subdomains S_j contains $n - 1 = 2$ exceptional tiles (red, green, blue) that are the pre-images of the (correspondingly colored) critical tiles in the chessboard plot of g with respect to the mapping f. Finally, each group $A_1, \dots, A_{n-1}$ of critical points in the decomposition result is represented by exactly one member in each subdomain S_j. The color of the corresponding exceptional tile indicates the group to which its critical point belongs.

Polar chessboard plots are also convenient for finding the relevant symmetries, as illustrated in Fig. 35. This figure shows several chains of tiles that are symmetric with respect to the critical points of f (contained in the yellow and violet exceptional tile) and connect exceptional tiles (red, green, and blue) that are associated with the same set A_1, A_2, and A_3, respectively. If such symmetries are absent at some level of discretization, the Blaschke product is indecomposable. Theoretically, it would also work the other way around, provided that one could verify these symmetries exactly. This requires two things: (1) finding appropriate symmetric paths connecting the exceptional tiles and (2) verifying that the connected critical tiles are conformally equivalent. The first step is basically a counting exercise, but the second is impracticable. On the other hand, if a Blaschke product is not a composition, this can always be detected by choosing a sufficiently fine discretized chessboard plot.

Conclusion

The goal of this chapter has been to demonstrate how visualization can help to understand concepts and results of a mathematical theory without recourse to formulas. In fact, many mathematicians consider their research to be one of discovery, and seeing the objects of their investigations can be a source of

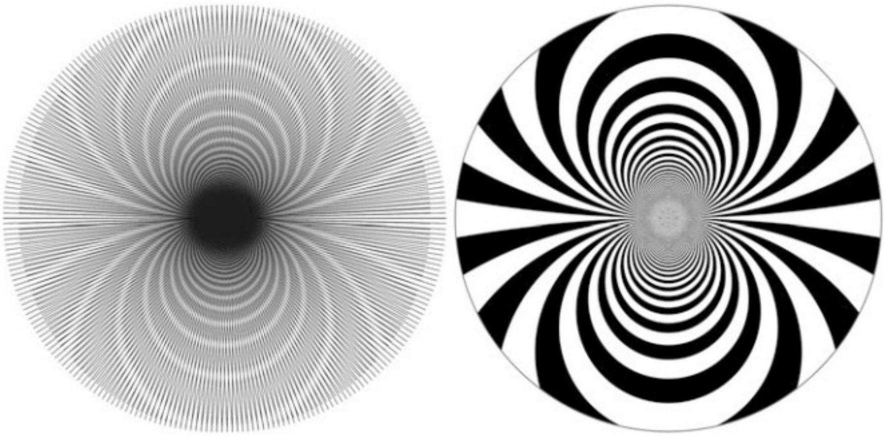

Fig. 36 Carsten Nicolai's stellar grating MI-RG-090 and a plot of $f(z) = \exp(1/z)$

inspiration. Beauty and symmetry are often guiding principles in these explorations. While beauty remains a matter of individual taste, experience, and convention, the concept of symmetry has a precise mathematical meaning, formally expressed in the language of group theory and reaching far beyond the common interpretation of this notion.

For centuries in the visual arts, beauty was a dominating criterion for the reception of artwork. In particular, during the Renaissance, strong composition rules were often based on symmetry and mathematical principles, and ingenious artists like Leonardo da Vinci or Albrecht Dürer made important contributions to mathematics.

During the twentieth century, the fundamental paradigm that art must be beautiful was abandoned, and art was assigned a new role as part of the human project of exploring nature, reality, and society. In the preface to the catalogue of Carsten Nicolai's exhibition "unidisplay," Eva Huttenlauch writes: "Art has become a category of thinking rather than seeing … ", Huttenlauch (2013, p. 13). As the aims of artists expanded, the border between mathematics and arts began to blur.

Artists like Victor Vasareli, Sol LeWitt, and Carsten Nicolai and scientists like Heinrich Heesch, Anatoly Fomenko, and Isaac Amidror are building bridges between arts and mathematics. Approaching a topic from opposite sides, emphasizing different aspects, and using tools specific to each discipline, mathematicians and artists sometimes seem to explore one and the same general phenomenon, indicating the presence of universal principles. For example, it is not an accident that the "stellar grating MI-RG-090" from the work "moiré index" (Nicolai, 2010b) resembles a black-and-white phase plot of the function $f(z) = e^{1/z}$ (Fig. 36). In the same vein, it would be interesting to do a comparative study of Niclolai's systematic listing of grids and tilings, Nicolai (2010a), (especially the semi-regular and irregular ones), with Frank Farris' wallpaper patterns, Farris (2015), and Isaac Amidror's theoretical foundation of moiré patterns, Amidror (2007, 2009).

Visualization is important for both the arts and mathematics. For the former, this has a long tradition. For the latter, tradition has focused on the subfield of geometry. However, advances of computer graphics opened up new possibilities for other branches of mathematics as well. In this chapter, it is the field of complex analysis that benefits from visual representations of its objects. In many mathematical subjects, the visual tradition has only just begun.

Fig. 8 Pairs of conjugate skew Sturmian sequences with different types and reciprocal frequencies

introduce an equivalence relation defined by $A_{\frac{q}{p}} \sim B_{\frac{p}{q}}$ and $B_{\frac{q}{p}} \sim A_{\frac{p}{q}}$. Given the geometric nature of prime numbers, it is natural to wonder about the geometrical behavior of these equivalence classes of a given skew Sturmian sequence. To this purpose, introduce the subset

$$Z_{\frac{q}{p}} = A_{\frac{q}{p}} \cup B_{\frac{p}{q}} \cup B_{\frac{q}{p}} \cup A_{\frac{p}{q}}$$

containing the (skew Sturmian) dynamical information associated to (p, q).

Since $Z_{\frac{q}{p}}$ has cardinality eight, it seemed more interesting to plot the points of $Z_{\frac{q}{p}}$ when the points (p, q) belong to a certain line.

Ford Circles and Farey Sequences

Ford circles (Ford, 1938) are "geometric picturizations" of fractions. For a given rational number $\frac{q}{p}$ with p and q coprime numbers, the Ford circle associated to $\frac{q}{p}$ is given by the equation

$$\left(x - \frac{q}{p}\right)^2 + \left(y - \frac{1}{2p^2}\right)^2 = \left(\frac{1}{2p^2}\right)^2.$$

A remarkable property of Ford circles is the following: If $\frac{Q}{P}$ is an adjacent fraction to $\frac{q}{p}$, that is to say, if $|qP - pQ| = 1$, then the Ford circles associated to $\frac{q}{p}$ and $\frac{Q}{P}$ are tangent. For example, the fractions $\frac{1}{2}, \frac{2}{3}$, and $\frac{4}{7}$ are adjacent to $\frac{3}{5}$. The Ford circles corresponding to these fractions are illustrated in Fig. 9.

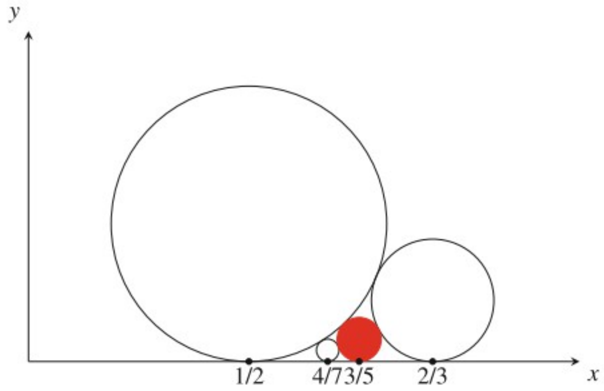

Fig. 9 Ford circles for $\frac{3}{5}$, in red, and the Ford circles of its adjacent fractions $\frac{1}{2}$, $\frac{4}{7}$, and $\frac{2}{3}$. Notice that the Ford circles are an infinite family of circles tangent to each other

Ford proved (Ford, 1938, Theorem 4) that any such irreducible fraction $\frac{q}{p}$ with $|p| > 1$ has exactly two adjacent fractions with denominators smaller than p. It follows that $A(p, q) = (a, b)$ and $B(p, q) = (c, d)$ are the only other two pairs with $0 < a, c < p$ such that both $\frac{b}{a}$ and $\frac{d}{c}$ are the *closest adjacent fractions* to $\frac{q}{p}$. Recall that a pth-Farey sequence consists of all proper reduced fractions with denominator up to p. Hence, $A(p, q)$ and $B(p, q)$ can be seen as the left and right neighbors, respectively, of $\frac{q}{p}$ in the p-th Farey sequence (Conway and Guy, 1996, Page 152). Recall that the mediant fraction of $\frac{b}{a}$ and $\frac{d}{c}$ is defined as $\frac{b+d}{a+c}$. Suppose that $A(p, q) = (a, b)$ and $B(p, q) = (c, d)$. Since $\frac{q}{p}$ is the mediant fraction of its neighbors, it follows that $\frac{q}{p} = \frac{b+d}{a+c}$ which implies $1 = aq - bp = a(b + d) - b(a + c) = ad - bc$. Therefore the pairs (p, q), $A(p, q)$, and $B(p, q)$ have mutually adjacent associated fractions. Thus, the Ford circles for (p, q), $A(p, q)$, and $B(p, q)$ are mutually tangent, as shown in Fig. 9.

Bézout Graphs

Let p be a positive integer. In (Itzá-Ortiz et al, 2020), the Bézout coefficients of the coprime pair (p, q) as $B_1(p, q) = A(p, q)$ and $B_{-1}(p, q) = B(p, q)$ were defined. Then the Bézout set $\mathscr{B}_p$ for p is

$$\mathscr{B}_p = \bigcup_{\substack{0<q<p \\ \gcd(p,q)=1}} Z_{\frac{q}{p}}.$$

In other words, the Bézout set $\mathscr{B}_p$ of p is the union of the sets $Z_{\frac{q}{p}}$ as the pairs (p, q) of coprime numbers move along the segment from $(p, 0)$ to (p, p). Notice

glue, you end up with the closed surface of genus 2. Figure 1 is a picture of two kinds of pants decompositions of the surface of genus 2.

If you use four pairs of pants, then you get the closed surface of genus 3. In fact, the surface of genus g can be obtained from 2g-2 pairs of pants by gluing 6g-6 boundary components of those pants pairwise. It does not matter how you glue them – you always get the same surface up to topological equivalence.

As an exercise, I invite the readers to try to decompose the closed surface of genus g into 2g-2 pairs of pants by drawing 3g-3 loops appropriately. Try with g = 2, 3, 4, … and see if you can generalize your idea for arbitrary genus. This is a fun mental exercise, and it is the base of the idea of building closed surfaces out of hexagons.

Hyperbolic Plane and Negative Curvature

In this section, we will briefly talk about the hyperbolic plane $\mathbb{H}^2$. This is like the usual plane in some way but very different in other ways, since it is not flat but curved weirdly. At every point, a small neighborhood looks like the saddle. It is curved in the way that in some direction, it looks like convex, and in other direction, it looks like concave.

In the world of hyperbolic plane, there are more "rooms" out there. For a straight line L and a point p which is not on the line L, there are infinitely many straight line passing through p but never meet the line L we started with! If you recall what you learned about the geometry of the usual plane, there should be a unique such line, but in the hyperbolic plane, there are infinitely many.

To grasp the idea how the hyperbolic plane actually looks like, I encourage the readers to check out the famous paintings of the tessellation of the hyperbolic plane by Escher (1959).

The reason why I mention the hyperbolic plane in this section is that the "natural geometric shape" of an arbitrary closed surface of genus at least two is like the hyperbolic plane. So far, we have always considered surfaces up to topological equivalence which ignore the precise shape such as the distance between two points and the angle between two lines. But each surface can be made into a geometric object by specifying the shape, and it is a remarkable fact that any closed surface of genus at least two has a geometric shape such that every point has a small neighborhood where the world looks exactly like the hyperbolic plane. When the surface is in such a shape, we call it a hyperbolic surface.

Once you have a decomposition of a hyperbolic surface of genus g into $2g - 2$ pairs of pants via $3g-3$ loops on the surface, we can straighten up the loops so that at every point on the loop, it locally looks like a piece of a straight line in the hyperbolic plane. On each pair of pants, we have three straight line boundary components. For each pair of boundary components, one can connect them via a straight line segment which meets the boundary components at the right angle. After connecting all three pairs, now one sees that the pair of pants is decomposed into two hexagons. Each of this hexagon geometrically lives in the hyperbolic plane, in the sense the it is exactly the same hexagon with some hexagon in the hyperbolic plane where each side is a straight line segment.

This is already an interesting fact, because now we have a pair of pants made out of two hexagons where each side is a straight line segment and each internal angle is the right angle. We call such a hexagon a right-angled hexagon. A right-angled hexagon cannot live in our usual world, since this would mean the total sum of the internal angles is 3π, while the total sum of the internal angles of a hexagon in the Euclidean plane is 4π. This is another feature of negative curvature. In fact, in the hyperbolic plane, one can have a hexagon whose internal angles sum up to any number between 0 and 4π.

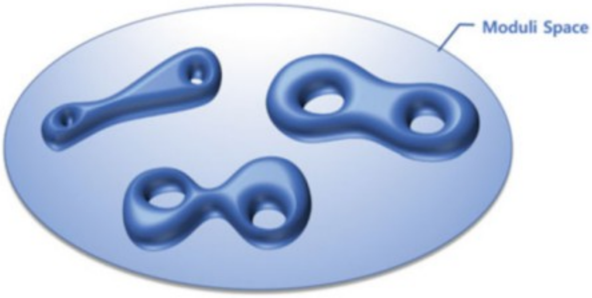
Above we expressed a hyperbolic surface of genus g as a collection of $4g - 4$ hexagons in the hyperbolic plane glued along their boundary. An elementary hyperbolic geometry can show that the geometric shape of a right-angled hexagon in the hyperbolic plane is completely determined by the length of the three alternating sides. Hence, the two hexagons forming one pair of pants are in the exactly same shape. In particular, this means, up to geometric equivalence, we only need $2g - 2$ hexagons to build a closed surface of genus g.

Each Surface Admits More Than One Geometric Shape

We have so far shown that all but two closed surfaces are built out of hexagons – more precisely, any closed surface of genus at least 2 can be obtained from gluing hyperbolic hexagons along their boundary. Since the surface is built upon pieces which live in the hyperbolic plane, it has the natural geometric shape as a hyperbolic surface. But the geometric shape of the surface is not unique, and by varying the shapes of hexagons, we can build surface which are topologically the same but geometrically different.

Perhaps this can be best explained in the pants decomposition point of view. For each loop used in the pants decomposition of a surface, one can change the length of the loop (but not all loops can be really short or really long due to our geometric constraints), and also when the lengths of the loops are fixed, there is still a room for further deformation of the shape. In fact, at each loop, one can think two pairs of pants are glued along the loop. But this gluing can be also altered by cutting it along the loop again and twist by an arbitrary angle and glue back. Mathematicians showed that each twisting will yield a surface of different geometric shape (although this is totally nontrivial). We have $3g - 3$ curves for a pants decomposition on the surface of genus g, and each curve has two degrees of freedom for the deformation – the length and the twisting. This means we have $6g - 6$ parameters to determine the geometric shape of the surface. In fact, if we collect all possible (hyperbolic) geometric shapes that a closed surface of genus g can admit, we get a huge $6g - 6$-dimensional space called the moduli space (Fig. 2).

Fig. 2 Moduli space for the surface of genus 2



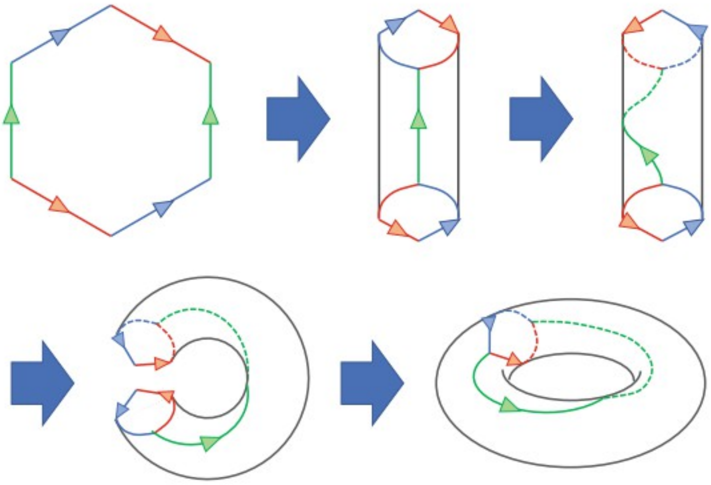


Fig. 3 From a regular hexagon on the plane to the torus

To conclude our journey, we go back to the case of the torus and see that the torus can be also obtained from a hexagon. In this case, it is obtained from a flat hexagon (i.e., a hexagon in the usual plane) by gluing sides pairwise.

Consider a regular hexagon in the plane, and glue the opposite sides pairwise. Then we get a torus – like a magic! Seeing is believing, so I describe the procedure of this side-gluing with a picture. See Fig. 3. To learn more about the torus and its symmetry, the readers are encouraged to see also the first chapter of Thurston (1997).

it will extend is an open question. So, more than explicit statements of absolute truth, these principles are implicit definitions of the gamut of experimental conditions under which they are verified. And they are interesting concepts if that gamut is interesting. That is the case with radial occlusion. Although far from universally valid, it is the default supposition of our interaction with light and the world. We will no longer be concerned in this section on the intricacies of when the principle works, but will reason on its consequences. All that lies ahead follows geometrically from this single assumption of radial occlusion that we will later abstract into our definition of anamorphosis (Definition 4).

Anamorphosis Formed Fast

We make a quick and informal summary here, before we proceed to the formal definitions and results.

If we accept the principle of radial occlusion, then it follows that many different $3D$ objects will look the same from O. The points of an object define a cone of rays from the observer O, the visual cone. If two objects define the same cone of rays, they should look the same. Such objects we will call *anamorphs* of each other relative to O (in fact we will require a technical condition for this *anamorphic equivalence* or *anamorphosis* that is slightly looser than equality of visual cones, but that is the subject of the next section; here we speak loosely).

The important things to note is that, unlike in perspective, the equivalence here is between 3D objects, and not just between objects and drawings. There is no need here to mention projection surfaces.

For instance, take the wireframe cube of Fig. 3 and an observer at O. If we slide each vertex along its ray from O, we get the object to the right of the cube. These

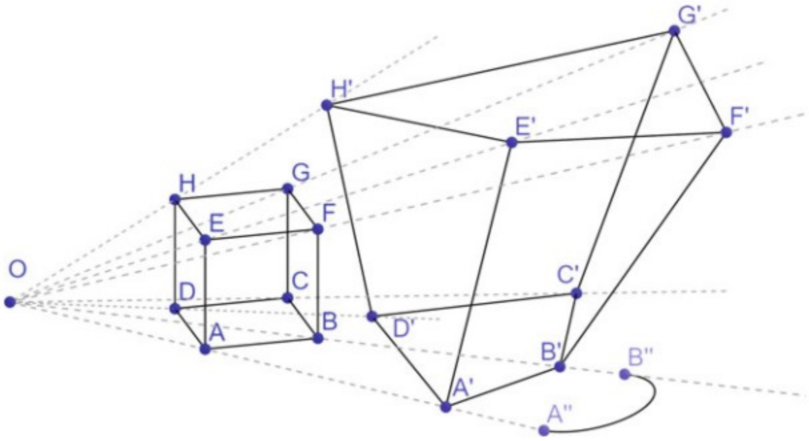

Fig. 3 Two very different 3D objects with the same visual cone. They will look the same when seen from O if the principle of radial occlusion is valid

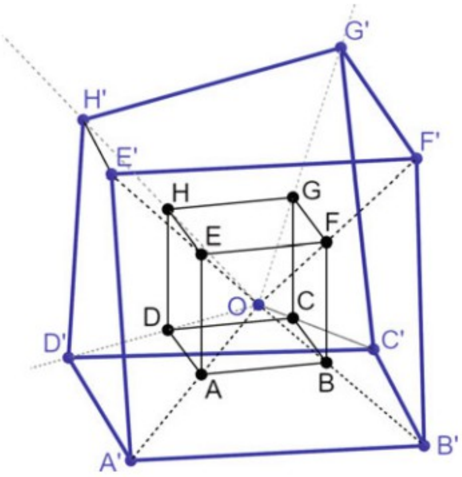
Fig. 4 Two very different 3D objects with the same visual cone, one surrounding the other. Anamorphosis is radial and isotropic, with no preferential axis



two shapes are very different, but they define exactly the same cone of rays from O, so, if we accept the principle of radial occlusion, we must accept that the two objects will look the same from O. Of course, the segments joining the vertices don't have to be straight. You could bend each segment freely within the cone of rays it generates, and it would preserve the equivalence. For instance, arc $A''B''$ in Fig. 3 is equivalent to rays AB and $A'B'$ as it lies within the cone of AB. This cone is just the angle $\angle AOB$.

This equivalence is radial and isotropic in nature. Unlike classical perspective, where there is a preferential axis defined by the perpendicular to the plane of the picture, here there is no such axis, plane, or even picture, hence no limitation of field of view: this is just an equivalence between objects. So the example of Fig. 4 works just as well as the previous one. This allows to give equal footing to immersive anamorphoses, that is, anamorphs that completely surround the observer (in turn, this proves foundational for spherical perspectives (Araújo 2018c)).

Remark 1. The limitation of a preferred axis is often kept in the literature from attachment either to the habits of perspective or to the convenient availability of the mathematical framework of projective geometry (see, for instance, (Sánchez-Reyes and Chacón 2016)). But in projective geometry all points on a line are equivalent, and this is a limited framework for anamorphosis. In anamorphosis the classes of equivalence are rays, not lines, so the sphere and not the projective plane will represent the visual data. The projective plane ignores exactly half of this visual data.

The principle of radial occlusion implies the existence of 2D anamorphs to any 3D object. Suppose S is a surface, not containing O. Then the intersection of the visual cone of a 3D object X with S is a 2D object that subtends the same cone as X itself. Hence it is a "drawing" that looks exactly like S when seen from O.

You could loosely say that the principle of radial occlusion is what makes *drawing* possible.

The most obvious case is the intersection of an object's cone with a plane. We see two examples in Fig. 5, the same object being projected onto a "vertical" and a "horizontal" plane.

There is no fundamental difference between horizontal and vertical, of course, since these are just named relative to the gravity field, which is quite irrelevant for optics. And yet the former anamorph is usually called a classical perspective, while the latter is called an "oblique anamorphosis." What is the difference? Any projection plane defines a preferred axis, the perpendicular to the plane through O. The difference is the angular distance of the object's cone with regard to that axis. When the object's cone is closely aligned with the main axis, the drawing is called a perspective; when the angular separation is "large," it is called an oblique anamorphosis. We see that the difference is one of degree, and both are

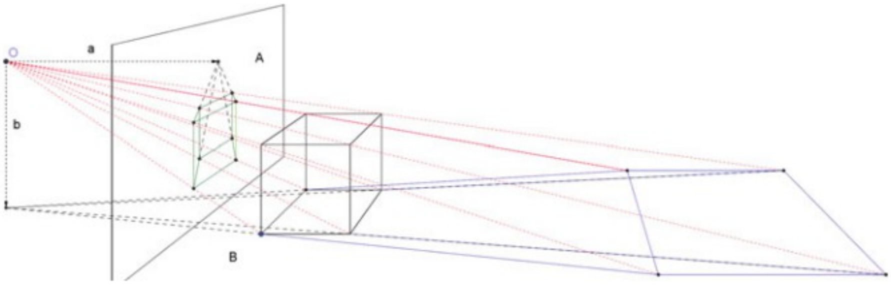


Fig. 5 Projection onto a plane. There is no absolute difference between the linear perspective and the oblique anamorphosis. Both are anamorphosis onto a plane; the latter merely projects the object to a region further away from the foot of the perpendicular

special cases of anamorphosis, the projection being just another anamorph that happens to be contained in a plane, whatever the plane's orientation may be. The projection is operationally the same in both cases; what makes it a "perspective" or "oblique anamorphosis" is the relative position of the body being projected, not the functional form of the projection itself. It is also quite indefensible to say, as is usually naively put, that the anamorphosis is "deformed," while the perspective isn't. What deformation is meant? By the principle of radial occlusion, none of them is *optically* deformed, being indistinguishable from O, while metrically both of them are deformed; the elongation of the edges in the oblique anamorphosis has a counterpart in their compression in the perspective. Of course some type of metrical deformation is inevitable if you lose one dimension.

Let us move to more complex setups. Nothing stops us from using several planes at once, as in Fig. 6. The cone projects onto this union of planes as several images that should all join seamlessly when viewed from O. We will see that this changes the global properties (such as the number of vanishing points) in a fundamental manner while preserving the local properties of classical perspective. This multi-plane projection is historically used in the so-called perspective boxes (Čučaković and Paunović 2016; Gay and Cazzaro 2019; Spencer 2018; Verweij 2010).

But of course we are not limited to planes. If we intersect the visual cone of an object with a curved surface, we still obtain a 2D anamorph. Now the line projections will themselves be curved in space, yet they will seem straight when seen from O. Ahead we will see how to investigate the shapes of these lines analytically and geometrically and how to draw them in practice. In Fig. 7 we see an example of

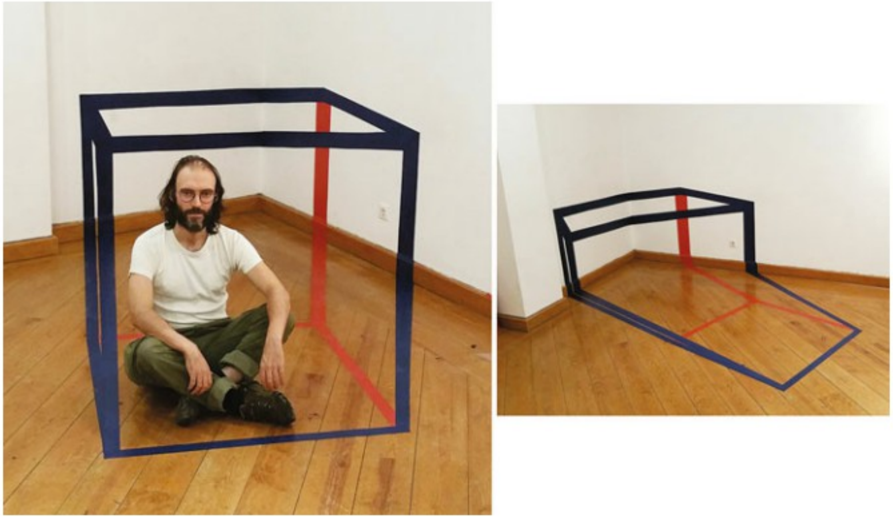

Fig. 6 Anamorphosis of a cube onto three planes. Locally these are just plane perspectives but globally, some lines in such multi-plane configurations may present up to two vanishing points. Temporary installation in Óbidos, Portugal, joint work by the author and Maria Bianchi Aguiar

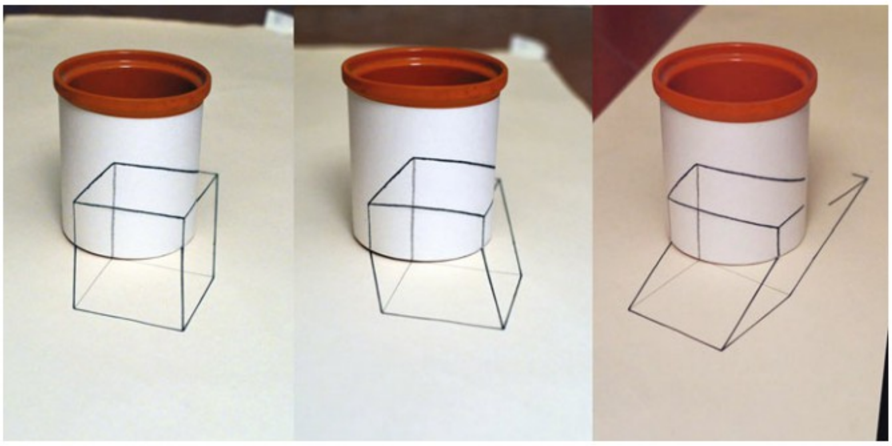

Fig. 7 Anamorphosis of a cube onto a union of a plane and a cylinder. (Drawing by the author)

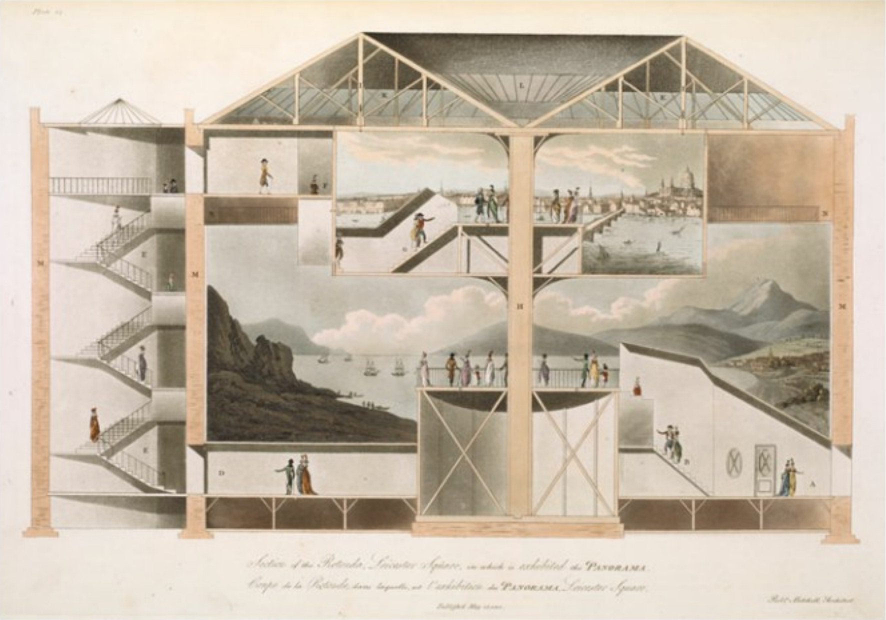
an anamorph onto a composite surface made up of a cylinder and a plane. We notice that the lines of the anamorph don't even have to be connected.

Further, if we wish to obtain an immersive anamorphosis, that is, an anamorphosis that surrounds the viewer, we may place *O* inside a surface, for example, in the axis of a cylinder. Then the observer may look in all directions around the vertical axis and have the illusion of being surrounded by an immersive landscape. This is the principle behind the famous panoramas of the nineteenth century, illusions so striking at the time that the word em *panorama*, originally created to signify these illusory pictures, became in time associated to the physical landscape itself. In fact the word seems to appear in print for the first time in 1791 in an advertisement promoting Robert Barker's large displays of immersive, cylindrical anamorphoses at his "panorama building," (Fig. 8) erected on Leicester square, in London (Huhtamo 2013). From the platform at the center of this building, large paintings were displayed, to immerse the spectators in foreign landscapes or representations of famous battles, such as that of Waterloo, that was pictured in the Leicester Square panorama in 1816, having been fought less than a year before. Such panoramas became widespread worldwide in the nineteenth century, and even today a panorama of the battle of Waterloo is on display at the museum erected on the field of battle, and a few depictions of civil war battles survive in the United States. It is important to note here that Barker's panoramas, striking as they were, were not strict cylindrical anamorphoses. According to Kemp (1990, p. 214) they were made by joining a series of adjacent linear drawings, with some care to soften the transitions. These are perfectly adequate as long as there are no exceedingly long architectural lines involved, which is not a problem for wide vistas where each building will occupy a small angle of view and the general landscape is one of natural forms that the eye cannot judge for exactness.

Of course, the most isotropic anamorphic view would be a spherical one, and this too has been exploited in various ways. The visual illusions of the planetarium



Section of the Rotunda, Leicester Square, in which is exhibited the PANORAMA
Coupe de la Rotunde, dans laquelle, est l'exhibition du PANORAMA Leicester Square.

or of a modern, digital full dome allow for hemispherical anamorphoses, and no more than architectural convenience and economy stops us from applying the same principle to build a full sphere, to provide a truly immersive anamorphosis, completely surrounding the observer. In fact, fully spherical immersive illusions were tried architecturally. Charles Delangard proposed the concept of the *Georama* to the Geographical Society of Paris in 1822, and the first exemplar was erected in that city in 1826 (Figs. 9) – a sphere of approximately 12 meters in diameter, whose interior was painted with a representation of the Earths geography, seen from within (Belisle 2015; Oettermann and Schneider 1997). Delangard's Georama, like the panorama before it, became widespread and was implemented elsewhere , the most famous example being James Wyld's Great Globe in Leicester Square. The concept was also used to represent the celestial globe. There was one such globe in the Paris exhibition of 1900 that visitors could enter to see the firmament rotate around their station point. Some Georamas paired these geographic and astronomical views, as in the case of Wyld's Great Globe, whose interior displayed the Earth's surface while having the celestial firmament painted on the exterior dome. This was to be expected, since the map making tradition has a long-standing pairing between the charts of the stars and those of the Earth (see, for instance, the ▸ Chap. 19, "Spherical Perspective" in the present volume). Again, like the

EUROPE
ASIE
OCEAN ATLANTIQUE
MER DES INDES
Das Georama auf den Elisäischen Feldern zu Paris.

panoramas before them, the Georamas were not strict anamorphoses, having often deformations to facilitate particular readings, or putting the viewers in observational platforms not necessarily located at the center of the sphere (Belisle 2015). Still, they demonstrate the architectural possibilities of a completely immersive anamorphosis. Of course in the present day, a type of immersive anamorphoses is daily achievable through digital means. Fist-person games or simulations work by creating a flat anamorphosis dynamically onto the screens of the 3D glasses, centered on a moving observational point O, the screen serving as a moving window into the virtual world that will be in anamorphosis if the distance to the screen is adequate. Of course, since the distances are small, the principle of radial occlusion will not really be verified, so the illusion is not really immersive. Better results are obtained with the help of 3D helmets, where lenses create a sense of size and distance and illusion pairs are created for each eye at a moving pair of observational points O_L and O_R. This is but another step in the evolution of moving panoramas.

Some Considerations on Anamorphosis

The Point of Observation

It is important to stress that anamorphic equivalence is always related to an observer O. It makes no sense to ask if something is an anamorphosis without context. Everything is an anamorphosis of some other things relative to some point. It only makes sense to ask if object X is an anamorphosis of object Y with relation to O. This is what is implied when in the usual dictionary definition of anamorphosis, we say that the object "looks right" from a certain point. But this vagueness causes all sorts of misconceptions. The issue is not that it looks "correct" (meaning recognizable as "something") but that it looks like something that has be prescribed in advance. The question is how much can be prescribed or, to put it more rigorously, how much does a prescribed anamorph determine the set of all possible anamorphs of it with relation to given viewpoints.

Multiple Points of Observation

We can prescribe the different appearances for the same object from two different points within some rather forgiving bounds. When one prescribes that X be anamorphic to Y_1 from O_1, this determines a cone of rays from O_1 to X, but does not determine X itself. Each point of X on that cone may still be freely moved along its ray. That degree of freedom allows one to specify another object (under constraints) Y_2 such that X will be anamorphic to Y_2 from another point O_2.

As beautifully demonstrated by the works of Kokichi Sugihara, the degrees of freedom of the conic projection allow quite some leeway. Sugihara wonderfully explored such double anamorphic constructions with ambiguous 3D objects that from one point may look cylindrical and from another box-like or star-shaped (Sugihara 2015a, b, 2016), and not only the geometry of such ambiguous cylinders but even their topology may be changed, when, for instance, a pair of cylinders may appear to be intersecting or not according to the choice of observation point (Sugihara 2018).

"Impossible" Objects

It may seem paradoxical, but a real object may be anamorphic to an *impossible* one, that is, it may look like an object that makes sense locally, but not globally, like Penrose's triangle (Draper 1978; Penrose and Penrose 1958), M. C. Escher's Belvedere cube (Escher 1958, 1972), or Huffman's various specimens of wireframe constructions (Huffman 1968, 1971). This is achieved by visually mimicking incompatible self-connections and other impossible features through hidden discontinuities or deformations of a real object (see Sánchez-Reyes and Chacón (2020) for a modern software-based treatment of this problem). Of course the apparent impossibility comes not so much from what we see as from what we assume, that is, not from the geometric constraints determined by the appearance of the object but from the psychological assumptions of how our brain makes sense of the limited visual information supplied by the view from a single point (Kulpa 1983; Sugihara 1982, 2000). Human visual processing relies on shortcuts and rules-of-thumb meant to work on the generic rather than the general case. For a simple example of an apparently impossible object, note that the rightmost object of Fig. 3 might be classified as one of Huffman's impossible polyhedra, but only if we assume that the implied faces are planar. The reader will verify that there is in fact no polyhedron whose faces are delimited by the edges shown. However, if we triangulate across the vertices, as in Fig. 10, then get a perfectly consistent polyhedron, only the number

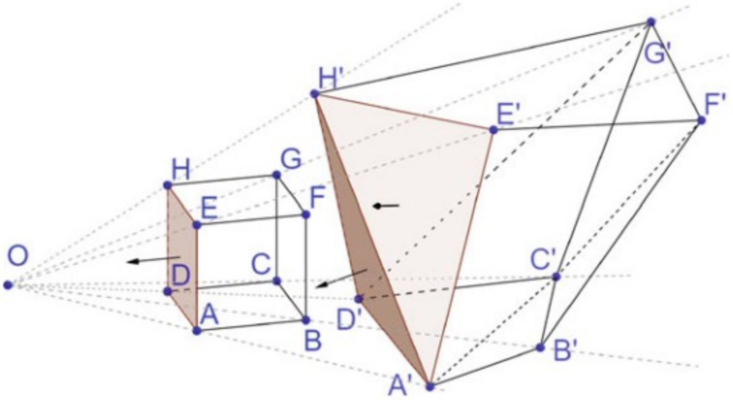

Fig. 10 The rightmost object of Fig. 3 can be made into a consistent polyhedron by a choice of triangulation. Corresponding triangulations would result in the anamorphically equivalent edges in the cube and the right side object, but the faces themselves would be shaded differently under a light source. In a Lambert model of illumination, the value (gray level) of the two faces $A'H'D'$ and $A'E'H'$ will vary with the inner product of the faces normals to the incidence direction of the light. This could be compensated by painting the faces with different shades of gray so as to make them seem uniform when seen from O, achieving "color anamorphosis"

of planar faces is greater than the six originally assumed. Due to the ambiguity of radial occlusion, it is no wonder that even the simplest of wireframe objects, like Necker's cube (Necker 1832), should make our brains oscillate between two readings undecisively; the wonder is that we may make any reading at all with confidence from among the infinite anamorphs that are mathematically consistent.

On Color

It is important to note that anamorphosis in our present sense refers only to mere equivalence of contours or outlines. This limited principle is necessary but not sufficient for proper anamorphoses in the usual sense, as most optical illusions going by that name – be it Pozzo's dome at St. Ignazio's or Holbein's painting of the ambassadors – require also mimesis of color to be effective. This aspect is usually unmentioned in the literature, as we assume that color will take care of itself once we use conical anamorphoses to define the contours of the objects we wish to represent in painting. This is true with careful diffuse lighting, but in a general setup color will certainly *not* take care of itself. Color anamorphoses (so to speak) are a whole new layer of complexity for mimesis that we will not treat it here with any detail, but would like to mention briefly. Color anamorphosis would require consideration of models of illumination, material properties, and, of course, consideration of color itself as a perceptual theory with its own principles. Color has its own mimetic principle, its own "anamorphosis" of sorts. The space of visual color stimuli may be identified with the set of all power distributions in the visible spectrum, which, as a vector space of functions, is of very high dimension (we could say infinite dimensional if we identify it with the set of all functions on the interval [0, 1], but there are restrictions so the space is probably better seen as very high – but finite – dimensional). This space is reduced by our perception to only a convex set in a space of three dimensions, identifiable (for instance) as something like value, saturation, and hue. This reduction in dimension is analogous to the way anamorphosis reduces the three dimensions of the real space to a two-dimensional perceptual space (though the reduction is much more drastic in color).

But all of this is beyond our scope. To consider the simplest of cases, take again the two anamorphic wireframe objects of Fig. 10. The situation is simple enough if we just consider the wireframe objects with ideal segments joining the points. If we consider a real object, then already we have some complications, as those lines will need some thickness to be visibly represented. We can naively conceive of them optically as painted matte black cylinders (with no specular reflections), thin, and featureless. If we now consider the polyhedron defined by a triangulation then both objects would just look like a black mass defined by their identical outlines. Let us now go a bit further and suppose the objects are made of triangles painted in some neutral gray. Suppose also they reflect light equally in every direction and with an intensity proportional to the inner product of the surface normal to the incident light ray direction. This is a simple Lambert model of illumination, adequate for rendering matte surfaces (Foley et al 1996).

Within such a model, the gray level of each face will be determined by its angle to the light source. Hence, mimicry of color will require us to paint each face in such a way as to compensate the difference in their normal vectors. For instance, in Fig. 10, face $ADHE$ of the cube is anamorphic to the union of the two triangular faces $A'D'H'$ and $A'H'E'$. Notice the difference in the normal vectors on the faces. If the faces were to be painted equally, and assuming light comes from front and high, the face that points downward would look darker than the cube's face, and the face that points upward would look brighter. So to compensate for this and achieve apparent equality of value ("color anamorphosis"), we would have to paint the upward facing triangle darker and the downward one lighter than the square face.

In Fig. 11 we see a simple hand-drawn example of color anamorphosis: a plane anamorph of a cube, side by side with a real cube of the same apparent dimensions. The physical cube is painted uniformly with white paint. The plane anamorph's normal vector coincides with the normal vector of the top face, so these corresponding faces can be painted with the same value. But the other "faces" of the plane anamorph had to be painted darker in order to match the appearance of the faces of the 3D cube that are turned at a larger angle from the incident light.

The rules of this color anamorphosis game depend on many factors and will vary with the type of light, its form, its location, the type of reflection we get from the materials, and so on. In most cases it will be impossible to match apparent color by simply changing the local color, as the ranges will be too large. Lambert reflection and a uniform light is just about the easiest situation for matching. Diffuse lighting helps, as cast shadows will create additional complications (or artistic opportunities).

If we were to attempt a formal treatment of color anamorphosis, we would start with something akin to the following definition: Two objects X_1 and X_2 are color-

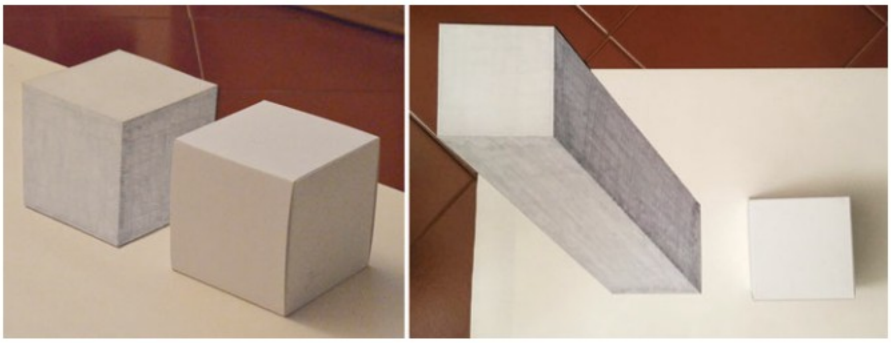

Fig. 11 A 3D cube and a plane anamorph

anamorphic relative to point O and light sources L_1, L_2 if X_1 seen from O under light source L_1 is visually indistinguishable from X_2 seen from point O under light source $L2$. Hence we have a dependence on the light sources quite analogous to the dependence on O in conical anamorphosis.

Such a concept allows us to speak, for instance, of a ball under an incandescent bulb being color-anamorphic to a disc under a halogen lamp, the disc being painted so as to simulate the color gradations of the ball. We will not, however, attempt here any formal development of this, but the concept is intuitively what any painter does when he paints a daylight scene to be seen under gallery lights and, more analytically, what a restoration expert has in mind when making sure that he uses not just the right color but the right pigment to restore a patch of color, so as to ensure color matching under change of light source spectrum.

We can sum up the observations of this section by saying (unpardonably boldy and omitting many qualifiers) anamorphosis is what makes drawing possible; color anamorphosis is what makes painting possible.

Binocular Anamorphoses

The abstract eye of anamorphosis is cyclopic, yet we can still easily work with binocular vision. Anamorphosis acts before the light hits the eye – it is a manipulation not so much of the eye, but of the light that reaches it. For this reason, arguments too concerned with what happens at the retina or the brain are missing the point. Whatever the complex workings of the visual system, feeding it equivalent inputs will result in equal perceptions. Hence, we don't need to understand how the brain combines binocular images; we just need to fool each eye separately, by figuring out what light packets it would be receiving from its position if the imaginary object was present. Then the brain will take care of the mixing. The problem is reduced to the technical one of showing each eye its own anamorph, built in the standard way, tailored to its specific position. The biggest problem is a suppressive one: to make sure that each eye *only* gets its corresponding picture. This can be achieved simply (but with limitations) by using a physical wall (septum) to

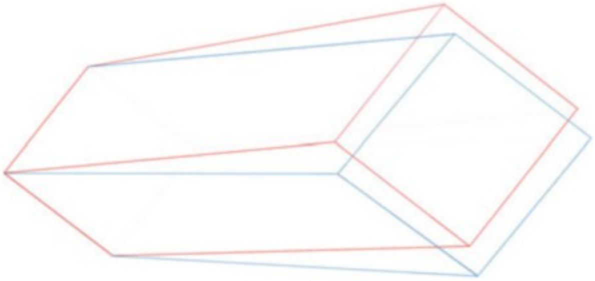

Fig. 12 Anamorphic anaglyph of a cube, to be viewed with red-blue 3D glasses

constrain each eye to its own compartment. This simple method, used by Dutour (1760) in the eighteenth century, is still an element used in contemporary solutions. Wheatstone (1838, 1852) achieved the separation through his mirror stereoscope in 1832 (Wade and Ono 2012). From that idea comes a long line of evolutions and simplifications, through the Holmes stereoscope in the 1860s and then the view-master in the late 1930s. These are not very different from modern VR viewers like Google Cardboard, except that today the illusions can move. All of these use in some measure either diffraction or reflection, so strictly speaking they are not working according to conical anamorphosis (although the distinction is superficial). A more strictly conical device is the anaglyph. Perspective anaglyphs were first published by Vuibert (1912) in a book with drawings by Henri Richard (Cabezos Bernal 2015). We are all familiar with the red-blue or red-cyan 3D anaglyphic glasses. The filter over each eye eliminates the opposite image, therefore separating the two anamorphoses, resulting in pictures that pop out of their frames. Doing the same procedure with an “oblique anamorphosis” instead of a “perspective” creates a far more startling result (Araújo 2017a; Cabezos Bernal 2015). For instance, Fig. 12, seen from the correct point, at a sharp angle to the page, will look like a cube popping out of the page, and young students get surprisingly amazed – in spite or perhaps because of their familiarity of computer graphics – to see what resembles a wireframe cube floating midair and wobbling as they move their head slightly. Moving the head in a vertical over the observation point gives the illusion of a bar chart animation, with a parallelepiped growing before one’s eyes. We will not remark further upon binocular vision, as it can be handled by this adaptation of monocular considerations. The reader can refer to Cabezos Bernal (2015) for more on this matter.

Anamorphosis Formally Reformed

Mathematical Preliminaries

We now proceed to the mathematical development of what we loosely described above.

We need some geometric background. We will model our three-dimensional world abstractly as an Euclidean three-dimensional space, denoted $\mathscr{E}$. You can think of $\mathscr{E}$ as $\mathbb{R}^3$. A point O of $\mathscr{E}$ will represent the location of the observer's eye. Let $\mathscr{E}_O = \mathscr{E}_O \setminus \{O\}$ denote the three-dimensional space except for point O. We will want to model objects. We define an *object* to mean a closed set of $\mathscr{E}_O$ and a *scene* to mean a finite union of objects. The term "closed" is a topological term. We recall some terminology briefly for the mathematician and then explain it at length. We beg the artist for bravery at this point. Hold the line for these will all be made more concrete later.

Definition 1. Let S be a subset of a topological space. We say that P is a *limit point* of S if every neighborhood of P contains a point Q of S other than P. The *closure* of S is the union of S with its limit points and is denoted by $cl(S)$. S is *closed* if $S = cl(S)$. The *residue* of S is the closure of S minus the set itself, denoted $Res(S) = cl(S) \setminus S$.

Intuitively: a limit point of a set is a point that can be approached indefinitely close without leaving the set. Closed sets are those that contain all their limit points. A point, a segment, a line, a plane, a circle, and a sphere are all closed sets. For a counterexample, take the set $S = \overline{AB} \setminus \{A, B\}$, a segment minus its endpoints. Both A and B can still be approached indefinitely close without leaving S, so they are limit points of S. But they are not in S; hence S is not closed.

We will find ahead sets that naturally will be missing limit points. For various reasons we do not like that, so we will add them in. Mathematicians have a fancy name for adding in those missing points – they call it *taking the closure*. The *closure* of S is the smallest closed set that contains it. So, going back to our example of the segment without endpoints S, the closure of S, denoted by $cl(S)$, is the full segment $\overline{AB}$, which contains all its limit points and is therefore a closed set. Finally, we call residue of S to the set of limit points that we have to add to a set S in order to close it. So, $Res(S) = cl(S) \setminus S$. In our example, the residue was the set of the missing endpoints of the segment, $\{A, B\}$.

We cannot really speak about closed sets, compacts, and so on, without having a topology. A topology on a set is a specification of which subsets are open (open sets are the complement of closed sets). In what follows we will be interested in studying the set of visual rays from the eye O. We will see how to put a topology on the set of these rays. First let us define what a ray is.

We say that a set S is *convex* if for any two points A and B of S, the segment $\overline{AB}$ is in S.

A point O on a line l divides $l \setminus \{O\}$ into two disjoint convex sets l_1, l_2. We say that l_1 and l_2 are each a ray over the line l, with origin (or vertex) in O. We interpret rays as directed half-lines going from O to infinity (in the case of l_1 and l_2, going in opposite directions from O). Note that rays are missing the point of origin O. Vectorially, if $\overrightarrow{v}$ is a vector, a ray is the set $O + a\overrightarrow{v}, a \in \mathbb{R}^+$. For $P \neq O$, $\overrightarrow{OP}$ denotes the ray with origin in O that passes through P. It is the same notation as for a vector, but we will allow context to disambiguate. Note that the usual definition of ray includes the origin point; ours doesn't because we don't want different rays to intersect each other. So a ray with origin in O is contained in $\mathscr{E}_O$.

Let $\mathscr{R}_O$ denote the set of all rays from O. Let S^2_O denote the unit sphere with center O. There is a canonical isomorphism between the set of rays and the sphere: we identify each ray with the point where it intersects the sphere. This bijection endows the set of rays with the topology of the sphere, giving it a notion of closed sets, limit points, and so on. We will therefore freely refer to rays or points on the sphere interchangeably.

Anamorphosis as a Mathematical Object

The principle of radial occlusion defined above expresses a notion of equivalence between points with regard to a reference point O, the eye of the observer. When the principle is valid, two points that are geometrically aligned along a ray from the eye are equivalent as far as visual perception goes. It follows that two objects should be equivalent if all their points are aligned or, equivalently, if they generate the same set of visual rays from O. We express this set as follows:

Definition 2. We say that the visual cone of an object Σ relative to O is the set of rays subtended by Σ with origin in O, which we denote $C_O(\Sigma)$. Hence $C_O(\Sigma) = \{\overrightarrow{OP}, P \in \Sigma\}$.

Now, from radial occlusion, it is natural to define that two sets "look the same" if they have the same visual cone. Later we will show that a somewhat looser equivalence is more interesting, which we will call *anamorphosis*. For now, for the purpose of motivation, we will concentrate on the stricter notion of conical equivalence.

Definition 3. We say that two objects Σ_1 and Σ_2 are *conically equivalent* relative to O if they have the same visual cone relative to O. We write this as $\Sigma_1 \overset{O}{=} \Sigma_2$.

It is clear that conical equivalence is indeed an equivalence relation between 3D objects, meaning a relation that is reflexive, symmetric, and transitive. We are interested in studying the classes of equivalence by this relation and how to construct the members of these classes.

Proposition 1. *Let P, Q be points of $\mathscr{E}_O$. $P \overset{O}{=} Q$ if and only if P and Q are on the same ray from O.*

Proposition 1 shows that the principle of radial equivalence for pairs of points is a particular case of Definition 3. This trivially follows from the fact that the cone of a point P is the ray $\overrightarrow{P}$.

Proposition 2. *if P, Q, P', Q' are points of $\mathscr{E}_O$ such that $P' \circeq P$ and $Q' \circeq Q$ then $\overline{PQ} \circeq \overline{P'Q'}$.*

Proof. By Proposition 1, triangles POQ and $P'OQ'$ define the same angle with vertex at O. Each ray inside the angle intersects sides $\overline{PQ}$ and $\overline{P'Q'}$ at a single point, which establishes a bijection between both the sides and the rays of the cone.

We can state this as the cone of rays of a segment AB is the angle $\angle AOB$.

Remark 2. The proof does not work for lines as the triangles do not capture the full cone of the line. In fact the proposition is false for lines.

Corollary 1. *If γ is a continuous curve with parametrization $g : [0, 1] \mapsto \angle AOB$ with $g(0) \circeq A$ and $g(0) \circeq B$ then $\gamma \circeq \overline{AB}$.*

Remark 3. This is the case of curve $A''B''$ in Fig. 3.

Proposition 3. *if ΔPQR and $\Delta P'Q'R'$ are triangles with vertices in $\mathscr{E}_O$, such that $P' \circeq P$, $Q' \circeq Q$, and $R' \circeq R$ then $\Delta PQR \circeq \Delta P'Q'R'$.*

Proof. For the sides of the triangles, the result follows from Proposition 2. Let I be an interior point of one of the triangles, say triangle ΔPQR. Then the ray from A through I finds a point J on $\overline{QR}$. Since $\overline{QR} \circeq \overline{Q'R'}$, there is a point J' on $\overline{Q'R'}$ such that $J' \circeq J$.

As in the previous proposition, this does not generalize to the full plane defined by a triangle.

Note that segments are convex combinations of two points and triangles are convex combinations of three. The result is valid for general convex combinations.

As a corollary of the propositions above, if Σ is a graph composed of vertices and segments (say, the cube of Fig. 3), we can obtain slide every vertex freely along its ray from O, and the graph obtained will have the same cone as the original graph. The same is true of the polyhedra obtained from the graph by triangulation (there are several choices of flat faces compatible with a graph). Moving the vertices will create a new polyhedron, equivalent to the first.

Corollary 2. *If S is a continuous surface with boundary on a continuous closed curve anamorphic to triangle $\triangle ABC$ and S is contained in the solid angle defined by $\triangle ABC$, then $S \circeq \triangle ABC$.*

Remark 4. When dealing in computer graphics, the propositions above can be used to obtain anamorphs very easily from a reference object. For instance, it is very easy, using the Geogebra software (Hohenwarter 2002; Hohenwarter et al 2013), to slide points on their rays from O to obtain anamorphic polyhedra as in Fig. 3 and even to deform these sides into simple curves. Sánchez-Reyes and Chacón (2016) do something analogous to obtain anamorphic deformations of a reference object using Bézier triangles and NURBS.

As we have seen, Proposition 2 does not generalize to full lines. A line l on a plane H divides the plane into a disjoint union of convex sets $\pi = \pi_1 \cup l \cup \pi_2$, where π_1 and π_2 the half-planes on either side of l. The cone of l is characterized by the following proposition.

Proposition 4. *Let l be a line in $\mathscr{E}_O$. O and l define a plane $\pi_O(l)$. Let l_O be the line parallel to l passing through O. l_O divides $\pi_O(l)$ in two disjoint half-planes. Then $C_O(l)$ is the set of rays through the half-plane of $\pi_O(l)$ that contains l.*

We remark that although l is closed in $\mathscr{E}$, its cone is not closed in $\mathscr{R}_O$. This will be important ahead. There are two rays missing to make the cone closed, these being the two diametrically opposite rays whose union is l_O. These mark the limits of the cone of l but do not belong to it. Intuitively, the line of sight approaches parallelism to l more and more as it follows it to infinity, but never reaches it. The reader probably recognizes line l_O as the line that in classical perspective defines the vanishing point of l by intersection with the plane of projection. Here we have no plane of projection, but this line is still important:

Proposition 5. *Let l and l' be lines in $\mathscr{E}_O$. Then $l \overset{O}{=} l'$ if and only if l and l' define the same plane with O and $l_O = l'_O$.*

In linear perspective line l_O is used to construct the projection of l. The construction is made by joining the intersection of l and l_O with the projection plane. This is a fundamental theorem of linear perspective (Andersen 1992, page 12), but it cannot even be stated for anamorphoses since we have no projection plane. Further we will see ahead that a general projection surface will not intersect l anyway. But we have the following analogous construction that uses l_O and l to obtain an arc of circle that is related to l in a canonical way.

Proposition 6. *There is a single circle $\mathscr{C}$ of center O that is tangent to l. Let $\mathscr{C}_O(l)$ be the intersection of $\mathscr{C}$ with the half-plane of $\pi_O(l)$ on the same side of l_O as l. Then $\mathscr{C}_O(l)$ and l define the same cone of rays from O.*

Proof. The perpendicular to l from O intersects l at the point I which is minimizes the distance from l. Hence the circle through I of center O will be tangent to l (Fig. 13). This circle intersect l_O at two points V and $V^\star$ diametrically opposite from O. Consider the half-circle obtained from $VIV^\star$ by excluding its endpoints V and $V^\star$. There is a one-to-one correspondence between points on this arc and points on the cone $C_O(l)$, obtained by intersection of the arc with $\overrightarrow{OP}$, for each P in l.

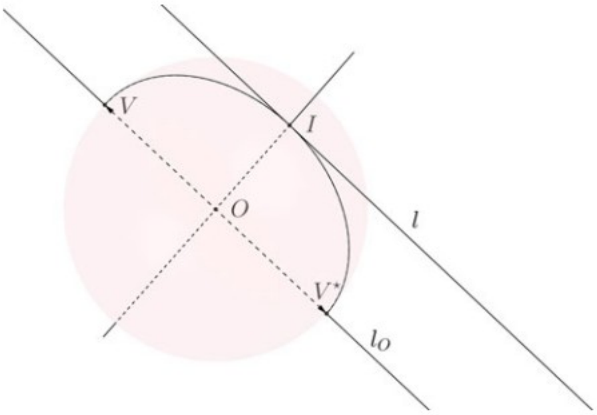

Fig. 13 The canonical meridian representative of a line's visual cone

This is nice result at first sight. There is a canonical arc of circle that has the same cone as the line. But there is a problem. The reader may have noticed that we didn't say that these were equivalent objects. That is false both for the arc with the endpoints and for the arc without them. The arc without the endpoints has the same cone of rays as the line, but it is *not* a closed set; hence it is not what we defined as an object. The arc with the endpoints is closed, but it is not conically equivalent to the line, as the rays corresponding to the endpoints are not a part of the line's cone.

We could solve this in several ways, for instance, by changing the definition of object, but the most satisfying seems to be to change our notion of equivalence. Hence we define anamorphic equivalence by slightly relaxing conical equivalence:

Definition 4. We say that two objects Σ_1 and Σ_2 are *equivalent by conical anamorphosis* relative to O; their visual cones are equal up to topological closure, that is, if $cl(C_O(\Sigma_1)) = cl(C_O(\Sigma_2))$. We write this as $\Sigma_1 \overset{\circ}{\sim} \Sigma_2$.

Some nomenclature, "equivalent by conical anamorphosis relative to O," is a mouthful, so for short we'll just say that two objects are *anamorphic*, or that they are *anamorphs* (of each other), or that one is an anamorphosis of the other. This definition fulfills well both the common usage of these expressions and our technical needs. These concessions to brevity and custom should not make us forget that any anamorphic equivalence is always relative to a specific observation point, so each of these phrases should be mentally ended with "relative to O."

Proposition 7. *If Σ_1, Σ_2 are objects such that $\Sigma_1 \overset{\circ}{=} \Sigma_2$, then $\Sigma_1 \overset{\circ}{\sim} \Sigma_2$.*

Obviously, conic equivalence implies anamorphic equivalence. Hence the results we obtained for conical equivalence above are still valid for anamorphosis.

Now let us reconsider the canonical semicircle we defined above. If we add to it its endpoints, by taking its closure, it becomes an anamorph to the line l. These two points are very important. They are the intersection of l_O with the sphere; hence they are the same for every line parallel to l. Hence they will be meeting points for all lines parallel to l. The two rays of l_O generalize the notion of vanishing points from classical perspective.

We can generalize the construction we did for the line, so as to get a canonical anamorph of any object, as well as a vanishing set:

Definition 5. We say that the *anamorphosis* of an object Σ relative to O is $\Lambda_O(\Sigma) = cl(C_O(\Sigma))$. We identify it with its projection onto the unit sphere, $cl(C_O(\Sigma)) \cap S^2_O$, when context is clear. The latter we also call the *canonical anamorph* of Σ.

It follows trivially from Definition 4 that an object is anamorphic to its anamorphosis thus defined. Its spherical anamorph is called canonical because it is the most natural of its 2D anamorphs, arising from the identification of the space of rays with the sphere.

Definition 6. We say that $\mathscr{V}_O(\Sigma) = Res(C_O(\Sigma)) = cl(C_O(\Sigma)) \setminus C_O(\Sigma)$ is the *vanishing set* of object Σ relative to O. We call *vanishing* points to the points of the vanishing set. We identify the rays of the vanishing set with the corresponding points on the unit sphere S^2_O.

The vanishing set is the residue of the visual cone of the object, that is, the points you must add to make it closed. This definition has the advantage that it works for any object and, when restricted to lines and planes, reduces to what you would expect from the classical definition, as we will see.

Remark 5. When teaching the concept of vanishing points to artists, it is hard to deal with topological concepts explicitly, especially on a short timeframe, such as a workshop. Then it is more practical to generalize the tradition of perspective started by Taylor and simply define vanishing points of lines as the points associated with the two opposite rays that make up l_O and then notice that these are at the end of the canonical semicircle; then it follows from the definition that parallel lines have the same vanishing points and that these are meeting points for those lines.

Proposition 8. *The canonical anamorph of a line $l \subset \mathscr{E}_O$ is a meridian of the unit sphere. The vanishing set of l is a pair of antipodal points located at the ends of the meridian, where l_O, the parallel to l through O, intersects the sphere.*

This proposition turns perspective into spherical geometry, so we can apply the tools of that discipline. See Catalano (1986) and Araújo (2018c). In particular we will be talking a lot about antipodal points, so let us recall that two points are called *antipodal* if they are diametrically opposite on a sphere. Given a point P on the sphere we denote its antipodal point by $P^\star$. The notion extends trivially to the corresponding rays through the center of the sphere.

This proposition has the obvious corollary that not only do parallel lines have the same vanishing points, but these are actual meeting points of their anamorphosis. This is a very concrete alternative to the abstract notion of parallel lines meeting at infinity – their spherical anamorphs actually meet on the sphere.

Corollary 3. *If l and l' are parallel lines, their canonical anamorphs intersect at their vanishing points.*

This is a beautifully unifying view of vanishing points, unlike the classical perspective view where a line has sometimes one and sometimes no vanishing points, or even the (hemi)spherical perspective of Barre and Flocon (Barre and Flocon 1968) where lines have either one or two vanishing points. This search for constancy in the number of vanishing points can be compared to the insistence of mathematicians in redefining numbers to ensure that an n-degree equation always has exactly n roots. The projective plane view of perspective answers the same desire for symmetry, but there we have always a single vanishing point. Our present notion of anamorphosis (and later of perspective) splits that point in two as we want no preferential axis and wish to capture the whole visual environment.

Now we consider the matter of construction of these anamorphs. Since the canonical anamorph of a line is an arc of circle, we might expect it to require three points for its construction. But since it is a meridian, and the two vanishing points are antipodal, two points are enough.

Recall that two points on a sphere define a plane through its center. The intersection of that plane with the sphere is a circle with the same radius as the sphere and to this is called a *great circle* of the sphere, or a *geodesic* . A meridian is a connected half of a great circle, so it can be specified by choosing two antipodal points and then picking one of the two possible halves of the geodesic. This picking of a meridian can be done by choosing a point in its interior. But since the two endpoints are mutually antipodal (hence knowing one is enough), all we really need to know to determine a meridian is two points of it, as long as one of them is specified to be an endpoint. For the same reason, only two points are needed to determine the image of a line, as long as one of them is specified to be a vanishing point.

Proposition 9. *The anamorphosis of a line l of $\mathscr{E}_O$ is determined by one vanishing point and by the projection on the sphere of one point of l.*

Proof. The vanishing point V and the measured point P' projected from l onto the sphere determine a plane through O, hence a geodesic. On this geodesic, the line image will be the meridian $VP'V^{\star}$.

Note that if the line l crosses O then its image is just a set of two points, these being located at the place of the vanishing points, which in this case are actual points of the projection. It is the line itself that vanishes. Taylor remarked on much the same situation in classical perspective, and that is one of the justifications for the terms "vanishing point," as the line "vanishes" into it in this degenerate case (Andersen, 2007, page 175). There is a technical difference in our definitions here, since by Definition 6, these two points are not in our vanishing set at all, while in classical perspective the vanishing point exists and coincides with the single projected point.

Example 1. In Figs. 14 and 15 we see two examples of pairs of spatial lines l and j relating to their vanishing points and to their spherical anamorphs.

In Fig. 14 we see two parallel lines. They have therefore the same translation to the origin, so $l_O \equiv j_O$; hence they have the same pair of antipodal vanishing points, V and $V^{\star}$. Their canonical anamorphs on the sphere are meridians ending at these vanishing points. Hence the vanishing points are actual meeting points for the canonical anamorphs.

As for construction of these spherical anamorphs, two projected points P and Q from l and j, respectively, define each meridian, as in Proposition 9. These points may be measured anywhere, but one way would be at the intersection of the meridian with the geodesic plane orthogonal to l_O.

In Fig. 15 we see two perpendicular lines. Now lines l_O and j_O are themselves orthogonal, crossing at O, and we get two pairs of vanishing points. The meridians are obtained from these by measuring a single additional point, the common point where the two lines cross. Hence we see that only vanishing point V_1 and point P need be measured to obtain the whole construction.

In Fig. 16 we see the spherical anamorph of a cube. The cube defines a set of six distinct vanishing points, which are meeting points for the lines that prolong the edges of the cube.

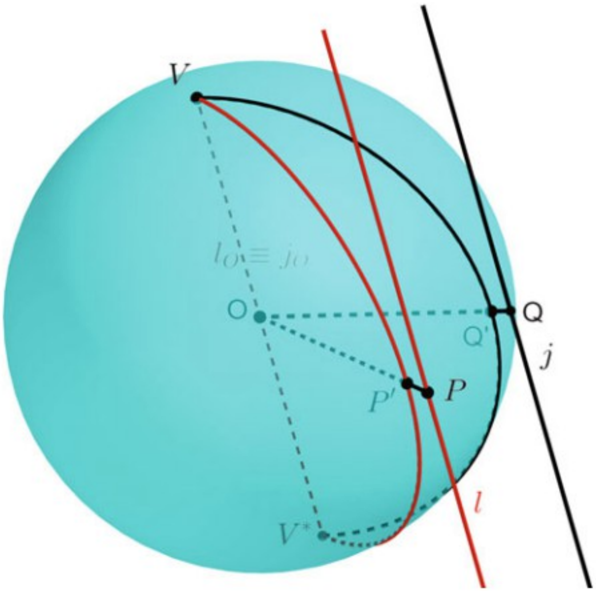

Fig. 14 Anamorphosis onto the sphere of two parallel lines. The lines project as meridians that meet at two common vanishing points V and $V^{\star}$, antipodal to each other

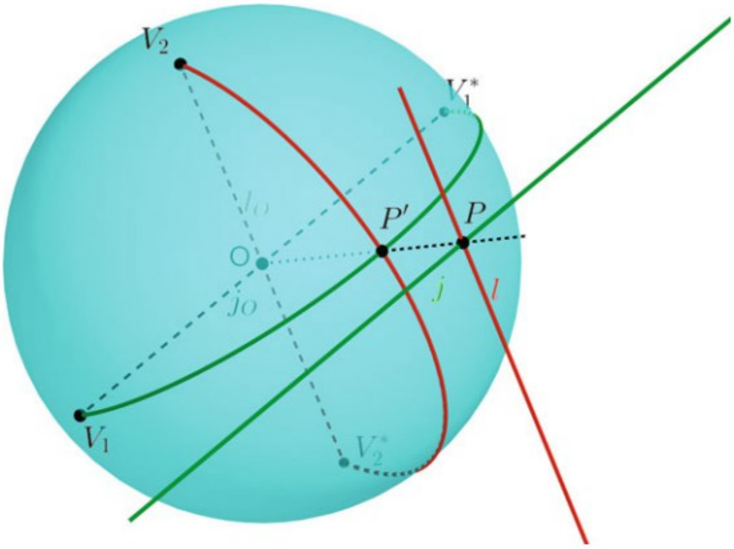

Fig. 15 Two lines l and j intersecting at a right angle. Their canonical anamorphs on the sphere go to pairs of vanishing points distributed at a regular separation of 90 degrees along the geodesic defined by the orthogonal lines l_O and j_O

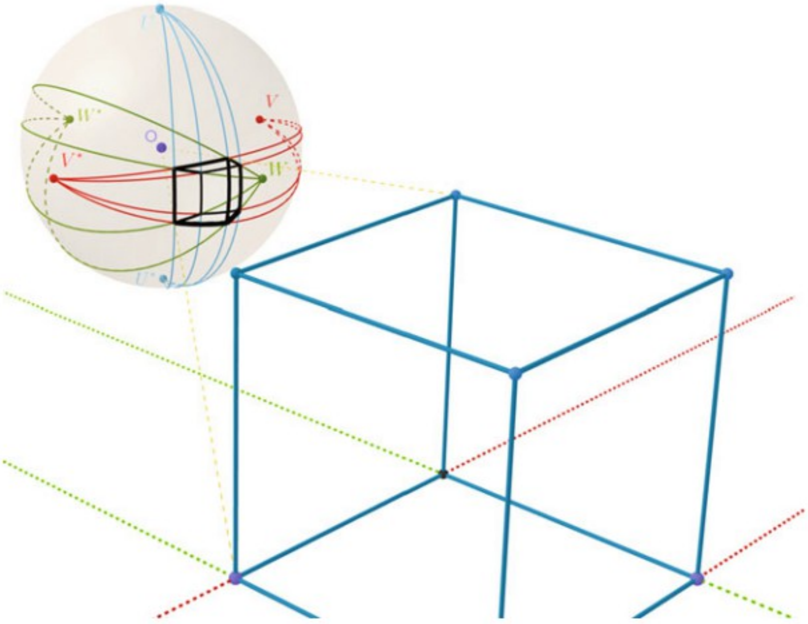

Fig. 16 Anamorph of a cube on a sphere. The cube defines a set of six distinct vanishing points, two for each set of parallel edges

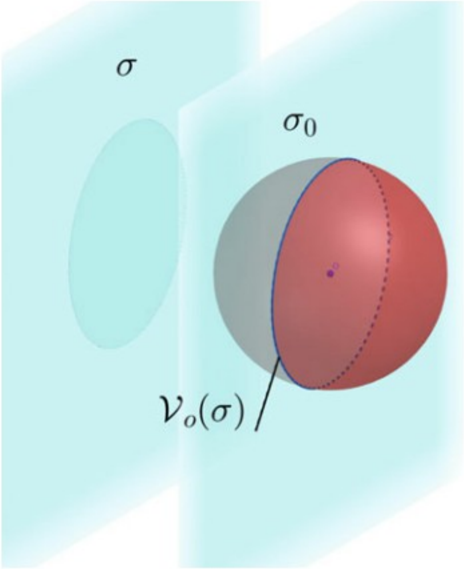

Fig. 17 A plane σ and its vanishing set $\mathcal{V}_O(\sigma)$ on the unit sphere

Proposition 10. *Let σ be a plane not containing O. Let σ_O be the plane parallel to σ through O. Then σ_O defines a great circle of the sphere, which is the vanishing set of σ (Fig. 17). This great circle divides the sphere in two hemispheres. The anamorphosis of σ is the hemisphere on the side of σ_O that contains σ.*

Proof. The construction is analogous to that of the canonical circle. Take a perpendicular from O to σ, and this defines a sphere tangent to σ, half of which will be the image of the visual cone of σ. To get the anamorphosis, scale it down to unit radius.

The vanishing points of lines and planes are quite analogous to the linear perspective case, in that they are obtained by translation to the observation point followed by intersection with the projection surface. But our Definition 6 applies also to general objects that cannot be treated in this fashion, such as the following example.

Example 2. Let l be the curve $t \mapsto (t, t^2, 0)$ and let $O = (0, 1, 0)$. Then the cone of l will the great circle defined by $z = 0$, minus point $(0, 0, 1)$. But the closure of this set on the sphere is the whole of the great circle. So the vanishing set is $(0, 0, 1)$ and the anamorphosis is the great circle through $z = 0$.

Example 3. Let S be the surface $z = x^2 + y^2$ and let $O = (0, 0, 1)$. Then the cone of S will the whole sphere, minus the point $(0, 0, 1)$. But the closure of this set on the sphere is the whole of the sphere, so the vanishing set is $(0, 0, 1)$ and the anamorphosis is the sphere itself.

This is a different perspective from the more traditional notion of "following the line to infinity." Although the vanishing set is the same, we can look for the vanishing points in the anamorphic projection itself, by looking for "missing points" or, if you will, at "vanished" points. This is also a better definition when we consider sets whose limit rays cannot be obtained by simple curve parametrizations like in our second example above.

We would now like to define an anamorphosis onto an arbitrary surface and its vanishing points.

In what follows we will define surface to mean a manifold of dimension two, that is, something that locally maps to a region of a plane. These will usually be manifolds with boundary, such as a sheet of paper or a half-sphere. Most of the time they will be smooth, but we only require them to be topological manifolds. Most of the time they will be connected, but not always.

We use the canonical anamorphosis onto the sphere as the blueprint from which all others are derived as projected images, usually partial ones. The idea is simple: the anamorphosis of an object onto a surface is just the closure of the conical projection of the object onto the surface. The vanishing points on the surface will be the subset of the canonical vanishing points that happen to fall on the surface. Technically, it takes some care not to count points multiple times if the surface has a complex shape that folds over itself or has several connected components.

To avoid these problems, and because that work is centered on spherical perspectives, Araújo (2018c) defines the anamorphosis only for compact starred surfaces, which are just radial deformations of the sphere. These are quite enough for most purposes, so we start with them and then discuss possible generalizations briefly.

Definition 7. We say that a compact surface S is starred relative to O, or that it is an O-starred surface, if every ray from O touches S at most once. A compact surface is said to be locally O-starred at $P \in S$ if there is a neighborhood B of P such that every ray through B intersects $S \cap B$ at most once.

You can think of an O-starred surface as being locally defined by $f(u) = h(u)u, u \in S^2_O$ where $h : U \subset S^2_O \to \mathbb{R}^+$ on a region U of the sphere S^2_O. Intuitively, $h(u)$ represent a ratio that pushes each point of the sphere closer or further away from the center O.

We can define anamorphosis onto an O-starred surface S as follows.

Definition 8. The anamorphosis relative to O of an object Σ onto an O-starred surface S is $\Lambda_{O,S}(\Sigma) = cl(C_O(\Sigma) \cap S)$. The vanishing set of Σ on S is $\mathscr{V}_{O,S}(\Sigma) = \Lambda_{O,S}(\Sigma) \setminus (C_O(\Sigma) \cap S)$.

Since the conical projection is a continuous map onto an O-starred surface, we have the following result.

Proposition 11. *Let S be a locally starred surface at V. Then V is a meeting point for the anamorphic images of lines with vanishing point $\overrightarrow{OV} \in \mathscr{R}_O$.*

When S is a starred surface, we can express these objects very simply as intersections.

Proposition 12. *Let S be an O-starred surface. Then $\Lambda_{O,S}(\Sigma) = \Lambda_O(\Sigma) \cap S$, and $\mathscr{V}_{O,S}(\Sigma) = \mathscr{V}_{O,S}(\Sigma) \cap S$.*

That is, the anamorphosis (resp. vanishing set) of Σ on S are just the intersection of the rays of the anamorphosis (resp. vanishing set) with S. When considering the actual construction of an anamorphosis on a surface, we can construct one anamorph – the simplest one we can find – and then project it onto the required surface. In particular, the canonical anamorphosis onto the unit sphere is a good candidate as a prototype for others, since it is so symmetrical. So it is natural to solve the anamorphosis there and then project it conically onto the required surface, using the fact that $\Lambda_{S,O}(\Sigma) \overset{\varrho}{\sim} C_{0,S}(\Lambda_{S^2,O}(\Sigma))$.

For this reason, we are compelled to study the projections of lines and planes on the sphere with special interest, as well as its projections onto various kinds of surfaces. Lines, as we have discussed, project as meridians onto the sphere, each meridian ending at two antipodal vanishing points. We will now consider how these meridians in turn project onto various surfaces.

Example 4. Consider the anamorphosis of a line l onto a compact region S of a plane $\pi \in \mathscr{E}_O$: this can be identified with (a compact subset of) linear perspective or with so-called oblique anamorphosis. Let π_O be the plane through O such that $\pi_O \parallel \pi$. l projects on the sphere as a meridian with vanishing set $\{V, V^\star\}$. Suppose the vanishing set is on π_O. Then if l is on the side of π, it projects onto a line; if on the other side, it projects as the empty set. In either case the rays corresponding to the vanishing points do not intersect π, so the line has no vanishing points on π. If the vanishing points are not on π_O, then the line intersect the plane π at a point I and one and only one of the vanishing points projects onto π as a point V_π. Then the line projects into the ray with origin at V_π that passes through I, and its vanishing point on π is V_π. Since we assume S to be a compact (hence bounded) subset of π, both the vanishing point and point I (as well as an unbounded section of the line projection) may be actually outside the anamorphosis proper, but they can still be used for the construction.

Remark 6. We can contrast classical perspective (or plane anamorphosis) with spherical anamorphosis by saying that in the former a line projects either as a line or as a ray, while in the latter a line projects as a "segment" (i.e., a meridian ending at vanishing points).

Example 5. Suppose S is a compact region of three intersecting planes disposed as the floor and walls in the corner of a room (Fig. 6). This is locally the same as a plane anamorphosis, but globally very different, as some lines may have two vanishing points. In rendering lines, we may consider the following strategy: in each plane plot two points of the line, thus finding two lines joining at the intersection of the projection planes. More efficiently, find only three points per line, one point on each plane and one on the intersection of the planes. But since two non-antipodal points define a geodesic, in fact two points anywhere on the planes must be enough to define the line across all projection planes. These constructions are maximally symmetric in the case of the anamorphosis onto a cube, which has been studied in Araújo et al (2019b) as a special case of spherical perspective. Then the geodesic associated with a line l projects as a set of six or of four segments on the cube, obtainable from any two points through simple descriptive geometry constructions.

Example 6. Let S be a compact region of a cylinder, with O outside the cylinder (Figs. 18 and 7). This is a good example of how we can make do with only starred surfaces. Although the cylinder is not starred from O we can consider as projection

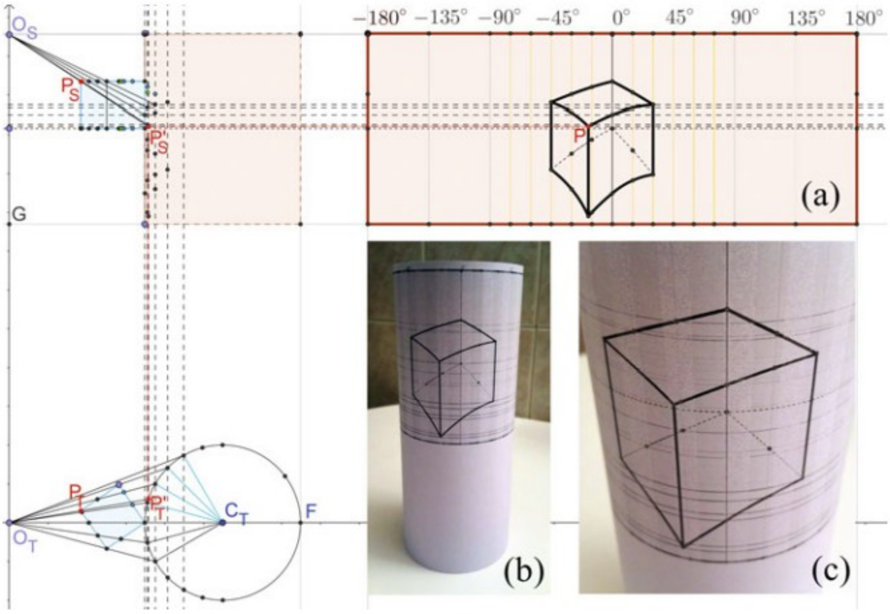

Fig. 18 Descriptive geometry construction of the anamorphosis of a cube onto a cyilinder. Each point is found on the top view (Bottom left) then lifted to the side view (Upper Left) and found on the developed (cut and unrolled) cylinder by transforming the angular coordinates from the top view and transporting the heights from the side view (**a**). The rectangle can be cut and rolled up to obtain the cylindrical anamorphosis (**b**) which will be correctly observed from the point O determined by the two projections O_S and O_T. From this point the edges of the cube appear straight (**c**)

surface only the proximal region of the cylinder, which is visible from O and exclude the distal, occluded part, thus obtaining a starred subset. A generic non-vertical line will define a plane that cuts the cylinder in an ellipse. A line will project as an arc of an ellipse, with at most one vanishing point. A large class of lines will have no vanishing points at all on the cylinder, as l_O will not intersect it. If the cylinder were to be cut at a vertical line and opened isometrically (unrolled), the ellipses would transform into segments of sinusoidal curves. See Apostol and Mnatsakanian (2007).

Example 7. Let S again be a cylinder as in the previous example, but now O is on its axis (Fig. 19). Now generic geodesics will project onto ellipses that are half above and half below the horizontal plane through O. The line will project as an arc of its ellipse, ended by two diametrically opposed vanishing points. Lines on the horizontal plane through O are special cases, projecting as horizontal half-circles. Lines with vanishing points along the axis of the cylinder will project as verticals.

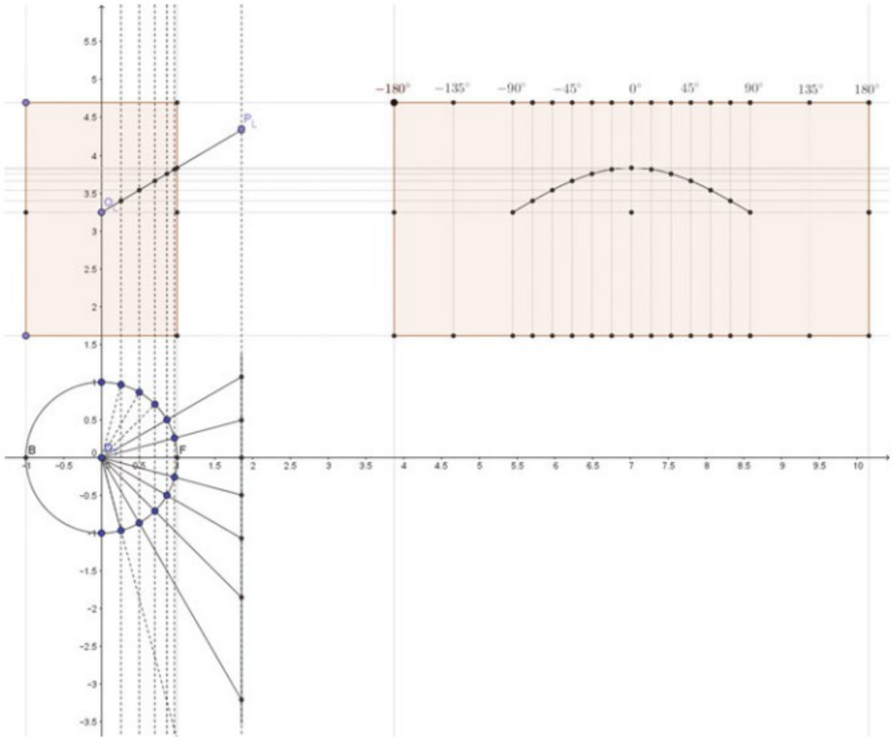

Fig. 19 Descriptive geometry construction of the anamorphosis of a line onto a cylinder with O on the axis. The image of the line on the unrolled cylinder is one half of a sinusoid whose axis of symmetry is the horizon line, at the height of O

All geodesics, projected as sinusoids in the opened cylinder, will share the same horizontal axis of symmetry, as the planes of their geodesics all intersect the axis of the cylinder at O. This was not true in the previous case, where the plane of a generic line could intersect the cylinder's axis at any point.

More General Surfaces

The following section is technically nitpicking that should be ignored by the artist (and probably by everyone on a first reading).

Although starred surfaces are quite enough for most purposes and provide the most elegant theoretical results, they can hardly model the large variety of real surfaces on which artists have constructed anamorphoses. Often these can be rather complex surfaces that fold over themselves in such a way as cut a ray from O multiple times; hence they are non-starred. Often they will have several connected components, sometimes so many that they might be better modeled as a point cloud.

It is in fact quite up for debate what the most desirable definition would be for a general anamorphic projection surface. We will not aim at closing that discussion here but just at exploring it a little.

First of all, we note that we could certainly extend our definitions to include all sorts of surfaces, even non-compact surfaces such as the whole Euclidean plane (in that case the formalism under consideration just becomes that of linear perspective). We would lose some of the elegance but things still work. It is interesting to consider what happens when we remain with compacts but relax conditions just a little.

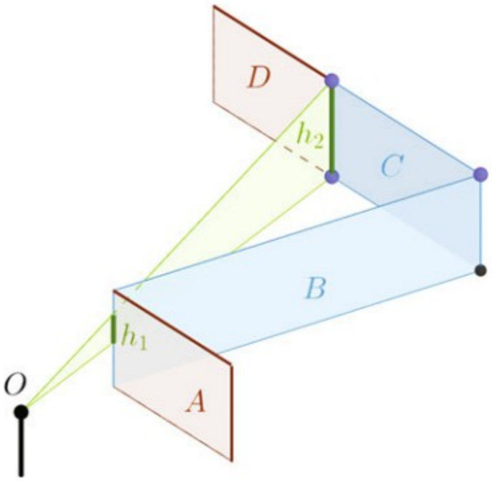
One way to deal with non-starred surfaces is by cropping or changing the surfaces into their minimal starred equivalents by considering only the subset that is visible from O. We did this informally with the cylinder in Example 6. We can formalize this procedure by generalizing conical projection to take occlusion into account, in the following way: given a point P and a surface S, the *proximal conical projection* sends P to the intersection with S which is closest to O (the reasoning is that the distal ones are occluded).

Definition 9. The proximal conical projection from O to a surface $S \subset \mathscr{E}_O$ is the map from $\mathscr{R}_O$ to S defined by $\varphi_{O,S}(\overrightarrow{r}) = \{P \in \overrightarrow{r} \cap S : \forall Q \in \overrightarrow{r} \cap S, |OQ| \geq |OP|\}$

Remark 7. When the surface is O-starred, the proximal conical map reduces to the ordinary conical projection $\overrightarrow{r} \mapsto \overrightarrow{r} \cap S$. We identify the map from $\mathscr{R}_O$ with the corresponding map from $\mathscr{E}_O$ defined by $P \mapsto \overrightarrow{OP} \cap S$ that maps each spatial point to its conical projection on the surface.

Identifying point of S with their rays, we can use the proximal conical projection map to define the minimal starred equivalent of S itself, i.e., the smallest locally starred surface that has the same anamorphosis as S. In fact $\varphi_{O,S}(S)$ has no double points, preserving only the *proximal* (closest to O) intersection of each ray going

Fig. 20 The object composed by the rectangles A, B, C, D is not starred. Taking the proximal projection $\varphi_{O,S}(S)$ eliminates sections B and C, leaving two connected components A and D, minus segment h_2, which is recovered by taking the closure



through a point of S. But since we insist on compact sets, we define the minimal O-starred equivalent of S to be $S^\star_O = cl(\varphi_{O,S}(S))$. Because of the possible existence of multiple connected components, this surface will generally have a non-empty set of repeated intersections, although one of measure zero. It will be locally starred *almost everywhere*, i.e., there will be a set δ of measure zero such that $S^\star_O$ is locally starred in $S^\star_O \setminus \delta$. We say that a surface with this property is *quasi-starred*.

Example 8. The object of Fig. 20, defined by the union of rectangles A, B, C, and D, is not O-starred. Taking the proximal projection $\varphi_{O,S}(S)$ eliminates sections B and C, which are occluded by A, leaving two connected components A and B, minus the segment h_2 of B, which is occluded by segment h_1 of A. This segment is recovered by taking the closure, so that $S^\star_O = A \cap B$ is the disjoint union of two compact rectangles. It is only quasi-starred, since $h_1 \overset{O}{\sim} h_2$ is a set of double points relative to O.

These double points have to be handled carefully. Continuing Example 8, consider Fig. 21. The vanishing points V and V', which are aligned with O, both belong to the surface and correspond to the same vanishing point on $\mathscr{R}_O$, but are meeting points for different sets of lines. We must take some care in defining vanishing points for general surfaces, to avoid duplication or the appearance of false vanishing points, as the equivalent of Proposition 12 is no longer valid.

Let us consider our requirements: the vanishing points of a set Σ on S are determined by projection of $\mathscr{V}_O(\Sigma)$, so clearly $\mathscr{V}_{O,S}(\Sigma)$ is a subset of the intersection of $\mathscr{V}_O(\Sigma) \subset \mathscr{R}_O$ with S. But this cannot be an equality otherwise we'd have double vanishing points. Also, we cannot define them as $\varphi_{O,S}(\mathscr{V}_O(\Sigma))$ as sometimes the proximal intersection with S of the vanishing rays are not the meeting

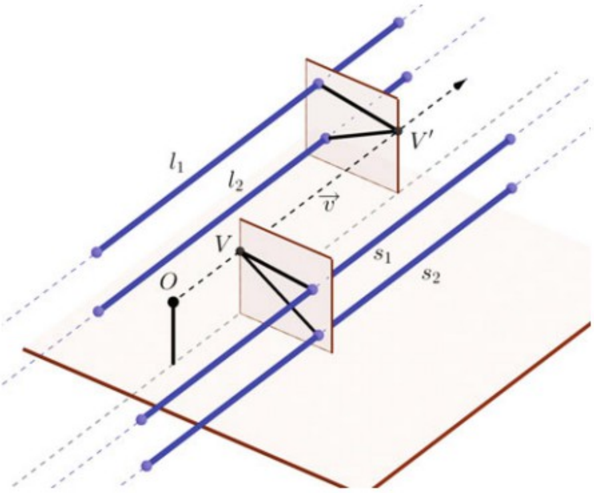


Fig. 21 Anamorphosis onto a quasi-starred set with two connected components. Points V and V' are in the ray of the same canonical vanishing point, but Definition 10 ensures that V (resp. V') is only a vanishing point for the family parallel lines s_1, s_2 (resp. l_1, l_2)

point of the projected lines, which is located in a distal connected component. The following solves all these difficulties:

Definition 10. The anamorphosis of an object Σ onto a projection surface S relative to O is $\Lambda_{O,S}(\Sigma) = cl(\varphi_{O,S}(C_O(\Sigma) \cap S^\star_O))$, where $S^\star_O = \varphi_{O,S}(S)$ is the minimal compact starred subset of S. The vanishing set of Σ on S is $\mathscr{V}_{O,S}(\Sigma) = \Lambda_{O,S} \setminus (C_O(\Sigma) \cap S^\star_O)$.

Let us see how this works with the example of Fig. 21. $S = S^\star_O$ is the union of two disjoint compact rectangles. Points V and V' are on the same ray from O, on the edge of the proximal and distal rectangle, respectively. Let Σ be the set of lines s_1, s_2. By Definition 10, the vanishing set is V', the meeting point of the lines projected on the distal rectangle, and V doesn't figure in either the vanishing set or the anamorphic image. That is because neither V nor V' are present in $\varphi_{O,S}(C_O(\Sigma) \cap S^\star_O)$, the latter only appearing when we take the closure. In the same way, V' will be ignored when calculating the vanishing set of lines s_1, s_2 by Definition 10, and only V will remain. This is why we define the vanishing set through topological closure and not mere projection from the canonical vanishing set. In this way we both avoid duplication of points and ensure that the vanishing set preserves its meaning as a location for the meeting of parallel line images.

Proposition 13. *If S is a surface, and its minimal quasi-starred equivalent $S^\star_O$ is locally starred at a point V, then V is a meeting point for the anamorphic images of lines that have the ray $\overrightarrow{OV}$ as a vanishing point.*

Note that if V is in $\delta \subset S^\star_O$ then it will be a meeting point for only a subset of those lines (see Fig. 21).

Simplifications: Talking to Artists

We would like to keep a balance between the concerns of artists and those of mathematicians. The technical details of Definition 10 are somewhat overwhelming for the former, so it behooves us to find some simplification. The trick is how to simplify without outright lying. The matter can be presented thus to an artist.

We are interested in drawing an anamorphosis of an object Σ onto a surface S. The surface can be anything. The artist is instructed that for the purposes of drawing, only the part that is visible from O must be considered. Points of S in the conical shadow of other points of S which are closer to O are to be discarded. The exception are points at the edge (boundary) of the shadow. These are allowed to remain. From this cropping we get a working surface S', the minimal surface, in which we will actually draw.

Each line l determines exactly two vanishing "points," V and $V^\star$, which are the rays from O that are parallel to l_O (you can also call them vanishing rays for clarity). These are always exactly two, and diametrically opposite to each other. These vanishing rays can be represented as actual points in a canonical way by intersecting them with the surface of an the imaginary "visual sphere" around O. When drawing an anamorphosis onto the minimal surface S', each of the two vanishing rays may intersect it several times. The multiple intersections of each ray with S' should be seen as multiple manifestations of the same vanishing point. So, for instance, V will manifest as points $V_1, \ldots, V_k$, which we can order by distance to O. Then all lines parallel to l which meet at V on the sphere will meet at one of the V_i on S'. Which one can be found a posteriori from drawing the lines near to their meeting points and seeing in which subsurface they are found (it will be the one that contains the projection of the germ of l around V – but here we'd be going all abstract again, so we won't).

This statement avoids the most difficult terminology and requires minimal abstraction. It can be easily explained graphically to even very young students, and yet it carries the essentials, as far as drawing is concerned, of the discussion above. In a later section we will see how to implement these concepts graphically through descriptive geometry constructions.

On Compactness

Why have we insisted on compact projection surfaces? If we think about it, this is quite strange. This was introduced by Araújo (2018c) for the needs of immersive perspectives as it is a very natural setting for the most usual such perspectives, namely, the cylindrical and spherical cases. Rather shockingly, however, it excludes classical perspective in its usual formulation, as the Euclidean plane, infinite and unbounded, is not a compact set. So it reformulates linear perspective onto a bounded region of the plane, though this region may be as large as you want it. You can imagine this region as a rectangle, for instance, representing a sheet of paper. Since we want it to be closed, it will technically be a manifold with boundary. Classical perspective will then become a degenerate limiting case as the region grows to infinity. This is analogous to the way in which orthogonal projection is usually considered a limiting case of conical projection as O becomes more and more distant from the projected object.

As we have seen in Example 5, classical perspective still remains, in our view, a fundamental object, as our constructions of the compact plane anamorphosis are better done considering the full plane, but only as a construction device, with the final result being cropped to a region that is bounded, though as large as we want it (reminding us of the Aristotelian philosophical distinction between *potential* and *actual* infinity). Even so, this is a frightful demotion of the infinite plane of classical perspective, so we must consider what we get in return.

Compactness is a desirable property. Ask a mathematician what linear perspective is as a mathematical object, and he will insist it is the projective plane. Like the sphere, the projection plane is a compact. Like the sphere, it gives you a definition of vanishing points that attributes a constant number of vanishing points to a line (this number being one, in the projective case, two in our case). This uniformity is pleasing to the mathematician's eye, like that of the number of roots in a polynomial equation of given degree. In the projective plane case, this is done by identifying the actual perspective drawing as a chart of the projective plane. Hence the drawing lives naturally in the infinite plane. On the other hand this implies that the vanishing point of lines parallel to the chart's plane actually lies nowhere in the chart. It lives only on the "point at infinity" of the chart, that is, on the one-dimensional projective line that lies outside of the chart's domain. We find that this is a rather immaterial satisfaction. The projective plane is not a surface that the draughtman can "see"; the gained vanishing point is more than a little ethereal. By contrast, the sphere is not only an abstraction, it lives in the actual scene to be drawn; it is as concrete a surface as the plane itself – in fact more so, because it is bounded. It is the natural object that requires the least abstraction, just a bounded surface of ordinary Euclidean space, and yet affords a more pleasing result than either the infinite plane or the comparably abstract projective plane, affording a distinction between directions that encompasses a fully immersive view.

What is formalized by the anamorphosis onto a compact surface is the notion of a *drawing* itself: the result is a real, drawing that can be materially executed and yet captures two vanishing points for every line. Mathematicians, of course, have no problem with the abstract notion of the infinite plane, but sometimes we want to deliberately keep to the finite. Just as we can abstract a notion of an infinite proof and yet for the most part decide that finite, actually executable proofs are our main object of interest, so here too, although plane perspective is certainly not a problematic concept – we could certainly accept the full Euclidean plane as a projection surface and still do our work – we decide that compact surfaces are the object of most interest to abstract the notion of drawing. This in fact corresponds neatly to the way in which plane perspective, or plane anamorphosis, is actually used by draughtsmen. Every drawing is made onto a finite canvas, although the canvas may be extended at will with no absolute limitation. And the draughstman knows the difference well between the bounded plane of the drawing and the unbounded plane that contains it and may be useful as a construction device though not part of the drawing itself. Often the draughtsman will have to use methods that find a vanishing point outside the drawing sheet in order to construct the lines inside it. And it is nice to have an abstraction of perspective that relates directly to the practical distinction.

Let us be more general: in a way we can say that compact – bounded and closed – objects are all that we can draw. Can we really draw a line? No. It is unbounded. We cannot draw infinite things. We draw a segment and end it with little dots to signify continuation. This is representing infinity, not drawing it. But when we project the line conically onto the sphere around O, it becomes a meridian. Can we now draw it? Not yet. As we have seen, it is not a closed meridian – it is missing its endpoints, as the vanishing points do not belong to the visual cone. We cannot draw open ended arcs. We can again only represent them, usually by drawing a small circles to signify that the ends are missing, but we cannot really perform the feat of drawing an arc without its endpoints. How to solve this? We could just add on those endpoints. In mathematics we do that and call it that fancy name: taking the closure. By taking the closure of the conical projection of the line, the cone becomes a closed half-plane, the meridian gets its endpoints. We now have a closed meridian on the closed and bounded – compact – sphere. A compact arc of circle. And compact sets are the right mathematical abstraction for that which can actually be drawn.

Descriptive Geometry Construction of Anamorphoses

In this section we will be concerned with constructing anamorphoses onto surfaces from the point of view of the draughtsman, using simple descriptive geometry. We focus on the mechanical device of a modified Dürer machine, both in physical form and abstracted through descriptive geometry constructions.

This is a matter intrinsic interest for our purposes, but we start with some lateral considerations of a didactic nature.

Handmade vs Digital Anamorphoses

It is undeniable that at present, digital means greatly simplify practical construction of anamorphosis, both in 2D, with *projection mapping* (Inglis 2018; Monroe and Redmann 1994) and in sculpture through 3D modeling and printing (we have already mentioned (Sugihara 2015a), but see also Ballegooijen and Kuiper's work in Dunham (2019)). These are the quickest and more efficient options for production purposes, and there is nothing wrong with that; the working artist knows that there is no such thing as cheating and anyway a vast gamut of anamorphosis would be unreachable or at least untried without such means. However, premature or excessive reliance on technological shortcuts not only lacks charm and intellectual appeal, but can lead to limiting results, as the tools that happen to be on offer define a scope of action and thought, the terms of the language of creativity, so to speak (Papert and Turkle 1991). This is always so, even if the tool is the brush, but digital tools, due to their complexity and opaqueness, tend to so in a more insidious manner. The expressive scope thus delimited may be inadequate for some artists , who then have little recourse to developers if they lack the understanding of the basics that is required for communication. The tendency will be for artists to adapt to tools rather than the other way around and end up chasing ever-changing flawed interfaces (Coates et al 2010; Norman 1990), so it is hard to say how much effort is really saved if time economies obtained by neglecting fundamentals are spent chasing transient knowledge of tools that never really *just work* as advertised (Kim and Chin 2019). The tendency is for these interfaces to help artists work with implicit principles they do not understand deeply, but there are limits to what can be achieved before the confused artist hits the walls of his ignorance. For instance, Tran Luciani and Lundberg (2016) reports both on the achievements of digital interfaces in helping artists create spherical panoramas and on the difficulties that always eventually arise from not knowing the essentials of the spherical perspective underlying the interface. Araújo (2019a) has argued that there is a need for more interfaces that force (and help) the artist to learn the fundamentals rather than helping them to avoid such learning; and that production software should ideally come in after the user has already mastered the discipline in its rudimentary form, so as to avoid the black box frame of mind. Further, the knowledge of the mathematical and geometrical fundamentals underlying their tools is better acquired, for most artists, not through formalism, but through manual practice in an embodied form. For this purpose, Araújo (2017b) proposed anamorphosis, in the form here discussed, as the central concept behind technologies such as virtual and augmented reality, 360-degree photography, and projection mapping; further, it proposed the modified Dürer machine, both physical and "virtualized" through descriptive geometry constructions, as an adequate physical embodyment for artistic exploration of the principle. This resulted in a teaching process that has been tested in students of a Ph.D. program in digital media arts and yet also, reworked and simplified, as a new way of introducing young students to the subjects of linear perspective and descriptive geometry (Araújo 2017c). In the latter case, making anamorphosis the fundamental concept and linear perspective the derived concept, in a reversal of the usual practice, and expressing this concept with constructions that are handmade, yet display their anamorphic properties through digital means (such as photography and VR), resulted in an enticing process to students that have grown with a view centered on digital media. This has shown promise in preliminary tests with Portuguese 9th grade students (approximately 15 years old). In what follows we present the descriptive geometry constructions of anamorphosis in a way that reflects the learning paths here mentioned.

Dürer Machines Running Back and Forth

Descriptive geometry constructions are adequate for constructing both planar and curvilinear anamorphoses. We will describe a path of growing generality leading swiftly from plane anamorphosis to curvilinear perspectives. This is both a descriptive path for our subject and a learning path a student might follow with exercises of growing difficulty and generality. Using conical anamorphosis as the central concept integrates the process and simplifies it to the point where the whole apparatus of both anamorphosis and spherical perspectives can be learned by an artist in a few weeks, even if starting from no formal knowledge of perspective (Araújo 2017b).

A practical way to teach anamorphic constructions to artists is to start by implementing a simple Dürer machine with a thread fixed on a tripod or other fixed point that will serve as the observer's point *O* (Fig. 22). We make the Dürer machine work forward to the ground plane rather than, as usual, backward to the perspective plane. For each reference point *P* on the object, we extend the thread from *O* through *P* and mark the image point *R* where the thread hits the ground plane. In this way Dürer's perspective machine becomes a machine for making anamorphoses, which can be used to obtain an oblique anamorphosis such as those of Figs. 11 and 23. The same setup can also be used to obtain curvilinear anamorphoses such as that of Fig. 7, onto a cylinder, only requiring more points for drawing each line segment that will now project as a curve.

This mechanical implementation of the Dürer machine is important to establish in the mind of the artist a concrete, physical, and operational notion of anamorphic equivalence. This makes it easier to then abstract it diagramatically, doing away with the thread. A simple diagram with a side view and top view – the most basic of descriptive geometry concepts – allows for construction of the oblique

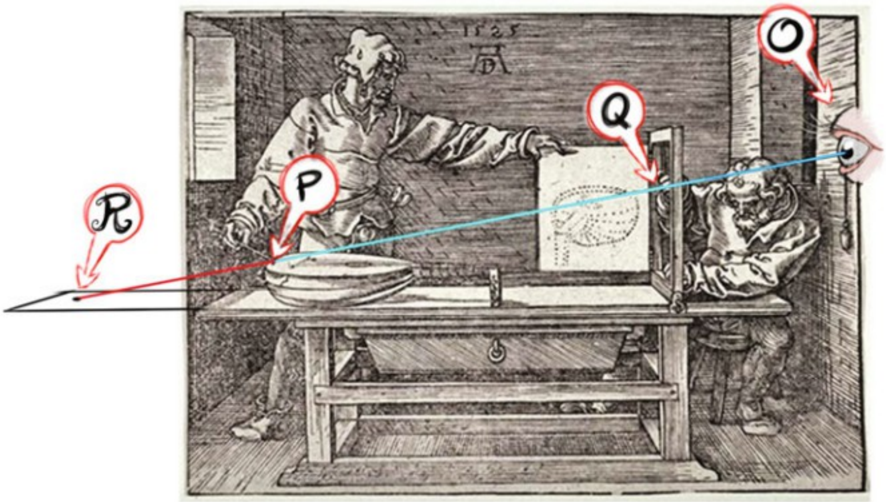

Fig. 22 A Dürer perspective machine can be run back or forth, to make either a "perspective" onto the vertical plane or an "oblique anamorphosis" onto the horizontal one. Points P, R, and Q are all anamorphically equivalent from *O*, so should be indistinguishable to a viewer at *O* (assuming radial occlusion). (Reproduction of a print by Albrech Dürer, defaced by the author)

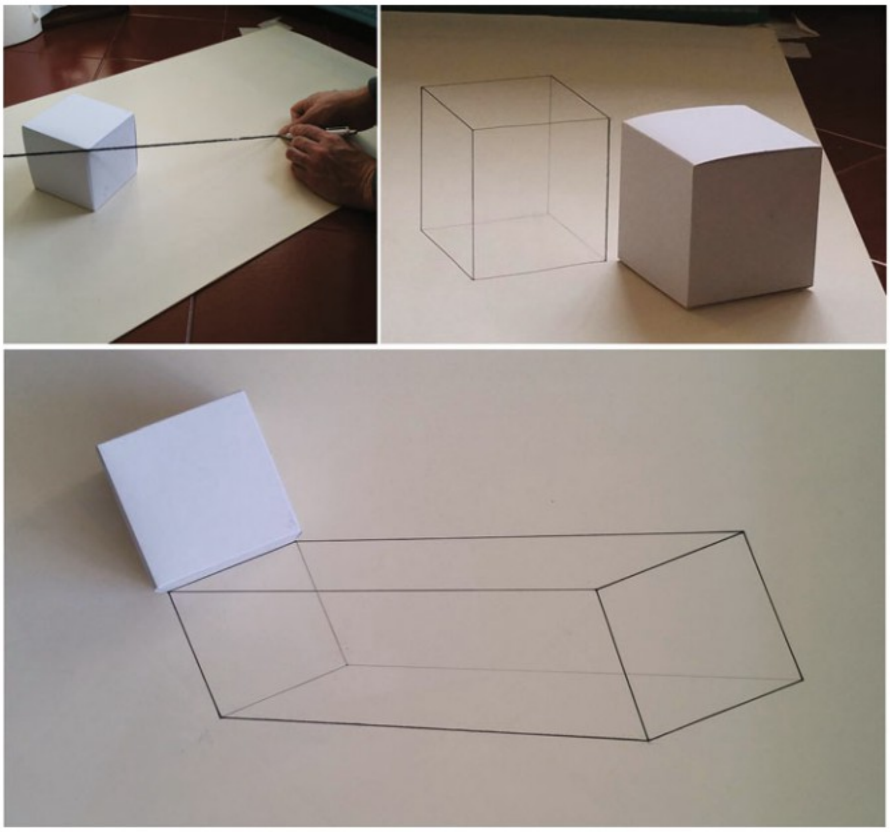

Fig. 23 Making a cube anamorph with a thread fixed to a point

anamorphosis with diagrammatic "thread" (see Fig. 24). The process integrates the anamorph and its construction on the same piece of paper.

Take the example of Fig. 24, a student's exercise. We start by establishing orthographic top and side views (a "plan and elevation") of the object to be projected, using the ground plane as a horizontal folding line. We establish the position of O by plotting its projection O_T on the horizontal plane and fixing its height at O_S in the side view. For the example presented, it is easier to start the object's drawing with the top view of the vertices of the base and then lifting them to the side view, through the folding line, for instance, starting from the top view projection of point P_T in the figure, lifting it through a vertical to get its side view P_S, by setting its height above the folding line. Then to plot the anamorph of the object onto the ground plane, start with the side view, as rays in the side view have *true* intersections with the ground plane. An intersection is said to be *true* if the intersection of the projection is the projection of the intersection. For instance, taking the vertex P, $\overrightarrow{OP}$ projects as $\overrightarrow{OP_S}$, and since the ground plane is

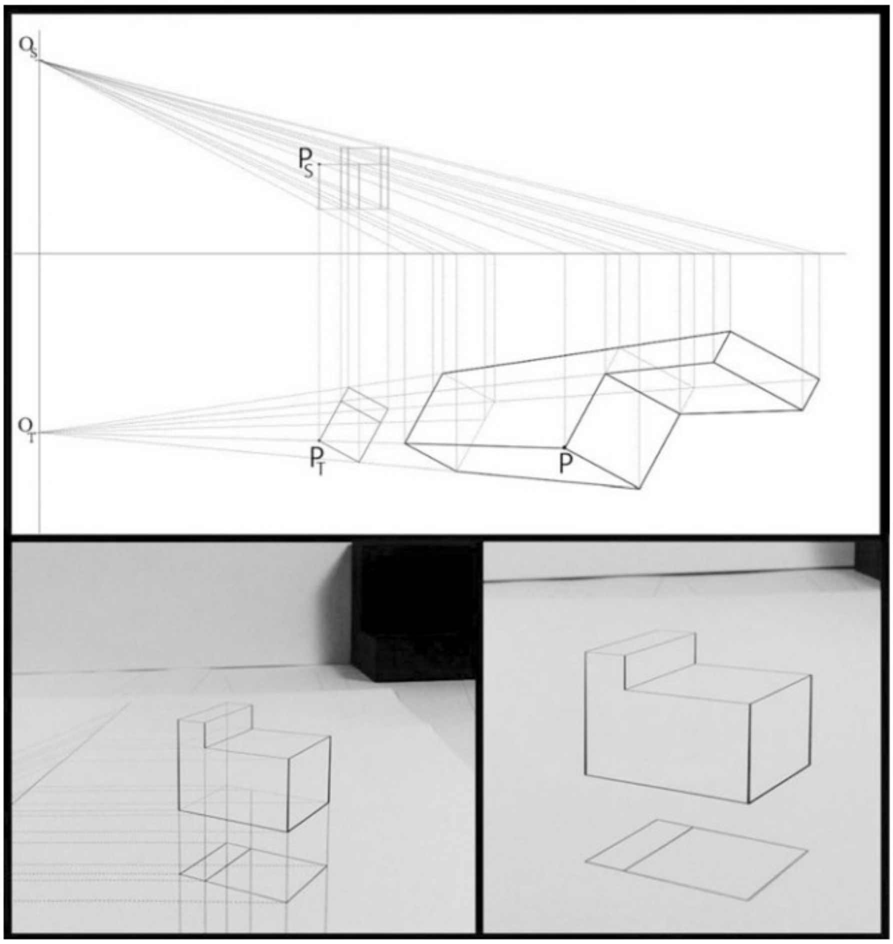

Fig. 24 Top: Abstracting a Dürer machine with plan and elevation views of the threads going through a cube's vertices. The anamorphosis is realized on the top view and should be observed with the eye above O_T at the height of O_S. Bottom: The anamorphic view from O. (Student work by Manuel Flores)

perpendicular to the folding line on the side view, ray $\overrightarrow{OP_S}$ has a *true* intersection with the ground line, that is, the side view of the intersection of $\overrightarrow{OP}$ with the ground plane is the intersection of the projected ray $\overrightarrow{OP_S}$ with the ground line. By contrast, the intersection of that ray with a vertical edge of the cube, for instance, would not necessarily be true. Obtaining the intersection with the ground line, drop it on a vertical to intersect ray $\overrightarrow{OP_T}$. Since $\overrightarrow{OP_T}$ is the projection of the vertical plane through $\overrightarrow{OP}$, the intersection is true and equal to the top view of the anamorphic image of P onto the ground plane.

In this way we obtain the image of all the vertices on the top view of the ground plane, which we can connect with line segments to get the full anamorph of the cube. Then the anamorphic illusion will be obtained if we observe it with our eye over point O_T at the height determined by O_S.

Of course this effect only happens in our perception if the principle of radial occlusion is verified. This will not be verified by the naked eye if the anamorphosis is too small, and the typical classroom anamorphosis will generally be far too small for the principle to be valid. However, the camera – especially the small sensor camera of mobile phones, with their large depth of field and close focusing distance – is just the right tool to simulate the eye of the perfect monocular observer. Most anamorphosis we have displayed here, being drawn in small A4 to A3 sheets of paper, are, in this situation, small constructions that cannot really fool the naked eye, but which display their magic perfectly on camera. Students, especially younger students, seem to find this extra step not a mere concession to convenience, but actually an added charm, a mathematical trick that is inherently *instagrammable*.

We can extend this descriptive geometry construction to many other situations; in fact we could use it as a pretext to teach all the usual operations of descriptive geometry, projecting objects against planes slanted at arbitrary angles, or against cones, cylinders, spheres, or various other classes of surfaces. One can also consider the problem of shadows, both volumetric shadows as we have considered above and also projected shadows (See Fig. 25) that can be constructed in much the same way as we construct oblique anamorphosis, as the mechanism is exactly the same, requiring only that we treat a point light source as an additional conic apex in the diagram of Fig. 24. Anaglyphic anamorphoses (Fig. 12) are also easily constructed in this way.

So many are the achievable constructions and the descriptive geometry techniques put to use that Araújo (2017c) proposes anamorphoses as a path into descriptive geometry for young students, given its motivational possibilities, and the

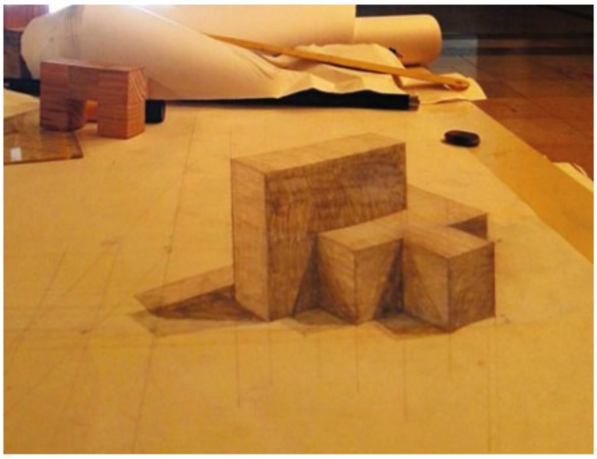

Fig. 25 Anamorphic structure with projected shadows, using orthographic projection. (Student work by Maria Bianchi Aguiar)

fact that, unlike many other constructions in this discipline, anamorphoses provides exercises without a need for an *oracle*, meaning that a student can, for the most part, independently *see* if the exercise was well executed, without a teacher to tell him so. This solves a good deal of the difficulties of descriptive geometry, the main ones being the student's inability to visualize the spatial construction that is being achieved, the other the lack of compelling incentives to achieving the result.

Let us consider, among the many constructions accessible through this scheme, a couple that will be of use in our transition to the study of perspective. We revisit, with the aid of descriptive geometry, the case of the cylinder.

First, revisit Example 6 (Fig. 18), where a cube is projected onto a cylinder with O located outside of the cylinder. In this case, and in contrast to the case of the oblique anamorphosis onto the ground plane, it is the top view that provides for the easier starting point, as rays from O_T have true intersections with the cylinder wall, which projects as a circle. So, as we see in Fig. 18a, a vertex P of the cube, with top view P_T may be projected from O_T in the top view until it hits a point P'_T in the cylinder's circular boundary; raise this point on a vertical to meet the side view of the same ray, $\overrightarrow{O_S P_S}$, finding P'_S. Transport the height of P'_S by sending a horizontal across to the flattened cylinder view, and find there the image of P where this horizontal intersect the vertical that marks the position of the radial plane through O defining angle $\alpha = \angle(P_T C_T F)$ in the top view, where point F is located at 180 degrees to the point where the cylinder is cut.

Consider next the case of Example 7 (Figs. 19 and 26) in which O is in the cylinders axis. The projection is made in the same way, illustrated in the figure with the plot of a vertex P of a cube. Consider, for instance, the horizontal edge of the cube going through point P and ending above point F, in the figure. The segment is contained in a line that projects as the curve $VPV^\star$.

As mentioned in Example 7 this curve is a sinusoid. It is easy to see why using descriptive geometry, in the particular case of horizontals (and the general case is easily obtained through a little trigonometry). One can always rotate the horizontal to assume it projects as a point in side view, as in Fig. 19. Then any point Q along that line, whose orthogonal projection Q_T subtends an angle $\alpha = Q_T O_T F$ in the top view, will project as $\cos(\alpha)$ on the horizontal line $O_T F$ in top view, and this measure will be transferred up to the line $O_L P_L$ on the side view, hence being equal to $m \cos(\alpha)$ with m determined by the slope of $O_L P_L$ and hence constant for all Q on the line. Once the cylinder is flattened, the vertical measurement is preserved, and the horizontal measurements are linear with the angle α, so the curve obtained as Q slides along the line is proportional to $\cos(\alpha)$, hence a sinusoidal curve.

Returning to Fig. 19 and to the line defined by the horizontal edge through P, its vanishing points V and $V^\star$ are obtained by translation to O and intersection with the cylinder. There are several ways to plot the sinusoid itself. In a variation of what was done in Fig. 19, one can simply plot points corresponding to regular angular intervals on the top view circle and project these onto the flat view, then interpolate. More interesting may be to note that the sinusoid is defined by any two of its (non-antipodal) points, for instance, V and P. A good choice is V and the apex of the

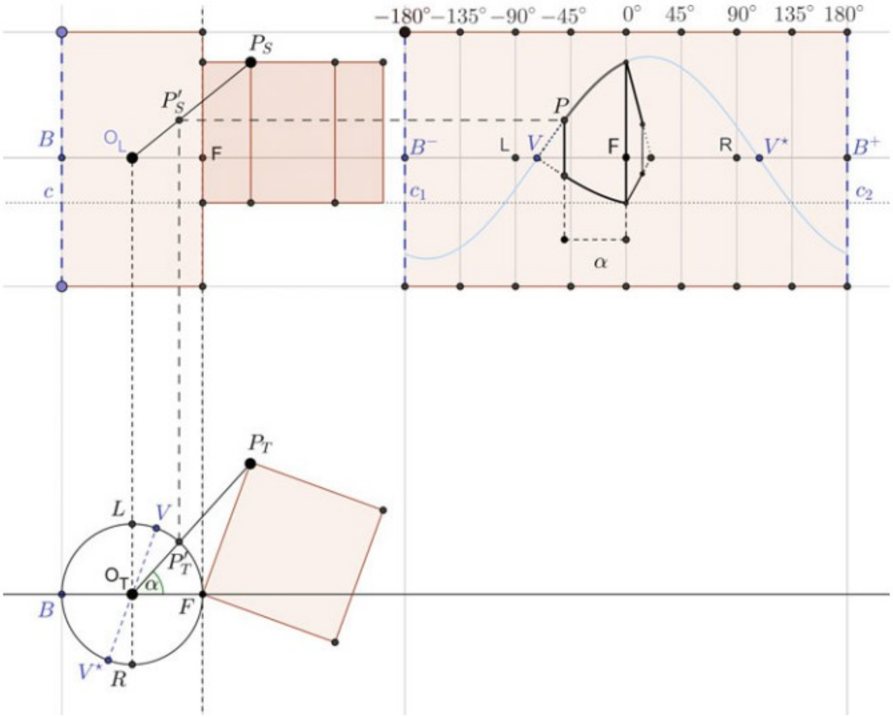

Fig. 26 Cylindrical anamorphosis of a cube onto a cylinder. The image on the flattened cylinder (upper right) is a cylindrical perspective. It transforms non-vertical lines into sinusoidal curves. Notice the blue sinusoidal curve defining the cube's top edge through point *P*

curve, where it reaches it maximum. This apex projects in top view at the point where the top view of the line meets its orthogonal through O_T. Given V and the apex image, it is easy to plot the sinusoid in the flat view.

Perspectives

We have talked from the start of considering perspectives, both linear and curvilinear, as a derived concept from anamorphosis. We are now in a position to develop that idea.

Let us begin once more intuitively and loosely: in our view, a perspective is just a flat representation of a surface anamorphosis, like a map is a flat representation of the Earth's globe. That is all. We want these maps to have certain properties, so we will need some technical details, but this is the main idea to keep in mind.

The notion of *curvilinear perspective* has a complicated past with a history that is often confusingly reported upon. The difficulties come not so much from the misconceptions of the past, but from those remaining in the present, under whose burden the historian must work. It is hard to argue whether Leonardo or Jean Fouquet are precursors of curvilinear perspective (Andersen 2007) without a proper definition of what those perspectives are. Often both the original sources and the historian fail to distinguish the perspective from the corresponding anamorphosis. This distinction, that so clarifies the subject, is our focus here. The matter of a perspective being "curvilinear" is comparatively minor. We will define as curvilinear any perspective that projects spatial straight lines into plane curves. This of course includes the cylindrical perspective and the usual spherical ones. Note that "curves" cannot mean only smooth curves; otherwise this has the curious result that at least one perspective (the cubical case) manages to be spherical without being curvilinear (in this perspective spatial lines project as sets of line segments). But we will not concern ourselves much with this. Curves will arise from Definition 11 as side effects of the need to project compact anamorphoses onto compact plane sets while preserving their main topological characteristics, such as vanishing points. The perspectives we will define are not so much characterized by being *curvilinear* as they are by being *central* (a side effect of being derived from conical anamorphosis) and *compact*.

We will motivate our definition of perspective by considering the simplest of curvilinear perspectives: cylindrical perspective. It has a long history. Whether you consider it defined by Herdman's 1853 treatise (Herdman 1853) or implicitly defined by Baldassare Lanci's 1557 (Kemp 1990, p. 175) perspective machine, curvilinear perspective was certainly textbook matter in the 1900 Ware (1900), and in the very early twentieth century was used for military balloon airmen spotting for artillery (Dept. of Military Aeronautics 1918). Its aspect is familiar to the modern reader, as it corresponds to that of the common panoramic photography.

We have already silently met cylindrical perspective, in Figs. 19 and 26. We have seen that in order to construct the anamorphosis of an object (in this case a cube) onto the cylinder, with O at the axis, it is convenient to first draw the scene in plan and elevation, flatten the cylinder into a rectangle by cutting and unrolling it on the plane, and project the object onto this rectangle (upper right corner of Fig. 26). Then, once the projection is drawn, the rectangle can be rolled up again and glued at the vertical edges to form the compact cylinder in 3D space, and the resulting picture on its surface will thus become the cylindrical anamorphosis. That auxiliary plane drawing on the rectangle, from which the anamorphosis is rolled up, is what we call the *cylindrical perspective*. Note that this is purely an affair of convenience. By definition, the anamorphosis is obtained on the spatial cylinder, through conical projection. But in practice, we find it convenient to draw on planes. This is analogous to cartography, where the exact shape and metric of features on a globe is sacrificed to the convenience of a plane chart. So, to us, perspective is merely this: a plane chart – a flat representation – of the spatial anamorphosis. The flat representation is not only easier to draw; it allows for they eye to capture the whole picture at a glance, at the price of introducing optical deformations. This is often the reason to use it, as in the case of Jean Fouquet's *Arrival of the Emperor Charles IV at the Basilica in Saint Denis* , where a deformation quite similar to cylindrical perspective allows us to see at a glance further down the street than would be possible with linear perspective.

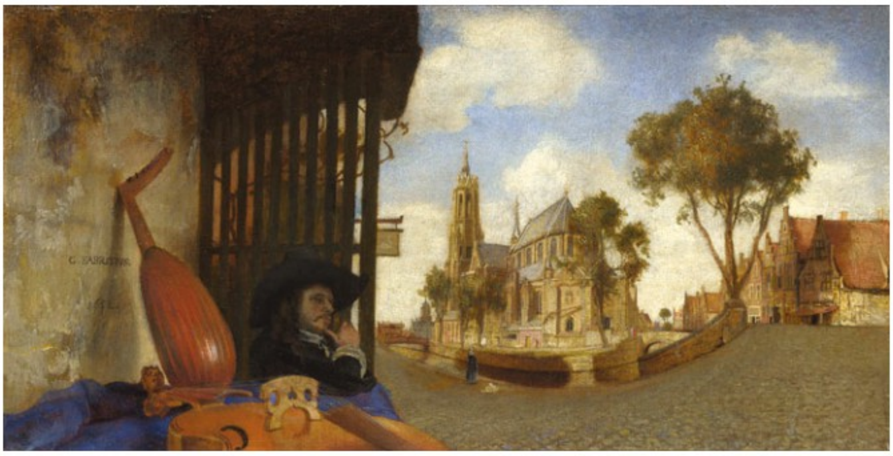

Fig. 27 A View of Delft, with a Musical Instrument Seller's Stall. Carel Fabritius, 1652. Currently at the National Gallery in London. Apparently a cylindrical perspective, although nothing is known regarding the method of its construction

Analogously to the case of cartography, we must pay for this convenience with deformations that result in perception inaccuracies. This is true even in the case of the cylinder that unrolls isometrically onto the plane. See, for instance, Fabritius' *View of Delft* (1652) (Fig. 27).The flat cylindrical perspective drawing, although it contains all the information of the cylindrical anamorphosis, and is isometric to it, is no longer an optical illusion; there is no point O from which the points can recreate the effect of the original object – the cones no longer align; hence it is no longer an anamorphosis. So the straight lines in the picture all get deformed. The line image of Fig. 19 looks nothing like a line (as we have seen, it is a sinusoidal curve), and the cube on Fig. 26 looks nothing like a cube. The non-vertical lines are bent; that in itself is not the problem, as they are also bent in the anamorphosis, and still they will look straight when seen from O. The problem is that in the perspective they are not just metrically but fundamentally *optically* deformed; there is no point O' from which they can all look straight. The perspective drawing is a *representation*, a storage of visual information – but it is not mimetic.

Of course it can still be *read* up to a point, even without training. But I challenge anyone to distinguish with perfect accuracy – a task easy in classical perspective – which lines in a cylindrical perspective are really bent and which are only bent through projection. The task can hardly be done by the untrained eye unless with an extreme reliance on context. The cylindrical perspective still evokes the scene, but no longer mimics it.

Let us be more precise. We view the perspective as a map from 3D space to a compact region of the plane, defined by a two-step process: the first step being the anamorphosis, from the 3D space to the surface S, the second step being the flattening of S. The anamorphosis is completely defined by the choice of S and O;

the flattening is a much more arbitrary map, just like in cartography. Because we will want to preserve the visual *information* , if not the visual aspect, we have some requirements. First, we would like it to be a bijection, so that no information is lost. Then, we'd like it to be a homeomorphism (continuous with continuous inverse) so as to preserve the topology and hence the vanishing sets and their meeting properties. Finally, we would like it to be as smooth as possible. We have a second set of more vague, yet crucial requirements: we would like it to preserve as much of the mimesis as possible; though it will not be an anamorphosis, it should be in some way recognizable as a picture; it should summon the visual presence – or at least the intellectual recognition – of what it represents. Finally, it should be solvable by elementary means. By this we mean that you should be able to draw it by hand, by ruler and compass, or some other simple means with adequate precision and in reasonable time, i.e., we would like it to be a perspective for humans and not just for computers.

We find that even the first three technical requirements are asking too much. We need to interpret them with some care. Look at the case of the cylinder in Fig. 26 and it will become apparent why. The cylinder is a developable surface; it can be unrolled onto the plane, preserving distances on the surface. Intuitively we would like to say that the flattening is the unrolling map that sends the cylinder to the rectangle. But this is not a bijection on the compact rectangle. Let c be the segment through B where the cylinder is cut, and let c_1 and c_2 be the corresponding vertical edges of the rectangle. Each point of c is sent to a point on c_1 and another equivalent one on c_2, so this "projection" is not even a map at all.

We solve this by noting first that the flattening π is well defined *almost everywhere*, meaning, on an open dense subset of the cylinder S. Namely, it is well defined on S minus the union of its boundary with the vertical segment c. This projects to an open rectangle that excludes c_1, c_2 and is a homeomorphism onto that open rectangle. Further, the inverse π^{-1} can be extended uniquely to a continuous map $\tilde{\pi}$ from the full compact rectangle to the complete cylinder. We just map both c_1 and c_2 to c, since in this direction the map has no problem of uniqueness. Apart from technicalities, we have the map we wanted. We define the cylindrical perspective to be the composition of π with the conical projection, and the perspective image/vanishing set to be the image of the anamorphosis/vanishing set, where we identify as the same point any points with equal images through $\tilde{\pi}$.

We will use this example as a template for the general case and say that π is a flattening if it can be extended to a continuous map in the way we just exemplified. We formalize this by the following definition, adapted from Araújo (2015):

Definition 11. Let S be an O-starred surface. Let U be an open dense subset of S. We say that $\pi : U \to \mathbb{R}^2$ is a *flattening* of S if π is an homeomorphism onto $\pi(U)$, and there is a continuous map $\tilde{\pi} : cl(\pi(U)) \to S$ such that $\tilde{\pi}|_{\pi(U)} = \pi^{-1}$. We say that $p = \pi \circ \varphi_{O,S}$ is the *perspective* associated to the flattening π, where $\varphi_{O,S}$ is the conical projection. Let $\tilde{p} = \varphi_{O,S}^{-1} \circ \tilde{\pi}$. Given an object Σ, we say that $\tilde{p}^{-1}(\Sigma)$ is the strict perspective image of Σ, that $\tilde{p}^{-1}(\mathscr{V}_O(\Sigma))$ is the vanishing set of Σ, and that the perspective image of Σ is the union of its strict perspective image with its vanishing set.

The following set is often useful in discussing perspectives. It is the minimal closed set we must take out of S for π to be well defined.

Definition 12. Given a flattening π of S, We call blowup to the subset of points of $cl(\pi(S))$ where $\tilde{\pi}$ is not injective.

The geometer may notice that we are here abusing the term "blowup," common in other areas of geometry, where it means, roughly, the replacement of a point by the projective line. Here it is in fact just the set where gluing (identification) of edges takes place. We use the term blowup by analogy to the important case of fisheye perspective where a point will identify to a circle or more precisely to the set of rays or directions defined by that circle. This is analogous to the usual sense of blowup of a point, which roughly is the replacement of the point with a projective line.

Example 9. Take again the case of the cylinder in Fig. 26. Let $O = (0, 0, 0)$; let the radius of the cylinder be $r = 1$ and its top boundary lie at $z = \pm h$. Suppose we cut the cylinder at the vertical segment c that passes through $B = (-1, 0, 0)$. Then, in cylindrical coordinates, we define $\tilde{\pi}(\theta, z) = (\cos(\theta), \sin(\theta), z)$, so the blowup set is $\mathscr{B} = c$, and $\tilde{\pi}$ implicitly defines π in the $S \setminus c$. Having defined π, the cylindrical perspective is defined by the entailment $p = \pi \circ \varphi_{O,S}$.

As seen above, spatial verticals are anamorphic to verticals on the cylinder and non-verticals to ellipses. Their perspective images by π are the curves we obtained above through the cylinder's unfolding: arcs of sinusoidal curves. For instance, in Fig. 26, the line that goes through P and has vanishing points V and $V^{\star}$ defines a plane through O that intersects the cylinder on an ellipse and that ellipse maps in perspective to the full sinusoid in blue. The line itself is the arc $VPV^{\star}$, one half of the sinusoid. These can be seen as the images through the cylindrical flattening of the great circle (resp. meridian) of the canonical anamorph of the plane (resp. line) in question.

Notice that although π, the flattening, is the more intuitive concept, $\tilde{\pi}$, the closure of its inverse, is the more natural map, defined everywhere and usually easier to work with analytically, as in the Example 9. This is very common in geometry.

Definition 11 is just a technical way of making sure that the perspective image of an object and its vanishing points are just the sets in the perspective image that correspond to the ones previously defined in the anamorphosis. As we stated before, everything important is already defined at the level of anamorphosis, perspective being relegated to a final step of convenient representation. This of course does not in deny the importance, both technical and aesthetic, of perspective, nor the intricacies of its construction, but it clarifies it meaning. In particular it does away with long-standing conceptual mistakes expressed in questions such as "do we see in classical/spherical perspective" or "does linear perspective cause deformations." It is not so much that we answer these questions; instead we show they are badly posed. There is no meaning to the question because we simply do not "see in perspective," whatever that perspective may be. Perspective is a map of the information in an anamorphosis and the anamorphosis is, when radial occlusion is verified, a mimetic object (a *trompe l'oeil*).

It is true that we can speak, more or less vaguely, of some perspectives preserving the aspect of the scene better than others, that is, of being "closer" to the mimesis than others. How close depends on the measure we use. (Araújo 2016) speaks of the *reading mode* of a perspective. For instance, a cylindrical perspective has a natural reading mode in the sense that when the cylinder of radius r is unrolled, we can think of the eye point O being transformed into a horizontal line floating parallel to the central axis of the picture, at a constant distance r. The natural reading mode is for the eye to travel horizontally, scanning the picture as it moves, one vertical thin strip at a time. At each point of the motion the vertical line in front of the viewer – and only that one – will be in anamorphosis. By contrast, in a fisheye perspective, only the central point in anamorphosis and a small neighborhood around it will show minimal differences if overlapped with the observation of the actual object. Notice that we take care to say "with the observation of the actual object" not with "its image," as otherwise we would be in the difficult situation of trying to define what the "image" means. Mimesis is checked not by comparing "images" but by looking at pairs of objects (that may be volumes or drawings on surfaces) and being unable to tell the difference between them, at least in some well-specified experimental sense (e.g., do the vertices of a wireframe anamorph of a cube seem to occupy the same spot as the vertices of the real cube it seeks to mimic).

In this sense we see that indeed classical perspective occupies a special place in the bestiary of perspectives, as it is the only one that is still an anamorphosis. This happens because the anamorphosis is already on a plane, so the flattening map is just the identity map. The reading mode of a perspective is the same as that of the anamorphosis: it consists of putting your eye in the point O and rotating it freely toward any spot of the plane of the picture. The so-called perspective deformations that happen for large angles of vision happen simply because the pictures in question are made in such a scale that they make the viewer unable to occupy point O without breaking the requirements of the principle of radial occlusion. Usually this happens because the perspective is draw at such a scale that the eye must be too close to the picture plane. And of course, the illusion will not work of the viewer leaves point O to look closer at some detail, or if he looks at the picture from some arbitrary point in a crowded room. But anamorphosis only works from point O. To blame it for not working otherwise is to blame a fork for not being a spoon.

Spherical Perspectives

We have seen that among anamorphoses, the spherical one holds a special place, due to its natural identification with the space of rays $\mathscr{R}_O$, or with the concept of *visual sphere*. For the same reason, the spherical case also holds special importance among perspectives.

Of course, while spherical anamorphosis is unique, spherical perspectives are innumerable. Every chart of the sphere defines a flattening and hence a spherical perspective according to Definition 11. In fact every central perspective (even classical perspective, if restricted to a compact subset of the plane) can be seen formally as a *spherical* perspective; hence the term is only as interesting as the qualifications we add to it: for instance, we can distinguish *total* spherical perspectives, i.e., one those in which all points of the sphere have a perspective image. Each spherical perspective, although it holds the same visual information and would generate the same anamorphosis, holds its own visual characteristics and artistic possibilities as a drawing type. These visual characteristics hold all sort of representational and expressive possibilities that have been explored in traditional media (Araújo 2019b; Barre and Flocon 1968; Casas 1983; Michel 2013; Moose 1986) as well as in purely digital visualizations (Correia et al 2013) and are more and more being investigated as *hybrid immersive media* (Araújo et al 2019a; Olivero and Sucurado 2019), a mode of artistic expression that allows handmade drawings to be visualized through immersive, digital means.

It is interesting to ask how we can solve a spherical perspective, where by *solving* we mean giving a systematic method to find and draw all vanishing sets of lines and planes through simple geometrical constructions (such as ruler and compass constructions).

Notice that since by Proposition 10 the perspective images of lines are subsets of the vanishing sets of planes, and since plane images are delimited by their vanishing sets, obtaining all vanishing sets also obtains all line and plane images; hence we can say that solving vanishing sets is the true subject of perspective.

We have seen that the vanishing sets of spherical perspective are all determined by the geodesics of the sphere. This suggests, if not an algorithm, at least a strategy for solving a spherical perspective: solving a given spherical perspective should be always attempted by focusing not on lines themselves, but on full geodesics, on classifying the geodesics according to the properties of their projection by the flattening and on finding an efficient method to plot the geodesics of each class.

In this, we will find there are features common to all spherical perspectives, and features peculiar to each. What common is the first step of the perspective projection, since it is just anamorphosis onto the sphere; what is particular is that each spherical perspective will have its own metric characteristics, which may vary widely. It will also have its own topological properties, but these are by design more limited in variation than the metric ones. Definition 11 ensures that π is continuous outside of the blowup set, so the topological variations will depend entirely on this set, which means that the blowup is a fundamental feature of perspective.

This view of perspective, first stated and applied to the case of the azimuthal equidistant perspective (Araújo 2018c), was later used to solve the equirectangular perspective case (Araújo 2018b) and then the case of cubical perspective (Araújo et al 2019b). The splitting of the anamorphosis from the flattening, and the focus on full geodesics instead of individual lines, proved an elegant solution for these perspectives. Previously, the only spherical perspective that had been solved systematically was the azimuthal equidistant in the hemispherical case, meaning that in fact only half of it had been solved. This is the perspective of Barre and Flocon (Barre and Flocon 1968), solved in the 1960s, which renders into images similar to those of a "fisheye" camera. The full azimuthal equidistant case had only been solved in either a qualitative way (Casas 1983) or through informal grid methods (Michel 2013) which lack the generality of Barre and Flocon's solution. So there stood this curious situation in which the first spherical perspective was not (fully) spherical, and the subsequent ones were not (formal) perspectives.

The approach here described and implemented in (Araújo 2018c) was able not only to extend Barre and Flocon's perspective to the full sphere but also simplified their solution in the frontal hemisphere, reducing it to two distinct classes, the focus on geodesics instead of lines providing a clearer, more unified view of the problem, for even when plotting only the frontal part of a line, it is helpful to be able to call on the antipode of every point (and the pair of any vanishing point) for auxiliary constructions.

As for the equirectangular case, it had previously been treated only computationally or through fixed grid constructions, the equirectangular grid being calculated at fixed intervals and used as a guide for drawing. The more general approach in Araújo (2018b) leads naturally to an exploitation of the translational symmetries of the perspective , which can be used with a system of dynamical moving grids that allow for the plotting of all lines in good approximation (Araújo 2018a, 2019a).

The cubical perspective case is an interesting one, since seeing it as a spherical perspective (Araújo et al 2019b) greatly simplifies previous approaches (Olivero et al 2019; Rossi et al 2018) that saw it as a conjunction of six related classical perspectives. It might not at all seem obvious that seeing a set of classical perspectives as a spherical one would be a simplification.

In all these three cases, the approach passes through understanding the flattening and its blowup set, classifying the geodesics of the sphere according to how they are projected in the plane, and finding a method to render each class through simple constructions. For this, the understanding of antipodes and how to plot them is essential , as the duality of vanishing point pairs usually results in symmetries that can be exploited. As these are curvilinear perspectives, approximations will be required to draw line projections, and in these the number of operations should be kept to a minimum. This will require a careful exploitation of the symmetries arising from the flattening. A general philosophical principle is that not only the perspective drawings themselves but also the auxiliary drawings should happen in a compact subset of the plane; in short, everything should be bounded.

We will not explore in any detail here the actual constructions of spherical perspectives, leaving that for another chapter in the present volume (see ▶ Chap. 19, "Spherical Perspective"). We will merely relate the fundamental properties of two of these cases, to see how they fit on our general scheme described above.

In the case of the azimuthal equidistant perspective (Fig. 28 (top)), the flattening works by choosing a reference point B (for "Back") and loosening the meridians there, straightening them without stretching to obtain a disc centered on the point

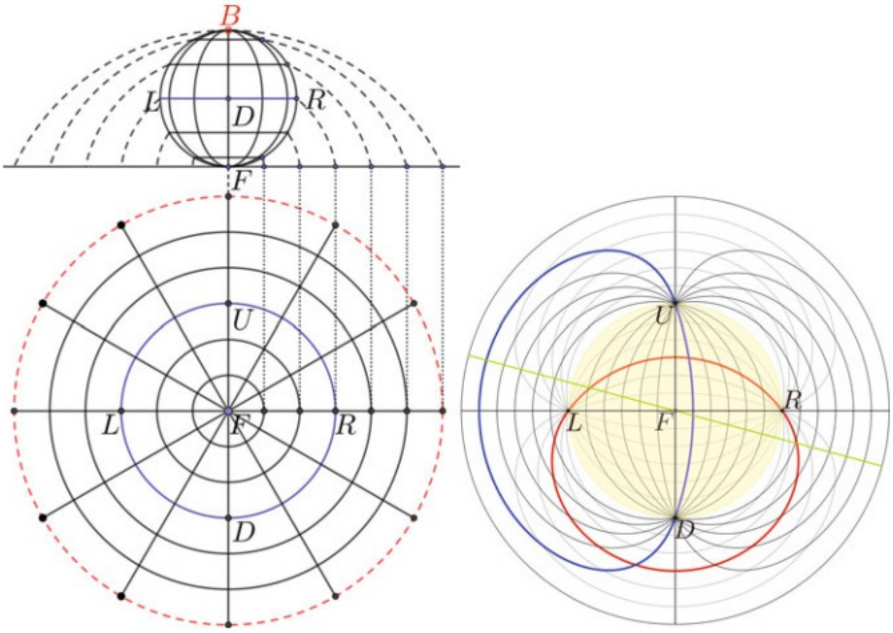

Fig. 28 Azimuthal equidistant flattening of the sphere. Left: Blowing up point B maps the sphere to a disc centered on the image of F, the antipode of B. Geodesics through F map to diameters of the disc. Right: The green line is a geodesic through F. Geodesics not through F (blue and red lines) map to closed convex curves, well approximated by arcs of circles in the yellow inner disc that represents the space in front of the observer

F (for “’Forward”) at the antipode of B. If we reference F and B as the “poles” of the sphere, then FB meridians flatten as rays of the disc and “parallels” flatten as circles, with the image of the equator separating an inner circle (the frontal view, rendered yellow on Fig. 28 (right)) from an outer ring, where the back view is rendered (see the examples in Fig. 29). The flattening is one-to-one at all points except at B. Taking the closure we get a compact disc, with the outer boundary circle (the blowup set) mapping entirely onto B. The flattening preserves the metric along each individual FB meridian, though of course not globally. This preservation of the metric is what allows measurements to be made, so drawing this perspective requires careful attention to these special meridians in the construction process. The natural measurements for this perspective are angle pairs, each point on the sphere being measured by one angle choosing the FB meridian where it lies and the other the length traversed from F along that chosen meridian. As for geodesics, these can be classified in two classes: geodesics through F render as diameters and all others as closed curves (see Fig. 28 (right)). For the latter, half the geodesics will be rendered in the anterior disc (yellow in Fig. 28 (right)) as an arc of circle c in good approximation, as shown by Barre and Flocon (1968); the other half can be rendered, as the locus of a point P that moves so as to keep at a distance of half

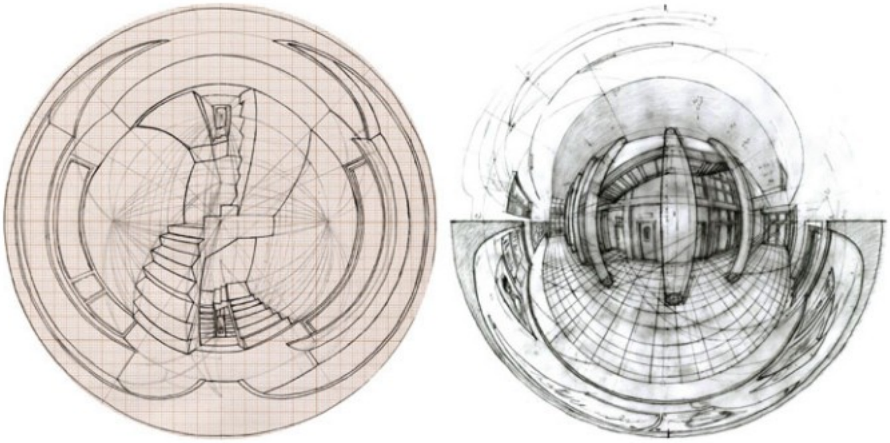

Fig. 29 Two handmade drawings of urban scenes, obtained through the process described in Araújo (2018c) (left) and Araújo (2019b) (right). All lines are contained in geodesic images of the azimuthal equidistant flattening. (Drawings by the author)

a diameter from the point of c that is across from it along the line that joins it to F. This locus can be drawn using a mechanical process involving a ruler sliding on a fixed point, as explained (Araújo 2018c) and in the ▶ Chap. 19, "Spherical Perspective" in the present volume. This can be simplified by a moving grid system using the rotational symmetries of the perspective around F (Araújo 2019b).

In the case of equirectangular perspective, we blowup the sphere at two points U and D (representing for instance the directions "up" and "down") and straighten the meridians, keeping them fixed at the circle halfway between U and D (the "equator"). In this way we obtain a cylinder, which we can now cut and unroll onto a rectangle. Unlike the case of cylindrical perspective, this rectangle will contain a record of the whole view around O. There are two classes of geodesics: geodesics through U that render onto straight vertical lines and all the others. The first (resp. second) type includes the image of vertical lines (resp. horizontals) but is not restricted to these. If we consider the set of all geodesics through two antipodal points on the equator (say, points L and R, corresponding to the observer's Left and Right), we can generate all other geodesics from translations of elements of this set. This allows for a construction of complex scenes such as that of Fig. 30 without explicit use of ruler and compass and without the limitations of a fixed grid (see (Araújo 2018a, 2019a)). As pointed shown in Araújo (2018b). These geodesics are very similar to sinusoidal curves when their apex (point of highest angular elevation) is low; hence this perspective looks like cylindrical perspective for low elevations (see Fig. 30). As the elevation rises, the geodesic images converge to a square wave, but even for high elevation they can still be rendered in good approximation with descriptive geometry constructions. In Fig. 30 we can see a drawing done on location of an equirectangular spherical perspective using the sliding grid method of (Araújo 2018a). On top of it we see a spherical anamorph of the same scene; the drawing was

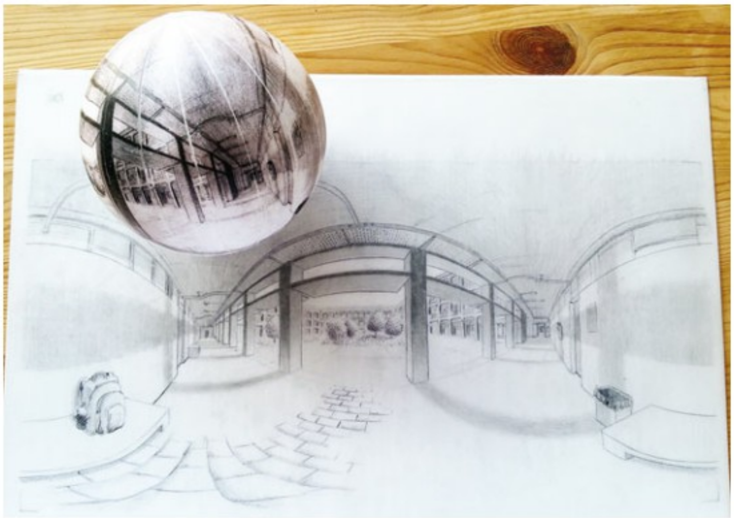

Fig. 30 A spherical anamorphosis and its equirectangular perspective. The spherical perspective drawing was done on location by the author. It was scanned, transformed on a computer, and then printed and glued on a ball to obtain the corresponding spherical anamorphosis. The author would like to thank Ph.D. student Lucas F. Olivero for making the 3D model on the top left of the picture

transformed by a computer into a sinusoidal projection, and then printed and glued onto a ball. This again shows that often the point of a perspective is to be a blueprint for the anamorphosis, instead of the other way around. We defined the perspective as the flattening of the anamorphosis because the anamorphosis is the uniquely defined object; but just as often the anamorphosis will be in practice treated as the folding of the flat perspective.

The Problem with Perspective

The view of anamorphosis we studied here was motivated mainly by the wish to solve conceptual problems with perspective. We will start by discussing what those problems are.

One might be surprised to hear are any conceptual problems with perspective at all. Linear perspective is universally used today to represent a 3D scene on a plane. Most working artists and architects take it for granted as an objective picture of an environment, identifying it with photographic representation. Mathematicians take it for a well-understood concept, made rigorous as an application of projective geometry (see ▶ Chap. 4, “Looking Through the Glass”).

Yet the nature and meaning of perspective has been a point of contention since its inception. We can see this as a contention between the views of Euclid and those of Leonardo.

Euclid and Psychophysics

We could argue that our view of anamorphosis in the present work is a recovery of concepts first formulated in Euclid's Optics with the addition of vanishing points. Or, put in another way, that the fourth axiom of Euclid's optics is the earliest known precedent for the concept of anamorphosis.

Axiom 1. *(4th axiom of Euclid's Optics) and that those things seen within a larger angle appear larger, and those seen within a smaller angle appear smaller, and those seen within equal angles appear to be of the same size (Burton 1945)*

Euclid here is postulating that for visual perception, the visual angle subtended by an object and its perceived size are the same thing. This is clearly true for a simple object in isolation of other stimuli. That is, if I take a black ball on a white background and I make it subtend progressively larger angles an observer will certainly report a larger apparent size. But it is too daring a proposition when related to complex visual environments. For instance, Ebbinghaus illusion (Ebbinghaus 1902) shows that the perceived size of a colored circle can depend strongly on the disposition of other colored circle's in its vicinity. What exactly is happening is still a matter for contention, with several theories extant (Roberts et al 2005). This is not uncommon for visual phenomena whenever global variables – rather than very well-controlled local experiments – are taken into account. Analogous problems occur in color theory, where the local phenomena are well understood and mathematically elegant, while the global theory is confusing and qualitative. So we must not take the term "apparent size" at face value. Astronomers use the term in the Euclidean sense to mean simply the size of the solid angle subtended, while in studies of perception, apparent size means the subjective impression of size as reported by human subjects.

In the latter sense, Euclid asserts too much, ignoring contextual matters. Still, a careful localized interpretation of the fourth axiom does hold water as empirical fact. Like we said before, it defines an implicit empirical scope wherein it is true, and therefore it is as interesting a concept as that scope happens to be relevant.

Still, in our own work here, we took a different, although related, path. We are not concerned with size but with form; not with the size of the solid angle subtended by the cone of an object but with the cone itself. Our principle of radial occlusion neither implies nor is implied by Euclid's 4th axiom of optics. But the emphasis on the visual angle, without reference to any projection surface, the isotropy of view, and the notion of visual cone as a function of the object rather than on some central axis is already present in Euclid, and a reading of his theorems shows that he has in mind something similar to us. The difference is his avoidance of infinity. Therefore we might say that the work here developed clarifies Euclid and adds to it the notion of points at infinity – of compactness, if you will. It is impressive to read Euclid in retrospect and notice the generality of his view at such an early time and how the late arrival of linear perspective seems by comparison a step back in generality, being a theory of representation of too particular a kind.

Leonardo's Axiom and Paradox

Leonardo considered there were many conceptual problems with perspective as formulated by Alberti. He distinguished between "natural" and "accidental" perspective. This is related (but not identical) with the more usual distinction between *natural* perspective (meaning optics, as a study of both light and visual perception) and *artificial* perspective (meaning linear perspective). Leonardo objected to the requirement in linear perspective of eye placement at single point of observation and thought that a spherical canvas would make for a more natural perspective; and he seems to have thought that in the absence of this a very distant canvas might do. In this he seemed to be concerned with the inclination of the surface normal with regard to the angle of view (in Kemp's (Kemp 1990) view, the foreshortening of the canvas just as much as the foreshortening of the picture). "Foreshortening of the canvas" is of course no more than a reference to the effects of oblique anamorphosis.

Leonardo's greatest difficulty, or at least the one that survived to our time, was based on the following axiom, which he considered a requirement of a natural perspective:

Axiom 2. *Leonardo's axiom: Among objects of equal size that which is most remote from the eye will look the smallest.*

This in itself is not contentious. But he then confusingly identified this notion with the completely different and in fact incompatible one that they should therefore be represented by metrically smaller projections. This in contrast with Euclid's fourth axiom of optics.

He gave the example still called *Leonardo's paradox* (Fig. 31): the conical projection of a sphere that moves along the plane projection actually grows as it moves away from the observer (see Araújo 2016; **?**). This "paradox" really isn't one. True, the perspective picture grows, but so does the distance of this projection to the observer, in such a way that the apparent size of the projection diminishes. By Euclid's fourth axiom, both the distal sphere and its projection will look smaller than the proximal one. Leonardo's real objection may be the disparity between the properties of the metric representation and the angular/visual properties. He would like a perspective that carried the proper visual properties of mimesis without the requirement of standing at a single point O. And he would like that the metric properties, along with the angular ones, should satisfy his axiom. Hence his preference for a spherical canvas. In this, there is a conflating of the two concepts that we separated in the present work: perspective and anamorphosis. This conflation would endure and persist as a philosophical difficulty until the twentieth century. It is in fact still a difficulty today in the way these affairs are discussed. This leads to asking the wrong questions such as whether a "perspective" has "deformations" or whether it is "natural" or whether it corresponds to the way we see. These questions vanish if we only separate the two concepts of mimesis and representation, anamorphosis, and its flattening into perspective. So that the point may be made that the paradox is no such thing – it does not point out to any failure of linear perspective in achieving what it sets out to do, but is merely a complaint

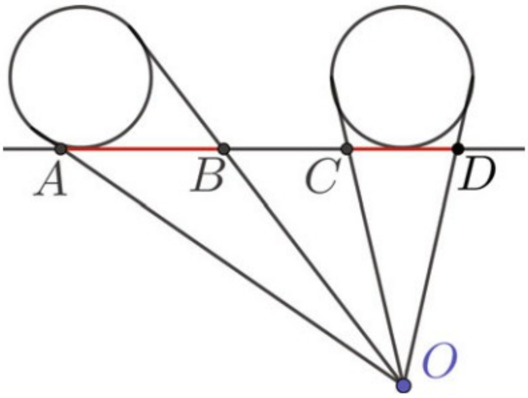

Fig. 31 Leonardo's paradox: $|AB| > |CD|$ even though the corresponding sphere is further away from O

that linear perspective does not do as much as Leonardo wishes from a perspective. But it is hard to see this as a flaw of perspective as much as a failure of Leonardo to settle on a consistent set of requirements. One cannot ask at the same time to preserve both angular and linear measurements. That linear perspective (as plane anamorphosis) does not preserve the latter is not a bug but a feature mathematically required to preserve the former.

This enduring failure to distinguish the mimetic role of anamorphosis from the representational role of perspective may be due to the fact that linear perspective and plane anamorphosis are the same physical object (the "flattening" being trivial); this identification between the anamorphosis and the corresponding perspective only happens in the case of linear perspective, and this coincidence probably made it all the harder to understand the distinction between the two concepts. It is rather unfortunate that the most "obvious" of perspectives is in fact a quite peculiar one. The matter was still contentious in dealing with cylindrical perspective, much later, and even when the practical difficulties of the drawing itself were well handled, mechanically and theoretically (Kemp 1990, p. 175).

Effects on the Development of Spherical Perspective

In the twentieth century, the discussion started by Leonardo took a particularly confusing turn and produced reams of papers in a polemic between the *realist* and *conventionalist* schools of thought. A simplified view of the matter is that the realist position, represented by Ernst Gombrich, attributes an objective quality to the ability of perspective pictures to mimic reality. This ability comes from the fact that the picture realized by the rules of perspective furnishes a properly located observer with the same bundle of light rays that he would receive from the original object. The conventionalist position, as championed by Goodman, argues that instead we see classical perspective pictures as realistic simply because we have been acculturated to them. Like in most such debates, things are not so clear as in this rapid caricature. First of all Gombrich's "realist" position is hardly clear-cut. In *Art and Illusion* (Gombrich 1960) he considered that there is no reality without interpretation and that seeing is inseparable from conceptualization: there is no *innocent eye*. Gilman (1992) argues that there is no *naturalistic* position on either side of the debate and sees it rather as a contention between conventionalist factions, Gombrich being merely a conventionalist with particular scruples where perspective is concerned, which Goodman saw as puzzling contradiction within the context of Gombrich's general position. Gombrich's objection was not so much against the contention that perception required interpretation but that this interpretation was just a cultural construct. According to Mitrović (Mitrović 2013b) it was this strong thesis of cultural relativism that the totality of perceived reality is culturally constructed, as well as associated collectivist notions that repulsed Gombrich. The positions are complex, and Vergsten (Verstegen 2011) argues that both Gombrich and Goodman are "guilty of letting extraneous issues color their discussion of the (non)conventionality of perspective." Be all this as it may, the opposing positions have been argued confusingly and in so many skirmishes that scholar's careers can be erected on the mere accountancy of blows. As in most such debates, the boxers have reached belatedly and by exhaustion the obvious conclusion that, while fresh, they refused to reach by good sense: that neither extreme position is tenable (Frigg and Hunter 2010, page xx) and that the interesting question is how exactly purely optical mimesis and convention interact.

Fortunately, however, we are not here concerned with fleshing out such intricate business. Goodman argued famously that representation cannot be mere resemblance, since resemblance is symmetric (A resembles B implies B resembles A) while representation is not (a picture may represent a horse but a horse doesn't represent its picture).

We argue that in our present formulation we have cut this gordian knot by separating the matter of *resemblance* (anamorphic equivalence, which is indeed symmetric) from that of *representation* (perspective, which is not; A being a perspective of B doesn't make B a perspective of A).

So we are not interested in dealing with this debate in the terms set by Goodman. We have answered it: linear perspective *is not* conventional – it is the only perspective that is also an anamorphosis, and anamorphosis is an optical principle that stands on top of an objective empirical fact: the principle of linear occlusion.

We still care about this debate, however, because it influenced contemporary understanding of the purely mimetic possibilities of perspective and anamorphosis. This is especially unfortunate as Goodman was at its weakest when intruding into the field of mimesis proper and has since been extensively refuted in detail – see, for instance, Mitrović (2013a). Consider the infamous phrase from *Languages of Art* (Goodman 1968). Goodman concedes for the moment the mimetic properties of perspective, but decried what he calls the "remarkable" requirements for such an illusion to occur:

> The picture must be viewed through a peephole, face on, from a distance, with one eye closed and the other motionless. The object also must be observed through a peephole, from a given (but not usually the same) angle and distance, and with a single unmoving eye. Otherwise, the light rays will not match (Goodman 1968, page 12).

The conditions of observation, as described, seem indeed remarkable, even reminiscent of an infamous scene from Kubrik's *A Clockwork Orange* when Alex is bound to a chair with eyes clamped wide open, his gaze forcedly fixed forward. But more remarkable is that the argument easily crumbles not only under the scrutiny of the empiricist but merely under that of the tourist. For all it takes is a casual stroll into the church of Saint Ignazio de Loyola in Rome and a look at its illusionary ceiling, where Andrea Pozzo indeed used "perspective" (anamorphosis in our view) as an alternative to architecture proper (Fig. 1). The Jesuits wanted a grander building than it could afford, and Pozzo constructed it in virtuality, going through all the steps of an architectural project, with plan and elevation constructions, perspective renderings, and finally anamorphic constructions . Here, the tourist looks to painted columns that extend the real ones so expertly that the seams are hard to identify. So expertly are these illusions constructed that it is hard to discern the true form of the curved ceiling. There is no peephole here, no need to close an eye and to keep the other unmoving. Goodman is stuck on the experience of small-scale anamorphoses and confuses the practical limitations of size with theoretical limitations. With a high ceiling at his disposal Pozzo constructs an *immersive* anamorphosis. At that large scale, the observer's two eyes work monocularly in good approximation. Also, the head can and is expected to rotate freely to contemplate the surrounding illusion. It is rather deceiving to say that the anamorphosis has to be seen "from a certain angle and distance." It has to be seen *from a certain point*, but on that point the eye is allowed to rotate freely. In such a large scale illusion as in Pozzo's ceiling at St. Ignazio's (or as in the large-scale nineteenth-century panoramas), the observer can even break a little with the theoretical impositions and get away with it. A large disk marks the spot from where the illusion of Pozzo should be observed, but a couple of steps away from it (or a few heads too tall or short) won't break the illusion substantially. It is quite remarkable that the arguments of Goodman could survive scrutiny in the twentieth century when Pozzo not only understood in practice the full possibilities of anamorphosis but wrote on them so eloquently and clearly in his treatise. If the eye is not innocent, far less is the mind so. It was simply the right cultural moment for such an argument to be entertained, in spite of the evidence of the eye. In the present work we would hardly engage with these arguments, which in our view have aged badly, except that they were also used in much the same way by none other than Barre and Flocon as a justification for their development of spherical perspective (Barre and Flocon 1968) or at least in the paper they wrote with Bouligand aiming at its mathematical and conceptual justification (Barre et al 1964). In the latter work the author's seek to justify their choice of spherical projection (the azimuthal equidistant projection, limited to one hemisphere) in the context of the search for a natural perspective, which in their view would satisfy the rather vague requirement of "ordering visible elements on a surface to form an image that causes on the spectator a sensation of volume and space" ("Ordonner sur une surface des éléments visibles, formant une image qui procure au spectateur des sensations de volumes e d'espace"). This desideratum (called "demande Δ") being somewhat vague, the authors seek to approach it by the constraint of an “axiome fondamental” A, a more geometrical axiom that should be, in their view, a necessary condition for such a perspective. This “axiome A” turns out to be just Leonardo’s axiom (Axiom 2). Watching what the authors proceed to do one finds that the “surface” mentioned in the requirement Δ is in fact assumed to be a plane and that “seems smaller” means metrically smaller. This is the exact same conflation of concepts that was made by Leonardo. The author’s give much the same objections to linear perspective as Leonardo, as Goodman, and in particular, two objections usually attributed to Panofsky (Panofsky 1927, 1991), but actually much older, which pretend to justify that whatever the “natural” perspective is, it can’t be classical perspective.

The first objection is that the projection of lines in the retina is curved, not straight; hence we must in fact not see lines as straight. This is a rather blunt misconception that implicitly assumes some sort of theater of the mind where some homunculus in the visual brain sits to see the retinal image (and then we might ask, in infinite regression, how does *its* visual system work?). This is in fact an old objection already aimed at Kepler’s model of vision, which Descartes answered by pointing out that the shape of the stimulus in the retina and the sensation caused by the stimuli are two different things. The retinal image is also inverted and yet we don’t see the world upside down (Kemp 1990, p. 234).

A second objection is that the example of two parallel lines going to infinity goes against Leonardo’s axiom, as we know from experience that the lines seem to converge yet in linear perspective the distance between their projections remains constant. This confuses the metric properties of the projection with the perception of these when seen from O. Araújo (2016) refutes this by pointing out that if we put the plane of projection on top of the lines then the lines will coincide with their perspective. Hence to claim that the perspective of the lines does not seem to converge would be to claim that the lines themselves don’t seem to converge. To put it more strikingly, if the perspective drawing of a long wall is not visually realistic then the real wall itself is not visually realistic. Of course the answer is that both the lines and their perspectives do appear to converge because the subtended angle from O decreases with distance in exactly the right way precisely because the drawn lines remain at a constant distance from each other. But much the same question had been raised by Schickhardt in 1623 and refuted by Kepler in a similar fashion (Kemp 1990, p.477-8). We can add that Leonardo’s paradox of the spheres has exactly the same answer: it doesn’t matter that the distal sphere has the largest projection, since the projection is seen from further away, in exactly the right measure to make it mimic the real sphere.

Being charitable and removing the layers of confusion and contradiction, one finds in the arguments of Barre, Flocon, and Bouligand one concrete and well-defined objective: to find a projection onto the plane that should cover a 180-degree angle of vision around an axis, project onto a bounded region of the plane, and be anamorphic in the whole representation. This would imply that the metric properties should be such as to save appearances (the angular properties). This is a concrete interpretation of desideratum Δ and Leonardo’s axiom. The only problem is that it can’t be done, which is also, in the end, the conclusion of Bouligand. So the azimuthal equidistant projection is chosen as simply the better compromise among the available candidates. It is all about minimizing metric deformations as far as possible. Hence the vagueness of desideratum Δ – the more strict requirement of actual mimesis could not be satisfied.

But of course, no matter what word juggling we use, nobody in the end mistakes a spherical perspective for the real thing. There is certainly a visual evocation of the object, but not mimesis in the strict sense. And this is not, as the authors seem to assume, a problem that comes merely from the sphere being non-developable. The cylinder is developable (isometric to the plane) and yet unrolling it destroys the anamorphic effect. In the case of Barre and Flocon's spherical perspective, there is simply no point O from which the drawing has a mimetic effect in the sense of the cone of the representation being the same as that of the represented object. The authors have it exactly the wrong way around: spherical perspective, unlike classical perspective (and unlike spherical *anamorphosis*), is entirely conventional. It requires an agreed upon, rather sophisticated intellectual translation in order to be read. It's achievements are of a different order: it is a flat record of one half of a spherical anamorphosis, which has good metrical properties and – crucially – is easy to draw by hand, since its line projections are arcs of circle. The authors do injustice to their own work by chasing a quixotic goal while underselling their true achievements – the rational description of a construction method for the first rigorous spherical perspective.

These philosophical misconceptions are not merely academic. Araújo (2016) argues that looking exclusively at the minimization of distortion is probably the main reason why Barre and Flocon did not extend their perspective beyond the hemispheric view. Extending their perspective to a full 360-degree view would require acceptance of rather egregious metric deformations, which would defeat their standard objections against linear perspective.

In the view we present in this work, these deformations are not a problem, as the spherical perspective does not intend to contend for the place of "natural perspective" and is by definition flawed in its mimetic properties. Mimesis is left to the anamorphic step, and we bind all the complicated phenomenological, optical, and physiological concepts purely within our axiom of radial occlusion. Rules of interpretation and empirical motivations are not allowed inside once the mathematical development begins.

In this view there is no contradiction between anamorphic mimesis and metric deformations on the perspective, just as there is no paradox between surveying and map making. The view that perspective is an entailment of an anamorphosis and a flattening also clarifies the fundamental role of anamorphosis and the arbitrary nature of perspective, giving a dual role to spherical anamorphosis and linear perspective: among anamorphoses, it gives the spherical one the canonical role, the points of the sphere being identified with rays, hence with the classes of anamorphic equivalence of spatial points; and to linear perspective it gives a special place, justifying the realist's view in its most naturalistic bent: linear perspective is indeed special, because it is the only perspective for which the flattening is trivial, that is, the only perspective that is still an anamorphosis. It therefore keeps a dual role of representation of visual information and of mimetic object, objectively creating a visual illusion, independently of any convention.

Conclusion

We have presented a theoretical framework that separates and delimits the notions of perspective and anamorphosis in such a way as to render mute long points of contention regarding whether or not curvilinear perspectives are "natural" or "correspond to the way we see." The question is found to be not well posed, and the difficulties vanish upon reformulation. Our view of anamorphosis may be seen as an update of Euclid's optics with a reworking of the assumptions involved and the addition of vanishing points, hence taming the notion of infinity, which Euclid is careful to avoid. We make a single empirical assumption – the principle of linear occlusion – abstracted into a simple geometrical notion, anamorphic equivalence, and proceed from there to obtain both practical geometrical constructions and an elegant, symmetric notion of vanishing set. We derive from this notion of anamorphosis a definition of compact central perspectives that includes all the usual curvilinear perspectives. This family, strictly speaking, excludes classical perspective, since the infinite plane is not a compact, yet it includes the restrictions of linear perspective to any compact, with classical perspective as a degenerate limiting case. Yet this notion – by viewing perspectives as an entailment of two separate steps, one being mimetic (anamorphosis) and the other representational (flattening) – clarifies the special role of linear perspective, giving it a distinguished position in the bestiary of perspectives, as the perspective that is simultaneously an anamorphosis. In this way we provide a language that naturally dissolves a philosophical misconception dating back at least to the Renaissance, simply by making the terms of discourse correspond to the operational practice of perspective.

and so

$$\begin{pmatrix} t' \\ \boldsymbol{x}' \end{pmatrix} = \begin{pmatrix} 1 & \boldsymbol{o}^\mathsf{T} \\ \boldsymbol{o} & \boldsymbol{D} \end{pmatrix} \begin{pmatrix} t \\ \boldsymbol{x} \end{pmatrix} + \begin{pmatrix} t_o \\ \boldsymbol{x}_o \end{pmatrix}. \tag{1.13}$$

By moving the origin of the new coordinate system with the velocity $\boldsymbol{v}$ as mentioned above, one finally gets the general Galilei transformation:

$$\vec{\boldsymbol{x}}' = \begin{pmatrix} 1 & \boldsymbol{o}^\mathsf{T} \\ -\boldsymbol{v} & \boldsymbol{D} \end{pmatrix} \vec{\boldsymbol{x}} + \vec{\boldsymbol{x}}_o, \tag{1.14}$$

with

$$\vec{\boldsymbol{x}} \overset{\text{def}}{=} \begin{pmatrix} t \\ \boldsymbol{x} \end{pmatrix} \quad \text{and} \quad \vec{\boldsymbol{x}}_o \overset{\text{def}}{=} \begin{pmatrix} t_o \\ \boldsymbol{x}_o \end{pmatrix}.$$

This is an *affine mapping*, or an *affine transformation*.

One gets a *linear transformation* by introducing the extended vector:

$$\begin{pmatrix} t \\ \boldsymbol{x} \\ 1 \end{pmatrix} \in \mathbb{R}^5, \tag{1.15}$$

namely

$$\begin{pmatrix} t' \\ \boldsymbol{x}' \\ 1 \end{pmatrix} = \begin{pmatrix} 1 & \boldsymbol{o}^\mathsf{T} & t_0 \\ -\boldsymbol{v} & \boldsymbol{D} & \boldsymbol{x}_0 \\ 0 & \boldsymbol{o}^\mathsf{T} & 1 \end{pmatrix} \begin{pmatrix} t \\ \boldsymbol{x} \\ 1 \end{pmatrix}. \tag{1.16}$$

Newton's fundamental laws are invariant also with respect to such a transformation. A general Galilei transformation is determined by 10 parameters: t_o, $\boldsymbol{x}_o \in \mathbb{R}^3$, $\boldsymbol{v} \in \mathbb{R}^3$ and $\boldsymbol{D} \in \mathbb{R}^{3\times 3}$. The rotation matrix $\boldsymbol{D}$, in fact, has only three main parameters since any general rotation consists of successive rotations performed around the x_1-, x_2- and x_3-axis, so the whole rotation is characterized by the three angles φ_1, φ_2 and φ_3, where, for example, the rotation around the x_1-axis is achieved by the matrix

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\varphi_1 & \sin\varphi_1 \\ 0 & -\sin\varphi_1 & \cos\varphi_1 \end{pmatrix}.$$

1.1.3 Maxwell's Equations and Galilei Transformation

The situation is completely different with Maxwell's equations of electromagnetic dynamics. They are not invariant with respect to a Galilei transformation! Indeed, in an inertial system $\mathcal{X}$, a static charge q generates only a static electric field; in an inertial frame, moving with the speed $\boldsymbol{v}$, $q\boldsymbol{v}$ is an electric current which generates there a magnetic field!

In the nineteenth century, it was believed that all physical phenomena are mechanical and electromagnetic forces could be traced to the stress states of a world-aether, the Maxwell's tensions. It was assumed that even a vacuum must be filled with aether. This aether then is the carrier of the electromagnetic phenomena.

Suppose an *inertial frame* is a reference system in which Galilei's principle of inertia is valid. Then Einstein in his *general relativity principle* claims:

The laws of nature take on the same form in all inertial systems.

For the fundamental law of mechanics, this is derived above. The principle of relativity applies neither to electrodynamics nor to optics. How should the basic equations of electrodynamics be modified so that the relativity principle is valid? This is the content of Einstein's *Theory of Special Relativity*. He expanded it in the *Theory of General Relativity*. This theory treats how the natural laws must be modified so that they are also valid in *accelerating* or not uniformly against each other moving reference systems.

1.2 Lorentz Transformation

1.2.1 Introduction

At the end of the nineteenth century, experiments were conceived which should determine the velocity of the Earth with respect to the resting cosmic aether. This speed relative to the aether can only be measured by an electromagnetic effect, e.g. the light wave propagation. But in the Michelson–Morley experiment in 1881 and 1887 no drift velocity was found. Einstein concluded:[1]

The speed of light c is always constant.

Independently of the movement of the light source and the observer, light has the same speed value in every inertial frame.

Assume a light pulse is produced at time $t = t' = 0$ in the two axis-parallel reference systems $\mathcal{X}$ and $\mathcal{X}'$ with a common origin. If the light spreads with the speed of light c in the reference system $\mathcal{X}'$, then, for example, it is true that $x_1' = c \cdot t$. From (1.7) it follows for the x_1-direction that if $\boldsymbol{v}$ has the x_1-directional component, then

$$x_1 = x_1' + vt = (c + v)t,$$

yielding, contrary to the Michelson–Morley experiment, a propagation velocity for light of $c + v > c$. Therefore, a transformation must be valid, different from the Galilei transformation. We try a linear transformation:

$$t = ft' + \boldsymbol{e}^{\mathsf{T}} \boldsymbol{x}', \tag{1.17}$$

---

[1] c from Latin celeritas: speed.

Fig. 1.3 Different ways of light: (**a**) seen by an observer in $\mathcal{X}'$, (**b**) seen by an observer in $\mathcal{X}$

$$\boldsymbol{x} = \boldsymbol{b}t' + \boldsymbol{A}\boldsymbol{x}', \tag{1.18}$$

i.e.

$$\vec{\boldsymbol{x}} = \hat{\boldsymbol{L}}'\vec{\boldsymbol{x}}' \in \mathbb{R}^4,$$

with

$$\hat{\boldsymbol{L}}' \overset{\text{def}}{=} \begin{pmatrix} f & \boldsymbol{e}^{\mathsf{T}} \\ \boldsymbol{b} & \boldsymbol{A} \end{pmatrix} \in \mathbb{R}^{4\times 4}.$$

1.2.2 Determining the Components of the Transformation Matrix

That t' is different from t (according to Galilei this was not the case, he took $t' = t$) is shown by the following reasoning. We consider two observers; observer **A** moves relative to the observer **B** in a spaceship with velocity $\boldsymbol{v}$ (Fig. 1.3). The spaceship with observer **A** has the inertial system $\mathcal{X}'$, and the observer **B** on Earth has the inertial system $\mathcal{X}$. A beam of light moves from the origin $\boldsymbol{x} = \boldsymbol{x}' = \boldsymbol{o}$ of the reference systems $\mathcal{X}$ and $\mathcal{X}'$ at time $t = t' = 0$ perpendicular to the velocity $\boldsymbol{v}$ and reaches after t' seconds for the observer **A** in the moving reference system $\mathcal{X}'$ a mirror moving also with the reference system $\mathcal{X}'$. For the observer **B** in the stationary reference system $\mathcal{X}$, the light beam reaches the mirror, which has been moved in the $\boldsymbol{v}$ direction a distance of $v \cdot t$ after t seconds. Since in all initial systems the speed of light is constant and equal to c, by Pythagorean theorem, one has

$$(ct)^2 = (vt)^2 + (L)^2 = (vt)^2 + \left(ct'\right)^2,$$

or, after solving for t,

$$\underline{\underline{t = \gamma t'}} \tag{1.19}$$

with

$$\boxed{\gamma \overset{\text{def}}{=} \frac{1}{\sqrt{1-\frac{v^2}{c^2}}}.} \tag{1.20}$$

A comparison of (1.19) with (1.17) provides for $\boldsymbol{x}' = \boldsymbol{o}$

$$\underline{\underline{f = \gamma}}. \tag{1.21}$$

For $\boldsymbol{x}' = \boldsymbol{o}$ one has $\boldsymbol{x} = \boldsymbol{v}t$, and from (1.18) it follows that $\boldsymbol{x} = \boldsymbol{b}t'$. Thus, $\boldsymbol{b}t' = \boldsymbol{v}t$, i.e. $\boldsymbol{b} = \boldsymbol{v}\frac{t}{t'}$. From (1.19) it follows, on the other hand, that $\frac{t}{t'} = \gamma$, so

$$\underline{\underline{\boldsymbol{b} = \gamma \boldsymbol{v}}}. \tag{1.22}$$

Up to now, the following transformation equations were determined:

$$t = \gamma t' + \boldsymbol{e}^{\mathsf{T}} \boldsymbol{x}', \tag{1.23}$$

$$\boldsymbol{x} = \gamma \boldsymbol{v} t' + \boldsymbol{A}\boldsymbol{x}'. \tag{1.24}$$

Equations (1.23) and (1.24) deliver a transformation of $\mathcal{X}'$ to $\mathcal{X}$. If one wants to invert this transformation, one must replace $\boldsymbol{v}$ by $-\boldsymbol{v}$, $\boldsymbol{x}$ by $\boldsymbol{x}'$, and vice versa, and t by t' and vice versa (as $\boldsymbol{A}$ and $\boldsymbol{e}$ may depend on $\boldsymbol{v}$, in the following we first write $\tilde{\boldsymbol{A}}$ and $\tilde{\boldsymbol{e}}$):

$$t' = \gamma t + \tilde{\boldsymbol{e}}^{\mathsf{T}} \boldsymbol{x},$$

$$\boldsymbol{x}' = -\gamma \boldsymbol{v} t + \tilde{\boldsymbol{A}}\boldsymbol{x},$$

which can be combined to

$$\vec{\boldsymbol{x}}' = \begin{pmatrix} \gamma & \tilde{\boldsymbol{e}}^{\mathsf{T}} \\ -\gamma \boldsymbol{v} & \tilde{\boldsymbol{A}} \end{pmatrix} \vec{\boldsymbol{x}} \overset{\text{def}}{=} \hat{\boldsymbol{L}}\vec{\boldsymbol{x}}. \tag{1.25}$$

Both transformations performed one after another must result in the identity matrix:

$$\hat{\boldsymbol{L}}'\hat{\boldsymbol{L}} \overset{!}{=} \boldsymbol{I}. \tag{1.26}$$

For the top left (1, 1)-element of the matrix product $\hat{\boldsymbol{L}}'\hat{\boldsymbol{L}}$ one gets:

$$\left(\gamma, \boldsymbol{e}^{\mathsf{T}}\right) \begin{pmatrix} \gamma \\ -\gamma \boldsymbol{v} \end{pmatrix} = \gamma^2 - \gamma \boldsymbol{e}^{\mathsf{T}} \boldsymbol{v} \overset{!}{=} 1.$$

Hence,

$$\gamma \boldsymbol{e}^{\mathsf{T}} \boldsymbol{v} = \gamma^2 - 1. \tag{1.27}$$

Taking for $\boldsymbol{e}$

$$\boldsymbol{e}^{\mathsf{T}} = \alpha \boldsymbol{v}^{\mathsf{T}} \tag{1.28}$$

and using (1.27) yields

$$\gamma \alpha v^2 = \gamma^2 - 1,$$

and moreover,

$$\gamma \alpha = \frac{1}{v^2}\left(\frac{c^2}{c^2 - v^2} - 1\right) = \frac{1}{c^2 - v^2} = \frac{\gamma^2}{c^2},$$

i.e.

$$\alpha = \frac{\gamma}{c^2}. \tag{1.29}$$

Equation (1.29) used in (1.28) finally yields

$$\underline{\underline{\boldsymbol{e}^\mathsf{T} = \frac{\gamma}{c^2}\boldsymbol{v}^\mathsf{T}.}} \tag{1.30}$$

Thus, till now we have calculated:

$$\hat{\boldsymbol{L}}' = \begin{pmatrix} \gamma & \frac{\gamma}{c^2}\boldsymbol{v}^\mathsf{T} \\ \gamma \boldsymbol{v} & \boldsymbol{A} \end{pmatrix}.$$

Obviously,

$$\tilde{\boldsymbol{e}}^\mathsf{T} = -\frac{\gamma}{c^2}\boldsymbol{v}^\mathsf{T}.$$

Suppose now that in (1.25) we have $\tilde{\boldsymbol{A}} = \boldsymbol{A}$. Then for the matrix element in the lower right corner of the matrix product $\hat{\boldsymbol{L}}'\hat{\boldsymbol{L}}$ in (1.26) we obtain

$$(\gamma \boldsymbol{v}, \boldsymbol{A}) \begin{pmatrix} -\frac{\gamma}{c^2}\boldsymbol{v}^\mathsf{T} \\ \boldsymbol{A} \end{pmatrix} = -\frac{\gamma^2}{c^2}\boldsymbol{v}\boldsymbol{v}^\mathsf{T} + \boldsymbol{A}^2 \overset{!}{=} \boldsymbol{I},$$

i.e.

$$\boldsymbol{A}^2 = \boldsymbol{I} + \frac{\gamma^2}{c^2}\boldsymbol{v}\boldsymbol{v}^\mathsf{T}. \tag{1.31}$$

From (1.27), by inserting (1.30), follows

$$\frac{\gamma^2}{c^2}v^2 = \gamma^2 - 1.$$

Plugging this into (1.31) provides

$$\boldsymbol{A}^2 = \boldsymbol{I} + \left(\gamma^2 - 1\right)\frac{\boldsymbol{v}\boldsymbol{v}^\mathsf{T}}{v^2}. \tag{1.32}$$

Since $(\gamma - 1)^2 = \gamma^2 - 2(\gamma - 1) - 1$, for $\gamma^2 - 1$ one can write

$$\gamma^2 - 1 = (\gamma - 1)^2 + 2(\gamma - 1). \tag{1.33}$$

Equation (1.33) inserted into (1.32) yields

$$\boldsymbol{A}^2 = \boldsymbol{I} + 2(\gamma - 1)\frac{\boldsymbol{v}\boldsymbol{v}^\intercal}{v^2} + (\gamma - 1)^2\frac{\boldsymbol{v}\boldsymbol{v}^\intercal}{v^2} = \left(\boldsymbol{I} + (\gamma - 1)\frac{\boldsymbol{v}\boldsymbol{v}^\intercal}{v^2}\right)^2,$$

where

$$\frac{\boldsymbol{v}\boldsymbol{v}^\intercal\boldsymbol{v}\boldsymbol{v}^\intercal}{v^4} = \frac{\boldsymbol{v}(\boldsymbol{v}^\intercal\boldsymbol{v})\boldsymbol{v}^\intercal}{v^4} = \frac{\boldsymbol{v}\boldsymbol{v}^\intercal}{v^2}$$

was used. Therefore,

$$\underline{\underline{\boldsymbol{A} = \boldsymbol{I} + (\gamma - 1)\frac{\boldsymbol{v}\boldsymbol{v}^\intercal}{v^2}}}. \tag{1.34}$$

It is, in fact, true that $\boldsymbol{A}(-\boldsymbol{v}) = \boldsymbol{A}(\boldsymbol{v})$, i.e. the above assumption that $\tilde{\boldsymbol{A}} = \boldsymbol{A}$ is correct.

Thus, the matrix $\hat{\boldsymbol{L}}$ of the Lorentz transformation is determined completely as

$$\boxed{\hat{\boldsymbol{L}} = \left(\begin{array}{c|c} \gamma & -\frac{\gamma}{c^2}\boldsymbol{v}^\intercal \\ \hline -\gamma\boldsymbol{v} & \boldsymbol{I} + (\gamma - 1)\frac{\boldsymbol{v}\boldsymbol{v}^\intercal}{v^2} \end{array}\right).} \tag{1.35}$$

For $c \to \infty$ we get $\gamma = 1$ and the Lorentz transformation turns into the Galilei transformation with $\boldsymbol{T}_{\text{Galilei}}$.

In the often in the textbooks treated special case when the velocity $\boldsymbol{v}$ is towards the x_1-axis, i.e.

$$\boldsymbol{v} = \begin{pmatrix} v \\ 0 \\ 0 \end{pmatrix},$$

one obtains

$$\hat{\boldsymbol{L}} = \left(\begin{array}{c|c} \gamma & -\frac{\gamma}{c^2}(v, 0, 0) \\ \hline -\gamma\begin{pmatrix} v \\ 0 \\ 0 \end{pmatrix} & \boldsymbol{I} + \frac{(\gamma-1)}{v^2}\begin{pmatrix} v^2 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \end{array}\right) = \begin{pmatrix} \gamma & -\frac{\gamma v}{c^2} & 0 & 0 \\ -\gamma v & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

so

$$\boxed{\begin{aligned} t' &= \gamma t - \tfrac{\gamma}{c^2} v x_1, \\ x_1' &= -\gamma v t + \gamma x_1, \\ x_2' &= x_2, \\ x_3' &= x_3. \end{aligned}} \tag{1.36}$$

Introducing as the time component in the vector $\vec{x}$ the time multiplied with the speed of light c, i.e. $x_0 = ct$, we obtain from (1.35) the transformation

$$\vec{x}' \overset{\text{def}}{=} \begin{pmatrix} ct' \\ \boldsymbol{x}' \end{pmatrix} = \left(\begin{array}{c|c} \gamma & -\frac{\gamma}{c}\boldsymbol{v}^\mathsf{T} \\ \hline -\frac{\gamma}{c}\boldsymbol{v} & \boldsymbol{I} + (\gamma - 1)\frac{\boldsymbol{v}\boldsymbol{v}^\mathsf{T}}{v^2} \end{array}\right) \begin{pmatrix} ct \\ \boldsymbol{x} \end{pmatrix}, \tag{1.37}$$

i.e. the new transformation matrix

$$\boxed{\boldsymbol{L}(\boldsymbol{v}) \overset{\text{def}}{=} \left(\begin{array}{c|c} \gamma & -\frac{\gamma}{c}\boldsymbol{v}^\mathsf{T} \\ \hline -\frac{\gamma}{c}\boldsymbol{v} & \boldsymbol{I} + (\gamma - 1)\frac{\boldsymbol{v}\boldsymbol{v}^\mathsf{T}}{v^2} \end{array}\right)} \tag{1.38}$$

is now a *symmetric matrix*, and so

$$\boxed{\begin{aligned} ct' &= \gamma ct - \frac{\gamma}{c}\boldsymbol{v}^\mathsf{T}\boldsymbol{x}, \\ \boldsymbol{x}' &= \boldsymbol{x} + (\gamma - 1)\frac{\boldsymbol{v}^\mathsf{T}\boldsymbol{x}}{v^2}\boldsymbol{v} - \gamma\boldsymbol{v}t. \end{aligned}} \tag{1.39}$$

1.2.3 Simultaneity at Different Places

It will be seen that events at different places which are simultaneous for an observer in $\mathcal{X}$ are not in general simultaneous for a moving observer in $\mathcal{X}'$. This is caused by the finite speed of light. The reference system $\mathcal{X}'$ may move towards the stationary reference system $\mathcal{X}$ with velocity $\boldsymbol{v}$. If the two events E_1 and E_2 in $\mathcal{X}$ have the coordinates $\vec{x}_1$ and $\vec{x}_2$, then they are *simultaneous* if $t_1 = t_2$. Do these two events then happen also at the same time for an observer in the reference system $\mathcal{X}'$? Due to (1.37),

$$ct_1' = \gamma ct_1 - \frac{\gamma}{c}\boldsymbol{v}^\mathsf{T}\boldsymbol{x}_1$$

and

$$ct_2' = \gamma ct_2 - \frac{\gamma}{c}\boldsymbol{v}^\mathsf{T}\boldsymbol{x}_2.$$

Dividing both equations by c and subtracting one from another yields

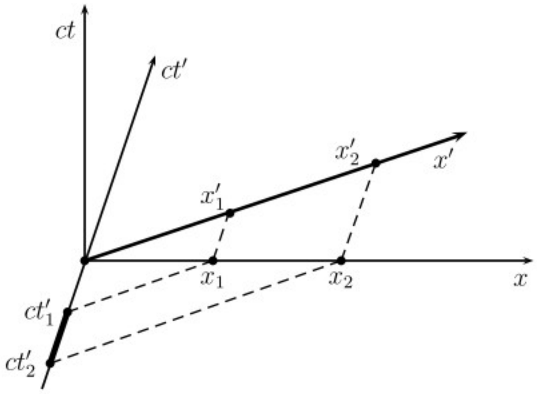
$$t_1' - t_2' = \gamma(t_1 - t_2) - \frac{\gamma}{c^2}\boldsymbol{v}^\mathsf{T}(\boldsymbol{x}_1 - \boldsymbol{x}_2),$$

so

$$\underline{\underline{t_2' - t_1' = \frac{\gamma}{c^2}\boldsymbol{v}^\mathsf{T}(\boldsymbol{x}_1 - \boldsymbol{x}_2).}}$$

The events $\vec{x}_1'$ and $\vec{x}_2'$ are also simultaneous only if the velocity $\boldsymbol{v}$ is perpendicular to the local difference $\boldsymbol{x}_1 - \boldsymbol{x}_2$. Conclusion:

Fig. 1.4 Simultaneity



> Events at different locations, which in the reference system $\mathcal{X}$ are simultaneous, need *not* be simultaneous when seen from the reference system $\mathcal{X}'$.

Example For the special case $\boldsymbol{v} = [v, 0, 0]^\mathsf{T}$ one only needs to consider the ct- and the x-coordinate (Minkowski diagram, Fig. 1.4). The Lorentz transformation does not change the x_2- and x_3-component. It is therefore possible to restrict the consideration to the two-dimensional transformations:

$$\begin{pmatrix} ct' \\ x' \end{pmatrix} = \begin{pmatrix} \gamma & -\frac{\gamma}{c}v \\ -\frac{\gamma}{c}v & \gamma \end{pmatrix} \begin{pmatrix} ct \\ x \end{pmatrix}.$$

The event $\binom{0}{x_1}$ is transformed to

$$\begin{pmatrix} ct'_1 \\ x'_1 \end{pmatrix} = \begin{pmatrix} \gamma & -\frac{\gamma}{c}v \\ -\frac{\gamma}{c}v & \gamma \end{pmatrix} \begin{pmatrix} 0 \\ x_1 \end{pmatrix} = \begin{pmatrix} -\frac{\gamma}{c}vx_1 \\ \gamma x_1 \end{pmatrix}$$

and accordingly the event $\binom{0}{x_2}$, simultaneous in $\mathcal{X}$, is transformed to $\binom{-\frac{\gamma}{c}vx_2}{\gamma x_2}$ in $\mathcal{X}'$. In Fig. 1.4, the difference on the ct'-axis is then

$$ct'_2 - ct'_1 = \frac{\gamma}{c}v(x_1 - x_2) \neq 0,$$

if $v \neq 0$ and $x_1 \neq x_2$, i.e. in the moving reference system $\mathcal{X}'$ the two events E_1 and E_2 are no longer simultaneous.

1.2.4 Length Contraction of Moving Bodies

Einstein (1905) was the first who completely demonstrated that length contraction is an effect due to the change in the notions of space, time and simultaneity brought about by special relativity. Length contraction can simply be derived from the Lorentz transformation. Let the reference system $\mathcal{X}$ be stationary and the reference system $\mathcal{X}'$ moving towards it with the speed $\boldsymbol{v}$. A yardstick has in the stationary system the two endpoints $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$. Its resting length is

$$\boldsymbol{l}_0 = \boldsymbol{x}_2 - \boldsymbol{x}_1, \tag{1.40}$$

i.e.

$$l_0^2 = (\boldsymbol{x}_2 - \boldsymbol{x}_1)^\mathsf{T}(\boldsymbol{x}_2 - \boldsymbol{x}_1). \tag{1.41}$$

At time t', the endpoints of the yardstick in the moving reference system $\mathcal{X}'$ have the coordinates $\boldsymbol{x}'_1$ and $\boldsymbol{x}'_2$. With (1.38) we obtain

$$\boldsymbol{l}_0 = \boldsymbol{x}_2 - \boldsymbol{x}_1 = \boldsymbol{A}\big(\boldsymbol{x}'_2 - \boldsymbol{x}'_1\big) \overset{\text{def}}{=} \boldsymbol{A}\boldsymbol{l}'. \tag{1.42}$$

It follows that

$$l_0^2 = \boldsymbol{l}_0^\mathsf{T}\boldsymbol{l}_0 = \boldsymbol{l}'^\mathsf{T}\boldsymbol{A}^2\boldsymbol{l}'. \tag{1.43}$$

With (1.32) one gets

$$l_0^2 = \boldsymbol{l}'^\mathsf{T}\left(\boldsymbol{I} + \big(\gamma^2 - 1\big)\frac{\boldsymbol{v}\boldsymbol{v}^\mathsf{T}}{v^2}\right)\boldsymbol{l}' = \boldsymbol{l}'^\mathsf{T}\boldsymbol{l}' + \big(\gamma^2 - 1\big)\frac{(\boldsymbol{v}^\mathsf{T}\boldsymbol{l}')^2}{v^2}. \tag{1.44}$$

In the product $\boldsymbol{v}^\mathsf{T}\boldsymbol{l}'$, only the component $\boldsymbol{l}'_\parallel$ of $\boldsymbol{l}'$ parallel to the velocity $\boldsymbol{v}$ comes into effect, i.e. it is true that $\boldsymbol{v}^\mathsf{T}\boldsymbol{l}' = \boldsymbol{v}^\mathsf{T}\boldsymbol{l}'_\parallel$. Thus,

$$l_0^2 = l'^2 + \big(\gamma^2 - 1\big)\frac{(\boldsymbol{v}^\mathsf{T}\boldsymbol{l}'_\parallel)^2}{v^2} = l'^2 + \big(\gamma^2 - 1\big){l'_\parallel}^2,$$

so

$$\underline{\underline{l'^2 = l_0^2 - \big(\gamma^2 - 1\big)l'^2_\parallel.}} \tag{1.45}$$

Since always $\gamma^2 - 1 \geq 0$, it follows from (1.45) that

$$\underline{\underline{l' \leq l_0.}} \tag{1.46}$$

The result of the yardstick length measurement therefore depends on the reference system in which the length measurement was made.

If the yardstick is parallel to the velocity $\boldsymbol{v}$, then $\boldsymbol{l}' = \boldsymbol{l}'_\parallel$ and (1.45) becomes $\gamma l' = l_0$, or

$$\boxed{l' = \frac{l_0}{\gamma} = l_0\sqrt{1 - \frac{v^2}{c^2}},} \tag{1.47}$$

i.e. as $v \to c$ one gets $l' \to 0$. For example, if the velocity is $v = 0.8c$ (i.e. 80 % of the speed of light), then the length is $l' = 0.6l_o$.

5.2.2 QUANTUM ENTANGLEMENT AND BELL STATES

Quantum entanglement for two-particle systems in a pure state was introduced in Sec. 1.3.3. It will be useful to redefine it, so that the definition also applies to *multiqubit states* of the form (5.23), as a property of states in a product Hilbert space. Moreover, it will be useful to redefine it for mixed states as well and for arbitrary n-level systems. First, consider a product of two spaces $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$. A pure state $|\Psi\rangle \in \mathcal{H}$ is said to be entangled if it cannot be written as a single tensor product of states $|\psi_1\rangle \in \mathcal{H}_1$ and $|\psi_2\rangle \in \mathcal{H}_2$, i.e., $|\Psi\rangle \neq |\psi_1\rangle \otimes |\psi_2\rangle$. Rather, it must be written as a *sum* of such products, for example, $|\Psi\rangle = a|\psi_1\rangle \otimes |\psi_2\rangle + b|\phi_1\rangle \otimes |\phi_2\rangle$.

Quantum entanglement occurring in multipartite qubit states is a powerful computation and information resource. For example, entanglement allows for dense coding of quantum information (see Sec. 5.2.5) and teleportation of quantum information (see Sec. 5.2.7). One of the central questions in quantum information is how to quantify entanglement for arbitrary n qubit states. For two-qubit pure states, there is a set of four *maximally entangled* states called *Bell states* denoted as $|BS\rangle$ and defined as follows:

$$|\Phi^+\rangle = \frac{1}{\sqrt{2}}[|00\rangle + |11\rangle], \quad |\Phi^-\rangle = \frac{1}{\sqrt{2}}[|00\rangle - |11\rangle], \tag{5.25a}$$

$$|\Psi^+\rangle = \frac{1}{\sqrt{2}}[|01\rangle + |10\rangle], \quad |\Psi^-\rangle = \frac{1}{\sqrt{2}}[|01\rangle - |10\rangle]. \tag{5.25b}$$

Clearly, Bell states cannot be written as a tensor product of single qubit states. In Sec. 5.2.3, we will present methods for explicitly constructing Bell states.

The Einstein Podolsky Rosen (EPR) paradox [20], Bell inequalities [52–55], and many quantum information and quantum computation algorithms use the Bell states extensively. Bell states and EPR concepts play an important role in testing fundamental concepts in quantum mechanics. EPR and Bell inequalities will be discussed in Secs 5.7 and 5.8.

An important property of Bell states $|BS\rangle$ (and entangled pure states in general) is: When a pure state density matrix $\rho_{\mathrm{BS}} = |\mathrm{BS}\rangle\langle\mathrm{BS}|$ is constructed from a Bell state, and is partially traced over (say) the second qubit, $\mathrm{Tr}_2\,[|\mathrm{BS}\rangle\langle\mathrm{BS}|] = \frac{1}{2}\,[|0\rangle\langle 0| + |1\rangle\langle 1|]$, the result is an incoherent state (mixed density matrix). In the case of Bell states, the first qubit, left after tracing out the second qubit, has 50% probability to be in either state $|0\rangle$ or $|1\rangle$.

The entangled pair of qubits in a Bell state could be spin 1/2 particles, where the state $|\downarrow\rangle$ can represent the qubit $|0\rangle$ and $|\uparrow\rangle$ can represent the qubit $|1\rangle$, or alternatively, the qubits could be photons, where a horizontal photon $|\leftrightarrow\rangle$ can represent the qubit $|0\rangle$ and a vertical photon $|\updownarrow\rangle$ can represent the qubit $|1\rangle$ as shown in Fig. 5.17 in Sec. 5.6.5. A method of entangling photons using degenerate down-conversion (degenerate difference frequency generation) will be described in Sec. 5.6.5. All one-qubit unitary transformations can be implemented using beam splitters and phase shifters, which will be described in Sec. 5.6.5. Moreover, beam splitters and phase shifters can be used to turn photons that are entangled in one of the Bell states into one of the other Bell states. So, photons are viable qubits that can be used for quantum information processing. The only problem is that photons do not interact (at least not in vacuum), so it might appear that two-qubit controlled gates (see below) cannot be engineered for photons, and these are essential for universal quantum computation (a universal set of gates are a set of gates such that any function can be computed using these gates). It was shown that *non-deterministic* two-qubit controlled gates for photons can be engineered [56], as described in Sec. 5.6.5.

An example of an entangled n-qubit state can be constructed using n photons in n different spatial modes (think of photon modes as being specified by the wavevector $\mathbf{k}$, such that photons in different modes correspond to photons with different wavevectors). Since photons are bosons, their state vector must be symmetrized (see Chapter 8). Such symmetrized states can be constructed by applying the symmetrization operator, $\mathcal{S}$,[4] to the state $|\mathbf{k}_1\rangle_1|\mathbf{k}_2\rangle_2 \ldots |\mathbf{k}_n\rangle_n$:

$$|\Psi_{\mathcal{S}}\rangle \equiv \sqrt{n!}\,\mathcal{S}\,|\mathbf{k}_1\rangle_1|\mathbf{k}_2\rangle_2 \ldots |\mathbf{k}_n\rangle_n = \frac{1}{\sqrt{n!}}\big[|\mathbf{k}_1\rangle_1|\mathbf{k}_2\rangle_2 \ldots |\mathbf{k}_n\rangle_n + |\mathbf{k}_2\rangle_1|\mathbf{k}_1\rangle_2 \ldots |\mathbf{k}_n\rangle_n + \cdots + |\mathbf{k}_n\rangle_1|\mathbf{k}_{n-1}\rangle_2 \ldots |\mathbf{k}_1\rangle_n\big]. \tag{5.26}$$

---

[4] The symmetrization operator, $\mathcal{S}$, [see Sec. 8.1, Eq. (8.7)], is the sum of all possible permutations of the n-qubits divided by $n!$. The additional factor of $\sqrt{n!}$ in Eq. (5.26) is for normalization, as detailed in Sec. 8.6.

There are $n!$ terms in Eq. (5.26) corresponding to the $n!$ permutations of the photons. One of the challenges of all-optical quantum computing is how to engineer such states, but, as mentioned earlier, another challenge is how to construct two-qubit gates for photons, since they do not interact in vacuum.

Problem 5.9

(a) Write the Bell states (5.25a) as four-component vectors using the notation of Problem 5.8.
(b) Write the density matrix for $|\Phi^-\rangle$ and $|\Psi^-\rangle$ as 4×4 matrices.

Answer:

$$|\Phi^+\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}1\\0\\0\\1\end{pmatrix}, \quad |\Phi^-\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}1\\0\\0\\-1\end{pmatrix}, \quad |\Psi^+\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\1\\1\\0\end{pmatrix}, \quad |\Psi^-\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\1\\-1\\0\end{pmatrix}. \tag{5.27}$$

$$\rho_{\Phi^-} = \frac{1}{2}\begin{pmatrix}1 & 0 & 0 & -1\\0 & 0 & 0 & 0\\0 & 0 & 0 & 0\\-1 & 0 & 0 & 1\end{pmatrix}, \quad \rho_{\Psi^-} = \frac{1}{2}\begin{pmatrix}0 & 0 & 0 & 0\\0 & 1 & -1 & 0\\0 & -1 & 1 & 0\\0 & 0 & 0 & 0\end{pmatrix}. \tag{5.28}$$

Entanglement Entropy

Let us try to quantify the degree of entanglement in a bipartite state, a topic that was briefly discussed in Sec. 2.5.2. We introduce a quantity called *entanglement entropy* that serves as a measure for the degree of entanglement for a bipartite pure state. Let $|\Psi\rangle \in \mathcal{H}_1 \otimes \mathcal{H}_2$ be an entangled state (e.g., $|\Psi\rangle = |BS\rangle$) and let $\rho_{12} = |\Psi\rangle\langle\Psi|$ be the pure state density matrix constructed from $|\Psi\rangle$. The reduced mixed density matrices for the two subsystems is obtained by partial tracing: $\rho_1 = \mathrm{Tr}_2\rho_{12}$, $\rho_2 = \mathrm{Tr}_1\rho_{12}$. The entanglement entropy of the bipartite pure state ρ_{12} is defined as,

$$\mathcal{E}(\rho_{12}) \equiv \mathcal{S}(\rho_1) = \mathcal{S}(\rho_2), \tag{5.29}$$

where $\mathcal{S}(\rho) = -\mathrm{Tr}\,\rho\log_2\rho$ is the von Neumann entropy of ρ. The proof that $\mathcal{S}(\rho_1) = \mathcal{S}(\rho_2)$ will be given below after discussing the Schmidt decomposition.

Problem 5.10

(a) Show that the entanglement entropy of $|BS\rangle\langle BS|$ equals 1.
(b) Consider the entangled state $|\Psi\rangle = 0.8|00\rangle + 0.6|11\rangle$. Show that the entanglement entropy $\mathcal{E}(\rho = |\Psi\rangle\langle\Psi|) = 0.699722$.
(c) Show that the result $\mathcal{E}(|BS\rangle\langle BS|) > \mathcal{E}(\rho = |\Psi\rangle\langle\Psi|)$ is not accidental, namely, $|BS\rangle\langle BS|$ has the maximal entanglement entropy $\mathcal{E}(|BS\rangle\langle BS|)$ among all pure states constructed from entangled states.

Greenberger–Horne–Zeilinger States

Entangled states can be composed of more than two qubits, e.g., the three-qubit state known as the *Greenberger–Horne–Zeilinger* (GHZ) state [52],

$$|\mathrm{GHZ}\rangle = \frac{1}{\sqrt{2}}(|000\rangle + |111\rangle), \tag{5.30}$$

or the n-qubit GHZ state,

$$|\text{GHZ}\rangle = \frac{|0\rangle^{\otimes n} + |1\rangle^{\otimes n}}{\sqrt{2}}. \tag{5.31}$$

These states are not a simple tensor product of the states of each qubit but rather a superposition that describes quantum correlations (entanglement) between the qubits. The entanglement between the n-qubits means that the state of the system cannot be specified in terms of the state of each of the n qubits individually (the state is not a product state).[5] Note that this sort of state is what we called a Schrödinger cat state at the end of Sec. 1.3.1. There we noted that these kinds of states tend to decohere quickly by virtue of interactions with an outside environment.

Although there is no standard measure for multi-qubit state entanglement (particularly for mixed states), the GHZ states are believed to be maximally entangled. Note that the trace over the third qubit (denoted by Tr_3) in a three-qubit GHZ state yields a maximally mixed two-qubit state:

$$\text{Tr}_3\left[(|000\rangle + |111\rangle)(\langle 000| + \langle 111|)\right] = \frac{1}{2}\left[|00\rangle\langle 00| + |11\rangle\langle 11|\right].$$

Entanglement of qubits will be discussed from the perspective of correlation between the particles in Sec. 6.1.8, where we consider two-qubit entanglement, three-qubit entanglement, mutli-qubit entanglement, and also qutrit entanglement (Sec. 6.2) as well as "continuous-variable entanglement" (Sec. 6.5).

Schmidt Decomposition

An important and useful result concerning pure states of a bipartite system emerges from the *Schmidt decomposition theorem* of linear algebra (see below). We have in mind two Hilbert spaces $\mathcal{H}_A$ and $\mathcal{H}_B$ of respective dimensions n_A and n_B and their tensor product space $\mathcal{H}_{AB} = \mathcal{H}_A \otimes \mathcal{H}_B$. The theorem states that for pure states $|\psi\rangle \in \mathcal{H}_{AB}$, there exist two orthonormal sets of states $\{|\xi_{i,A}\rangle \in \mathcal{H}_A\}$ and $\{|\varphi_{i,B}\rangle \in \mathcal{H}_B\}$ with $i = 1, 2, \ldots, \mathcal{N}_S$, where $\mathcal{N}_S = \min(n_A, n_B)$, such that the state $|\psi\rangle$ can be written as a sum,

$$\boxed{|\psi\rangle = \sum_{i=1}^{\mathcal{N}_S} \lambda_i \, |\xi_{i,A}\rangle|\varphi_{i,B}\rangle, \quad 0 \le \lambda_i \le 1, \ \sum_{i=1}^{\mathcal{N}_S} \lambda_i^2 = 1.} \tag{5.32}$$

The numbers λ_i are called *Schmidt coefficients*, and their number $\mathcal{N}_S$ is called the *Schmidt number*. The basis functions $|\xi_{i,A}\rangle$ and $|\varphi_{i,B}\rangle$ are called *Schmidt basis functions*. Note that we can write Eq. (5.32) as $|\psi\rangle = \sum_i \sqrt{p_i}\, |\xi_{i,A}\rangle|\varphi_{i,B}\rangle$, where p_i are the occupation probabilities for the states $|\xi_{i,A}\rangle$ and $|\varphi_{i,A}\rangle$, i.e., $\lambda_i = \sqrt{p_i}$.

The proof of Eq. (5.32) uses the singular value decomposition theorem [57]. Consider the expansion of the pure state $|\psi\rangle \in \mathcal{H}_A \otimes \mathcal{H}_B$ in terms of bases $\{|j\rangle \in \mathcal{H}_A$ and $\{|k\rangle \in \mathcal{H}_B$, $|\psi\rangle = \sum_{j,k} a_{jk}|j\rangle|k\rangle$. If $\dim \mathcal{H}_A \neq \dim \mathcal{H}_B$, then the matrix $a = \{a_{jk}\}$ is not a square matrix and therefore cannot be diagonalized. The theorem states that the matrix a can be written as a product $a = u\, d\, v^\dagger$, where u and v are unitary matrices and d is a diagonal matrix with nonnegative elements d_{ii}; these nonzero diagonal elements of d are called the *singular values* of the matrix a. Thus,

$$|\psi\rangle = \sum_{j,k} a_{jk}|j\rangle|k\rangle = \sum_{i=1}^{\mathcal{N}_S} \sum_{j,k} u_{ji} d_{ii} v_{ki}^\dagger |j\rangle|k\rangle. \tag{5.33}$$

Letting $|\xi_{i,A}\rangle = \sum_j u_{ji}|j\rangle$, $|\varphi_{i,B}\rangle = \sum_k v_{ki}^\dagger|k\rangle$, and $\lambda_i = d_{ii}$, yields Eq. (5.32). The singular value decomposition of a matrix a is pictorially shown in Fig. 5.2.

---

[5] The state in Eq. (5.31) is sometimes called a *noon* state, since it can be written as $|\text{noon}\rangle = (|n\rangle_0|0\rangle_1 + |0\rangle_0|n\rangle_1)/\sqrt{2}$, which is a superposition of n particles in state 0 and zero particles in state 1, and vise versa. A more general form of Eq. (5.31) that contains a phase angle is $|\text{GHZ}\rangle = (|0\rangle^{\otimes n} + e^{i\theta}|1\rangle^{\otimes n})/\sqrt{2}$.

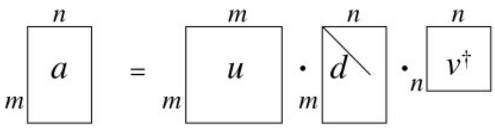

FIG 5.2 Singular value decomposition of an $m \times n$ matrix a into $a = u\,d\,v^\dagger$. The bullets imply matrix multiplication. u is an $m \times m$ matrix, d is an $m \times n$ matrix, and v is an $n \times n$ matrix.

Problem 5.11

(a) Show that $\{|\xi_{i,A}\rangle\}$ and $\{|\varphi_{i,B}\rangle\}$ are orthonormal sets of vectors using the unitarity of u and v.
(b) Under what condition on the amplitudes a_{jk}, is the condition $\sum_i \lambda_i^2 = 1$ satisfied?

Problem 5.12

If ABC is a composite system composed of three subsystems, A, B, and C, are there pure states $|\psi\rangle$ of ABC that cannot be written in the form $|\psi\rangle = \sum_i \lambda_i\, |\xi_{i,A}\rangle|\varphi_{i,B}\rangle|\chi_{i,C}\rangle$, where the λ_i are nonnegative, $\sum_i \lambda_i^2 = 1$ and the basis states are orthonormal? That is, can we always write $|\psi\rangle_{ABC} = \sum_i \sqrt{p_i}\, |\xi_{i,A}\rangle|\varphi_{i,B}\rangle|\chi_{i,C}\rangle$ with orthogonal basis functions?

Answer: Schmidt decomposition of tripartite pure states is not possible in general. If it was possible, the partial trace of the density matrix ρ_{ABC} over A and B would have the same "spectrum" of probabilities as would the trace of ρ_{ABC} over C (this is called a strong "equal spectrum" condition of the partial traces). Now, consider the state $\frac{1}{2}(|00\rangle_{AB} + |11\rangle_{AB})|0\rangle_C$, and show that this "equal spectrum" condition is not satisfied.

Schmidt Decomposition and Entanglement Entropy: The Schmidt decomposition theorem can be used to determine the entanglement entropy of an entangled pure state [defined in Eq. (5.29)],

$$\rho_{AB} = |\psi\rangle\langle\psi| = \sum_{i=1}^{\mathcal{N}_S} \lambda_i\, |\xi_{i,A}\rangle|\varphi_{i,B}\rangle \sum_{j=1}^{\mathcal{N}_S} \lambda_j\, \langle\xi_{j,A}|\langle\varphi_{j,B}|. \tag{5.34}$$

Taking the partial trace of ρ_{AB} over B yields,

$$\rho_A = \mathrm{Tr}_B[\rho_{AB}] = \sum_{i=1}^{\mathcal{N}_S} \lambda_i^2\, |\xi_{i,A}\rangle\langle\xi_{i,A}|, \tag{5.35}$$

which is a mixed state of subsystem A. Similarly, taking partial trace of ρ_{AB} over A yields,

$$\rho_B = \mathrm{Tr}_A[\rho_{AB}] = \sum_{i=1}^{\mathcal{N}_S} \lambda_i^2\, |\varphi_{i,B}\rangle\langle\varphi_{i,B}|, \tag{5.36}$$

which is a mixed state of subsystem B. We conclude that there is spectral equality of ρ_A and ρ_B, i.e., since $\{|\xi_{i,A}\rangle \in \mathcal{H}_A\}$ and $\{|\varphi_{i,B}\rangle \in \mathcal{H}_B\}$ are orthonormal sets, then $\{\lambda_i^2\}$, $(i = 1, 2, \ldots \mathcal{N}_S)$ are the nonzero eigenvalues of both ρ_A acting in $\mathcal{H}_A$ and ρ_B acting in $\mathcal{H}_B$. Thus,

If $|\psi\rangle \in \mathcal{H}_A \otimes \mathcal{H}_B$ and $\rho_{AB} = |\psi\rangle\langle\psi|$ is *the pure density operator constructed from* $|\psi\rangle$, then $\rho_A = \mathrm{Tr}_B[\rho_{AB}]$ and $\rho_B = \mathrm{Tr}_A[\rho_{AB}]$ have the same spectrum, $\{\lambda_i^2\}$, $(i = 1, 2, \ldots \mathcal{N}_S)$.

Since λ_i^2 is the probability for observing the states $|\xi_{iA}\rangle\langle\xi_{iA}|$ and $|\varphi_{iB}\rangle\langle\varphi_{iB}|$,

$$\mathcal{S}_A = \mathcal{S}_B = -\sum_{i=1}^{\mathcal{N}_S} \lambda_i^2 \log_2 \lambda_i^2, \tag{5.37}$$

i.e., the von Neumann entropies of the subsystems of a pure state are equal. These range between 0 (for a pure state, $\mathcal{N}_S = 1$) and $\log_2 \mathcal{N}_S$. Unless only one of the λ_i is nonzero, i.e., the Schmidt number is unity, the purity of the subsystems is not unity, and their von Neumann entropy are non-zero. Clearly, this "*entanglement entropy*" is not the entropy we consider in statistical mechanics and thermodynamics; here, we start with a system in a pure state, divide the system into two subsystems, and find that the entropy of the whole system is not the sum of the entropies of the subsystems; this von Neumann entropy is not extensive; hence, it is not always identical to the thermodynamic entropy.

Problem 5.13

(a) Take the partial trace over subsystem B of the pure state density matrix $\rho = |\psi\rangle\langle\psi|$ with $|\psi\rangle = \sum_{j,k} a_{jk}|j\rangle|k\rangle$ and show that $\rho_A = \mathrm{Tr}_B\ \rho = aa^\dagger$.
(b) Find ρ_A for the Bell state $|\Phi^+\rangle$.
(c) Calculate the entropy $\mathcal{S}_A$.

Answers: (a) $\rho_A = \mathrm{Tr}_B\ \rho = \sum_k a_{jk}a^*_{kj}$. (b) For the Bell state $|\Phi^+\rangle$, $a = \begin{pmatrix} \frac{1}{\sqrt{2}} & 0 \\ 0 & \frac{1}{\sqrt{2}} \end{pmatrix}$, so $\rho_A = aa^\dagger = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}$.

(c) $\mathcal{S}_A = 1$.

The Schmidt coefficients, λ_i, can be used to distinguish separable pure states from entangled pure states. A separable pure state is characterized by a vector of Schmidt coefficients with only one nonvanishing entry, whereas the Schmidt vector of an entangled state has at least two nonvanishing components. A pure state has maximal entanglement entropy if its Schmidt coefficient vector is

$$\{\lambda_i\} = \{1/\sqrt{\mathcal{N}_S}, \ldots, 1/\sqrt{\mathcal{N}_S}\}, \tag{5.38}$$

where $\mathcal{N}_S$ is the Schmidt number. The Schmidt coefficients relate the degree of entanglement of pure bipartite states to the von Neumann entropy of the corresponding reduced density matrices of the two subsystems composing the system—a pure reduced density matrix with vanishing von Neumann entropy corresponds to a separable state, whereas a maximally entangled state leads to the maximum von Neumann entropy density matrix. It is easy to verify that Eq. (5.38) maximizes the entropy of the subsystems, $\mathcal{S}(\{\lambda_i\}) = -\sum_{i=1}^{\mathcal{N}_S} \lambda_i^2 \log_2 \lambda_i^2$, by maximizing the von Neumann entropy $\mathcal{S}(\{\lambda_i\})$ with respect to the λ_i under the density matrix trace constraint condition $\mathcal{G}(\{\lambda_i^2\}) \equiv \sum_{i=1}^{\mathcal{N}_S} \lambda_i^2 = 1$ by forming the function $\mathcal{F}(\{\lambda_i\}) = \mathcal{S} + \gamma\mathcal{G}$, where γ is a Lagrange multiplier, setting $\frac{\partial \mathcal{F}}{\partial \lambda_i} = 0$ for all i, and determining γ, such that the constraint condition is satisfied [25].

Mixed-State Entanglement

Not only pure states but also mixed states of a quantum system consisting of two or more subsystems can be entangled. Consider two quantum systems A and B with corresponding density matrices ρ_A and ρ_B, and let ρ_{AB} be the density matrix of the composite system. Is $\rho_{AB} = \rho_A \otimes \rho_B$? The answer is affirmative only if there is no correlation between the two systems. (Correlation between systems will be discussed in Sec. 6.1.8.) The nature of the correlations between systems is related to the notion of *separability*. Two systems A and B are said to be separable if the density matrix ρ_{AB} can be written as a convex sum of product states,

$$\rho_{AB} = \sum_{i=1}^{M} p_i\, \rho_A^i \otimes \rho_B^i, \quad p_i > 0, \quad \sum_{i=1}^{M} p_i = 1, \tag{5.39}$$

where ρ_A^i and ρ_B^i $(i = 1, 2, \ldots, M)$ are proper density matrices (hermiticity, unit trace, and semipositivity). A mixed state was defined by Werner [58] to be entangled if it is *inseparable*, i.e., if it *cannot* be written in the form (5.39).

1.3. Integrals involving vectors

Circulation of a vector field

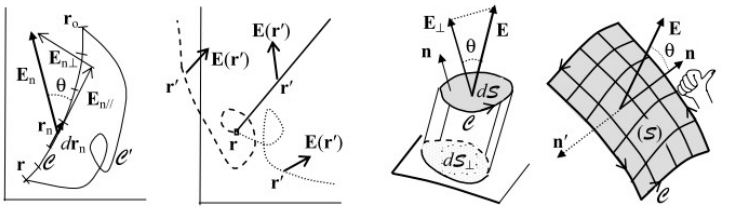
The circulation of a vector field $\mathbf{E}$ in a displacement $d\mathbf{r} = dx\,\mathbf{e}_x + dy\,\mathbf{e}_y + dz\,\mathbf{e}_z$ is $\mathbf{E}.d\mathbf{r}$ (Figure 1.2a). The work of a force is a typical example of circulation. The circulation of $\mathbf{E}$ along a curve $\mathcal{C}$ going from $\mathbf{r}$ to $\mathbf{r}_o$ is the *line integral*

$$C = \int_{\mathcal{C}} d\mathbf{r}.\mathbf{E} = \int_{\mathbf{r}}^{\mathbf{r}_o} d\mathbf{r}.\mathbf{E} = \int_{\mathbf{r}}^{\mathbf{r}_o} dr\, E_{//} = \int_{\mathbf{r}}^{\mathbf{r}_o} [dx\, E_1 + dy\, E_2 + dz\, E_3]\,, \qquad [1.24]$$

where $d\mathbf{r}$ is the infinitesimal displacement along the path $\mathcal{C}$ and $E_{//}$ is the tangential component of $\mathbf{E}$. The circulation is a scalar quantity defined as the limit of the sum of the scalar products $d\mathbf{r}_n.\mathbf{E}_n$ of the infinitesimal elements $d\mathbf{r}_n$ of $\mathcal{C}$ and the fields $\mathbf{E}_n$ at these elements. To calculate the integral in the general case, a parametric representation of the curve $x = x(u)$, $y = y(u)$ and $z = z(u)$ may be used, where u is any parameter with u and u_o corresponding to the extreme positions $\mathbf{r}$ and $\mathbf{r}_o$. The components E_α become functions of u and the circulation becomes an integral over u

$$C = \int_{\mathcal{C}} d\mathbf{r}.\mathbf{E} = \int_{u}^{u_o} du\ [\ (dx/du)\, E_1(u) + (dy/du)\, E_2(u) + (dz/du)\, E_3(u)\ ]. \qquad [1.25]$$

If the field has a uniform tangential component $E_{//} = E$ along the path $\mathcal{C}$, its circulation is $C = EL_{\mathcal{C}}$, where $L_{\mathcal{C}}$ is the length of the path. On the other hand, if $\mathbf{E} = E\,\mathbf{e}_z$ is uniform in the direction Oz, its circulation is $\int_{\mathcal{C}} d\mathbf{r}.\mathbf{E} = \int_{z}^{z_o} dz\ E = (z_o - z)E$.



(a) (b) (c) (d)

Figure 1.2. *a) Circulation of* $\mathbf{E}$ *along a path* $\mathcal{C}$ *going from* $\mathbf{r}$ *to* $\mathbf{r}_o$. If $\mathbf{E}$ *is conservative, this circulation is equal to* $V(\mathbf{r}) - V(\mathbf{r}_o)$ for any $\mathcal{C}$. *b) Setting* $V(\infty) = 0$, $V(\mathbf{r})$ *is the circulation of* $\mathbf{E}$ *along an arbitrary path going from* $\mathbf{r}$ *to infinity. c) The flux of* $\mathbf{E}$ *through an infinitesimal surface* $d\mathcal{S}$. *d) The flux through an open surface* $\mathcal{S}$ *bounded by an oriented contour* $\mathcal{C}$

Flux of a vector field

Consider the integral over a surface $\mathcal{S}$

$$\Phi = \iint_{\mathcal{S}} d\mathcal{S}\,\mathbf{n}.\mathbf{E}(\mathbf{r}) = \iint_{\mathcal{S}} d\mathcal{S}\,E(\mathbf{r})\cos\theta = \iint_{\mathcal{S}} d\mathcal{S}\,E_\perp(\mathbf{r}), \qquad [1.26]$$

where $\mathbf{E}(\mathbf{r})$ is a vector field, $\mathbf{n}$ is the unit vector normal to the surface $\mathcal{S}$ at the running point $\mathbf{r}$, θ is the angle of $\mathbf{E}$ with $\mathbf{n}$ and $E_\perp$ is the component of $\mathbf{E}$ in the direction of $\mathbf{n}$. This integral is the *flux* of $\mathbf{E}$ through $\mathcal{S}$. The flux $d\Phi = d\mathcal{S}\,\mathbf{n}.\mathbf{E}(\mathbf{r})$ through the infinitesimal area $d\mathcal{S}$ is a scalar quantity and so is the flux. Note that we may write $d\Phi = d\mathcal{S}\,E_\perp(\mathbf{r})$, where $E_\perp(\mathbf{r})$ is the normal component of $\mathbf{E}$, or $d\Phi = d\mathcal{S}_\perp\,E(\mathbf{r})$, where $d\mathcal{S}_\perp$ is the projection of $d\mathcal{S}$ on the normal plane to $\mathbf{E}$ (Figure 1.2c). $d\Phi$ is positive or negative, depending on whether θ is acute or obtuse, and it vanishes if $\mathbf{E}$ is tangent to $\mathcal{S}$. Note also that $\mathbf{n}$ has two possible orientations; by changing the direction of $\mathbf{n}$, we change the sign of Φ. In the case of an open surface, which is bounded by an oriented closed curve $\mathcal{C}$, we choose $\mathbf{n}$ according to the right-hand rule (Figure 1.2d). In the case of a closed surface $\mathcal{S}$, we choose $\mathbf{n}$ oriented outward; Φ is then the outgoing flux.

The flux is additive both for the vector field and for the area. In the particular case of a field having a uniform component in the direction of $\mathbf{n}$, its flux is $\Phi = B_\perp \mathcal{S}$. Another physically interesting case is that of a radial field $\mathbf{E} = Kq\mathbf{r}/r^3$ of a charge q. Its flux through a closed surface $\mathcal{S}$ is $\Phi = Kq \iint_{\mathcal{S}} d\mathcal{S}\,\mathbf{n}.\mathbf{r}/r^3 = Kq\Omega$, where Ω is the solid angle of the cone, whose apex is at q and which is subtended by $\mathcal{S}$: it is equal to 4π if q is inside $\mathcal{S}$ and equal to 0 if q is outside $\mathcal{S}$.

1.4. Gradient and curl, conservative field and scalar potential

The work of a force $\mathbf{F}$ acting on a particle of mass m in a displacement $d\mathbf{r}$ is $dW = \mathbf{F}.d\mathbf{r}$. This work is transformed into kinetic energy if no other force acts on the particle. Conversely, to displace the particle without acquiring kinetic energy dU_K, an external agent must exert a force $\mathbf{F}' = -\mathbf{F}$ and supply a work $dW' = -\mathbf{F}.d\mathbf{r}$. If the force is *conservative*, this work is transformed into potential energy dU_P of the particle in the field of force $\mathbf{F}$. This analysis can be repeated for any vector field $\mathbf{E}$. Its circulation along a path $\mathcal{C}$ going from $\mathbf{r}$ to $\mathbf{r}_o$ depends in general on $\mathbf{r}$ and $\mathbf{r}_o$ and also on the path $\mathcal{C}$. Its circulation on a closed path is not necessarily equal to zero. The differential form $dx\,E_1 + dy\,E_2 + dz\,E_3$ is a total differential if the components E_α are the partial derivatives of a scalar function $-V$ where V is called the *scalar potential* corresponding to the field of force $\mathbf{F}$. Then, we have $E_1 = -\partial_1 V$, $E_2 = -\partial_2 V$, and $E_3 = -\partial_3 V$, which we write in the vector form

trigonometry in section 5.5 in many contexts. The material at the end of the chapter is aimed straight at a wonderful result, Feuerbach's theorem about five circles related to a triangle. This tour de force shows the depth you can achieve with these methods.

En route you'll encounter more strands of advanced Euclidean geometry that you could follow to many fascinating parts of the subject. To limit the excursions, these strands are generally abandoned quickly. The exercises in section 5.11 will pursue some of them. Return to others as you please in later years, and follow them into the vast literature of this fascinating part of geometry!

5.1 Four concurrence theorems

Concepts

- Standard triangle terminology and notation
- Edge bisectors of ΔABC
- Circumcircle, circumcenter O, and circumradius R
- Angle bisectors
- Incircle, incenter I, and inradius r
- Medians and centroid G
- Altitudes and orthocenter H

The theorems in this section often constitute the most intricate part of an elementary geometry text. They're related to almost all advanced work in triangle and circle geometry.

For triangle ΔABC as in figure 5.1.1, let A', B', and C' denote the midpoints of the edges a, b, and c opposite vertices A, B, and C. That notation is used throughout this chapter. The perpendicular bisectors of a and b meet at a point O; if they coincided or were parallel, the transitivity theorem for parallel lines and the alternate interior angles theorem would imply $a \parallel b$. By the perpendicular bisector theorem, O is equidistant from

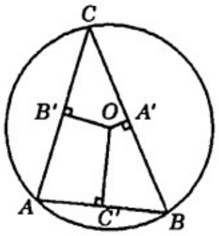

Figure 5.1.1 ΔABC, its circumcenter O, and its circumcircle

B and C and from C and A, hence from A and B, so it lies on the perpendicular bisector of c. This proves

***Theorem 1* (*Edge bisectors theorem*).** The perpendicular bisectors of the edges of ΔABC meet at a point O equidistant from its vertices.

O is called the *circumcenter* of ΔABC. The circle with center O through A, B, and C is the *circumcircle* of ΔABC. Its radius R is the *circumradius.*

Theorem 2. Any three noncollinear points lie on a unique circle.

Proof. Theorem 1 shows that the circle exists. To prove its uniqueness, note that the center of any circle through the vertices of a triangle is equidistant from them, hence must lie on the edge bisectors, so must coincide with the circumcenter. ♦

The *bisector* of angle $\angle POQ$ is the line g through its vertex O such that, if R is a point on g inside $\angle POQ$, then $\angle POR \cong \angle ROQ$. An argument suggested by figure 5.1.2 shows that the bisector consists of O and all points equidistant from lines $\overleftrightarrow{OP}$ and $\overleftrightarrow{OQ}$ that are interior to $\angle POQ$ or its vertical counterpart.

Now consider the bisectors of the angles of ΔABC, as in figure 5.1.3. Since the ends of edge a lie on different rays of $\angle A$, that angle's bisector meets a at some point X. For the same reason, the bisector of $\angle C$ meets segment $\overline{AX}$. The bisectors' intersection I is equidistant from edge lines $\overleftrightarrow{AB}$ and $\overleftrightarrow{CA}$ and from $\overleftrightarrow{CA}$ and $\overleftrightarrow{BC}$, hence from $\overleftrightarrow{BC}$ and $\overleftrightarrow{AB}$, so it lies on the bisector of $\angle B$. This proves

***Theorem 3* (*Angle bisectors theorem*).** The angle bisectors of ΔABC meet at an interior point I equidistant from the edge lines.

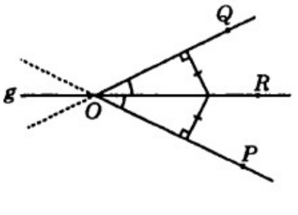

Figure 5.1.2 Bisector of $\angle POQ$

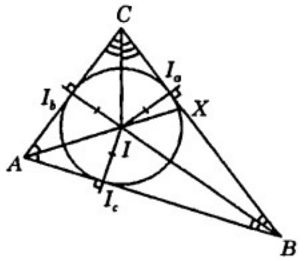

Figure 5.1.3 ΔABC, its incenter I, and its incircle

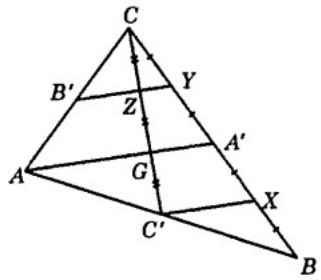

Figure 5.1.4 Proof of lemma 4: ΔABC, two medians, and centroid G

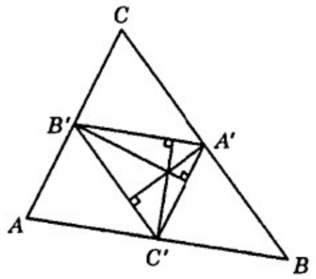

Figure 5.1.5 ΔABC and its medial triangle $\Delta A'B'C'$

I is called the *incenter* of ΔABC. The common distance r from I to the edge lines is the triangle's *inradius*. The circle with center I and radius r is the *incircle*. It's tangent to the edge lines at points I_a, I_b, and I_c within edges a, b, and c. You can show easily that the incircle is the only circle tangent to all three lines at points interior to the edges. Three more circles are tangent to these lines, however, at points outside the edges. They're studied in detail in section 5.9.

Segments $\overline{AA'}$, $\overline{BB'}$, and $\overline{CC'}$ in ΔABC are called its *medians*.

Lemma 4. $\overline{AA'}$ and $\overline{CC'}$ meet at a point G two thirds of the way from C to C'.

Proof. As shown in figure 5.1.4, C and C' lie on different legs of $\angle A$ and $\overrightarrow{AA'}$ lies in the interior of $\angle A$, so $\overline{AA'}$ and $\overline{CC'}$ meet. Let X and Y be the midpoints of $\overline{BA'}$ and $\overline{CA'}$. By the same argument, $\overline{YB'}$ and $\overline{CC'}$ meet at a point Z. Then $\overleftrightarrow{YB'} \parallel \overleftrightarrow{AA'}$ since Y and B' are edge midpoints of $\Delta AA'C$. Similarly, $\overleftrightarrow{AA'} \parallel \overleftrightarrow{XC'}$, hence $CZ = ZG = GC'$. ♦

Theorem 5 (Medians theorem). The medians of ΔABC meet at a point G two thirds of the way from any vertex to the midpoint of the opposite side.

Proof. Apply lemma 4 to ΔBAC: $\overline{BB'}$ and $\overline{CC'}$ meet at the same point G as $\overline{AA'}$ and $\overline{CC'}$. ♦

G is called the *centroid* of ΔABC. $\Delta A'B'C'$ is its *medial* triangle. The following properties of these triangles, shown in figure 5.1.5, are easy to verify.

Theorem 6. The edges of the medial triangle are parallel to those of ΔABC and half their length. Also,

$$\Delta ABC \sim \Delta A'B'C' \cong \Delta AB'C' \cong \Delta A'BC' \cong \Delta A'B'C.$$

The medians of ΔABC contain those of the medial triangle, hence these triangles have the same centroid. The edge bisectors of ΔABC contain the altitudes of the medial triangle.

The feet of the altitudes of ΔABC through vertices A, B, and C are denoted by D, E, and F. From a given ΔABC it's simple to construct a new triangle whose medial triangle is ΔABC. Since the altitudes of ΔABC lie in the edge bisectors of the new triangle, the altitude lines are concurrent. This proves

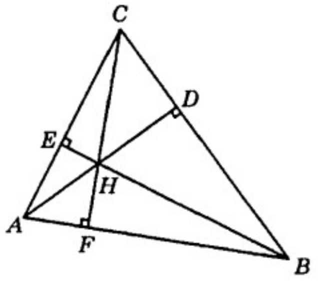
***Corollary 7* (*Altitudes theorem*).** The altitude lines of triangle ΔABC meet at a point H.

H is called the *orthocenter*[1] of ΔABC. It's shown in figure 5.1.6.

***Corollary** 8.* The circumcenter of a triangle is the orthocenter of its medial triangle.

A set of lines that pass through a single point is called *concurrent*.[2] Euclid described the concurrence of the edge bisectors and angle bisectors of a triangle.[3] He didn't mention concurrence of altitudes or medians. But the altitudes' concurrence is so closely related to that of the angle bisectors that it must have been familiar then. The medians' concurrence is included as a very elementary result in Archimedes' treatise "On plane equilibria."[4] The terminology *circumcircle*, *inradius*, etc., was introduced in the late

Figure 5.1.6 ΔABC and its orthocenter H



---

[1] The prefix *ortho-* occurs in many areas of mathematics. It stems from a Greek word for *upright*. Here that refers to the altitudes.

[2] From the Latin verb *curro* and prefix *con-*, which mean *run* and *together*.

[3] Euclid [1908] 1956, book IV, propositions 4 and 5.

[4] Archimedes [1912] n.d., book I, proposition 14.

nineteenth century.[5] At that time the following notation for points and distances related to ΔABC was standardized:

$A\ B\ C$ .... vertices,
$a\ b\ c$ ..... opposite edges,
$A'\ B'\ C'$ ... midpoints of opposite edges,
$D\ E\ F$ .... feet of corresponding altitudes,
$I_a\ I_b\ I_c$ .... opposite incircle tangency points,
$G\ H$ ...... centroid, orthocenter,
$O\ I$ .... circumcenter, incenter,
$R\ r$ .... circumradius, inradius.

Further standard notation is introduced later in this chapter.

5.2 Menelaus' theorem

Concepts

Directed distances
Menelaus' product
Menelaus' theorem

Menelaus' theorem is included in this chapter for two reasons. In the next section, it leads to Desargues' theorem, which was used in section 1.1 to settle a question in perspective drawing. In section 5.4, Menelaus yields Ceva's theorem, a generalization of three of the four concurrence theorems that started this chapter.

Menelaus' and several related theorems involve both the order of points on various lines and some ratios of distances between them. To consider these simultaneously, it's convenient to use coordinate geometry on one line g at a time. Give g a scale c. In place of the distance $PQ = |c(P) - c(Q)|$ between points P and Q on g consider their *directed distance*

$$P \text{ to } Q = c(Q) - c(P),$$

so that

$$P \text{ to } Q = -(Q \text{ to } P) \qquad PQ = |P \text{ to } Q|.$$

Although the scale c is suppressed in this notation, you need it to compute the directed distance. Most authors use the same symbol PQ for directed and undirected distances; you must rely on the context to distinguish the concepts. However, directed distances see only limited use in this text, and

---

[5] See W. H. H. H. 1883.

.2 ! ?

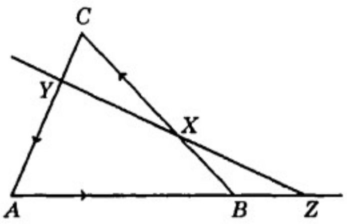


Figure 5.2.1
Menelaus' theorem

it seems worthwhile to make them visibly different. In a diagram, you can indicate the use of an unnamed scale for a line g by drawing an arrow from some point on g to a point with a larger coordinate, like this: —>— .

Directed distances usually appear by twos, in ratios. That explains why the scale is suppressed from the notation: For any points P, Q, R, and S on g with $R \neq S$, the ratio $(P \text{ to } Q)/(R \text{ to } S)$ doesn't depend on the scale. That is, if d is another scale for g, then

$$\frac{P \text{ to } Q}{R \text{ to } S} = \frac{c(Q) - c(P)}{c(S) - c(R)} = \frac{d(Q) - d(P)}{d(S) - d(R)} .$$

It's easy to prove that; see exercise 4.1.7. Signs of ratios like this are often used to convey information about the order of points on g. For example, if P, Q, and R lie on g and $Q \neq R$, then

$$\frac{P \text{ to } Q}{Q \text{ to } R} \geq 0 \leftrightarrow P\text{-}Q\text{-}R.$$

Menelaus' theorem involves a product of ratios of directed distances between points on the edge lines of a triangle ΔABC. Assign scales to lines $\overleftrightarrow{BC}$, $\overleftrightarrow{CA}$, and $\overleftrightarrow{AB}$, as indicated by the arrows in figure 5.2.1. Then select points X to Z on these lines but distinct from the vertices. The product

$$\frac{A \text{ to } Z}{Z \text{ to } B} \, \frac{B \text{ to } X}{X \text{ to } C} \, \frac{C \text{ to } Y}{Y \text{ to } A}$$

of ratios of two directed distances on each line is called *Menelaus' product*. It doesn't depend on the choice of scales. Its sign gives information about how many of the points X, Y, and Z may lie between the vertices. The product is positive if all three lie within the edges or just one does, but negative if just two lie within the edges.

***Theorem 1* (*Menelaus' theorem*).** X, Y, and Z are collinear if and only if Menelaus' product equals -1.

Proof. Suppose X, Y, and Z lie on a line g, as in figure 5.2.2. Find a line $h \neq \overleftrightarrow{AB}, \overleftrightarrow{CA}$ through A not parallel to $\overleftrightarrow{BC}$ nor g. Construct lines j and k parallel to h through B and C. Then h, j, and k intersect

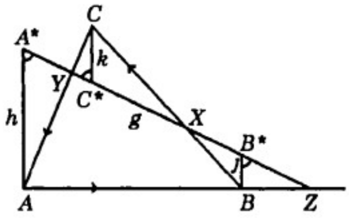

Figure 5.2.2
Proof of Menelaus' theorem

g at points A^*, B^*, and C^* that form three pairs of similar triangles with associated ratios as follows:

$$\Delta AZA^* \sim \Delta BZB^* \qquad \Delta BXB^* \sim \Delta CXC^* \qquad \Delta CYC^* \sim \Delta AYA^*$$

$$\frac{A \text{ to } Z}{Z \text{ to } B} = -\frac{AA^*}{BB^*} \qquad \frac{B \text{ to } X}{X \text{ to } C} = \frac{BB^*}{CC^*} \qquad \frac{C \text{ to } Y}{Y \text{ to } A} = \frac{CC^*}{AA^*}.$$

These equations imply

$$\frac{A \text{ to } Z}{Z \text{ to } B}\,\frac{B \text{ to } X}{X \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} = -1.$$

This computation depends on the positions of X, Y, and Z. Since they're collinear, they can't all lie within the edges, nor can just one of them. Thus, just one or all of them must lie outside ΔABC. Figure 5.2.2 shows the case when just one—namely, Z —lies outside. If all three lay outside, then all three ratios of directed distances would be negative, and their product would still equal -1.

Conversely, suppose Menelaus' product equals -1. Then all three or just one of X, Y, and Z must lie outside ΔABC. You can assume that X and Y both lie within the edges, as in figure 5.2.2, or both lie outside. Let $g = \overleftrightarrow{XY}$. If g / c, then

$$\frac{B \text{ to } X}{X \text{ to } C} = \frac{Y \text{ to } A}{C \text{ to } Y}$$

Mathematics flourished at Alexandria for many centuries after Euclid, waning gradually with the rise of Christianity and its antipathy toward Greek culture. MENELAUS worked there around A.D. 100. Principally an astronomer, he studied the precession of the equinoxes and other phenomena. To further that work he founded the subject of spherical trigonometry with a book, *Sphaerica*. Menelaus authored several other texts on geometry and astronomy as well. This section's theorem carrying his name is related to his work in spherical trigonometry, but here it's used as a key to some important theorems in plane geometry.

hence

$$\frac{A \text{ to } Z}{Z \text{ to } B} = -1,$$

and it would follow that A to $Z = B$ to Z, hence $A = B$ —contradiction! Therefore, g must intersect c at a point $Z' \neq A, B$. By the previous paragraph,

$$\frac{A \text{ to } Z'}{Z' \text{ to } B}\,\frac{B \text{ to } X}{X \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} = -1,$$

hence

$$\frac{A \text{ to } Z'}{Z' \text{ to } B} = \frac{A \text{ to } Z}{Z \text{ to } B}.$$

This equation clearly implies $Z = Z'$, so Z also falls on g. ♦

5.3 Desargues' theorem

Concepts

Pencils of lines
Euclidean forms of Desargues' theorem
Does Desargues' theorem require metric notions?

Section 1.1 used a form of Desargues' theorem to solve a fundamental problem in descriptive geometry. Desargues' theorem underlies various fundamental techniques in that field; in fact, it was originally discovered in that context.[6] There are several forms of the theorem in Euclidean geometry. They can all be interpreted as specific instances of a single result in projective geometry, the theory that was developed to serve as a basis for the techniques of perspective drawing. That unified form of the theorem plays a central role in the modern axiomatic development of projective geometry.

In this section, however, Desargues' theorem is considered only in the context of Euclidean geometry, hence some forms must be treated separately. Some of the distinctions have to do with situations where three lines are parallel or have a common intersection. To simplify the terminology, the families of all lines parallel to a given line and of all lines through a given point are called parallel and concurrent *pencils*.[7] A set of lines is called *copencilar* if they all belong to the same pencil. Several styles of proof are

Concurrent case Parallel case

Figure 5.3.1 First form of Desargues' theorem

useful for various forms of Desargues' theorem. The first form considered here can be proved neatly from Menelaus' theorem.

Theorem 1 ***(First form of Desargues' theorem and its converse).*** Consider coplanar triangles ΔABC and $\Delta A^*B^*C^*$ as in figure 5.3.1, with three distinct lines l, m, and n and three distinct points L, M, and N such that

A and A^* lie on l but not on m nor n,
B and B^* lie on m but not on n nor l,
C and C^* lie on n but not on l nor m,

$$L = \overleftrightarrow{BC} \cap \overleftrightarrow{B^*C^*}, \quad M = \overleftrightarrow{CA} \cap \overleftrightarrow{C^*A^*}, \quad N = \overleftrightarrow{AB} \cap \overleftrightarrow{A^*B^*}.$$

Then l, m, and n are copencilar if and only if L, M, and N are collinear.

Proof. The hypotheses imply $A \neq A^*$, $B \neq B^*$, and $C \neq C^*$. In order to use directed distances, assign scales to all lines under consideration. Suppose l, m, and n all pass through a point O. Apply Menelaus' theorem first to the collinear points L, B^*, and C^* on the edge lines of ΔOBC to get

$$\frac{O \text{ to } B^*}{B^* \text{ to } B} \, \frac{B \text{ to } L}{L \text{ to } C} \, \frac{C \text{ to } C^*}{C^* \text{ to } O} = -1,$$

then to the collinear points M, C^*, and A^* on the edge lines of ΔOAC to get

$$\frac{C \text{ to } M}{M \text{ to } A} \, \frac{A \text{ to } A^*}{A^* \text{ to } O} \, \frac{O \text{ to } C^*}{C^* \text{ to } C} = -1,$$

Gérard DESARGUES was born in 1593 in Lyon, the son of a minor government official. Nothing is known of his education. By 1626 he'd moved to Paris and developed a reputation as a mathematician and engineer, particularly interested in problems arising in graphic arts and architecture. There he met Descartes. They became lifelong friends, and influenced each other's mathematical work. Richelieu appointed Desargues an army engineer officer in 1628. He assisted in the design of the fortifications and dikes at La Rochelle. During the late 1620s and 1630s, Desargues researched and gave mathematics lectures in Paris. His principal interest was the analysis and application of perspective techniques, and he pioneered the projective theory of conic sections. His work was published in the late 1630s and 1640s, but in scattered fashion, and sometimes only as appendices to his students' works. His style was novel and overly concise. For these reasons, and because of the great attention given to the 1637 publication of Descartes' elements of analytic geometry, Desargues' work received little note during his lifetime and in fact for the next two hundred years. His student Blaise Pascal, however, achieved fame with a treatise on conic sections based on Desargues' work. Desargues continued to practice engineering and architecture until he retired to his country estate near Lyon in 1650. He died there in 1662.

and to the collinear points N, A^*, and B^* on the edge lines of ΔOAB to get

$$\frac{O \text{ to } A^*}{A^* \text{ to } A}\,\frac{A \text{ to } N}{N \text{ to } B}\,\frac{B \text{ to } B^*}{B^* \text{ to } O} = -1.$$

Now multiply these three equations and simplify to get

$$\frac{A \text{ to } N}{N \text{ to } B}\,\frac{B \text{ to } L}{L \text{ to } C}\,\frac{C \text{ to } M}{M \text{ to } A} = -1.$$

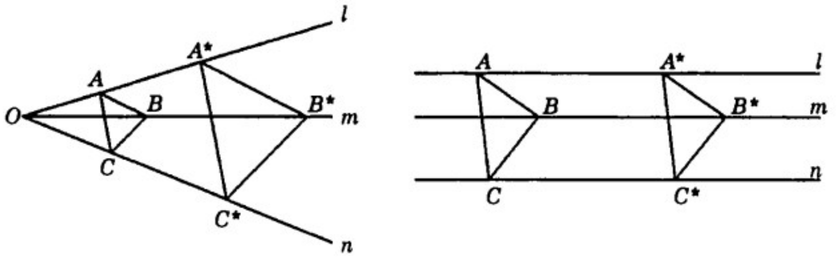
By Menelaus' theorem, points N, L, and M on the edge lines of ΔABC are collinear. The proof that concurrence of l, m, and n implies collinearity of L, M, and N is complete.

Next, suppose that L, M, and N are collinear but l, m, and n aren't all parallel. Then two of these lines, say n and l, intersect at a point O. Collinearity of B^*, O, and B follows by the previous paragraph's argument with

A, B, C, A^*, B^*, C^*, L, M, N, and O replaced by
C, L, C^*, A, N, A^*, B^*, O, B, and M.

That is, O lies on m as well. Thus, collinearity of L, M, and N implies copencilarity of l, m, and n.

Finally, suppose that l, m, and n are parallel. Considering similar triangles, you get



Concurrent case Parallel case

Figure 5.3.2 Second form of Desargues' theorem

$$\frac{A \text{ to } N}{N \text{ to } B}\,\frac{B \text{ to } L}{L \text{ to } C}\,\frac{C \text{ to } M}{M \text{ to } A} = \left[-\frac{A \text{ to } A^*}{B \text{ to } B^*}\right]\left[-\frac{B \text{ to } B^*}{C \text{ to } C^*}\right]\left[-\frac{C \text{ to } C^*}{A \text{ to } A^*}\right] = -1.$$

By Menelaus' theorem, points N, L, and M on the edge lines of ΔABC are collinear. ♦

In the second form of Desargues' theorem, ΔABC and $\Delta A^*B^*C^*$ have parallel edges. You can supply the proof by considering similar triangles.

***Theorem 2* (*Second form of Desargues' theorem and its converse*).** Consider coplanar triangles ΔABC and $\Delta A^*B^*C^*$ as in figure 5.3.2, with three distinct lines l, m, and n such that

A and A^* lie on l but not on m nor n,
B and B^* lie on m but not on n nor l,
C and C^* lie on n but not on l nor m,
$\overleftrightarrow{AB} \parallel \overleftrightarrow{A^*B^*}$, $\overleftrightarrow{BC} \parallel \overleftrightarrow{B^*C^*}$.

Then l, m, and n are copencilar if and only if $\overleftrightarrow{CA} \parallel \overleftrightarrow{C^*A^*}$.

The statements of Desargues' theorem involve only incidence notions (collinearity, concurrence, parallelism, etc.), but the proofs given and suggested above involve metric notions (directed distances, similar triangles, etc.). When the figures are three-dimensional, however, as in the following form of the theorem, you can avoid metric techniques.

***Theorem 3* (*Third form of Desargues' theorem and its converse*).** Consider noncoplanar triangles ΔABC and $\Delta A^*B^*C^*$ with three distinct lines l, m, and n and three distinct points L, M, and N such that

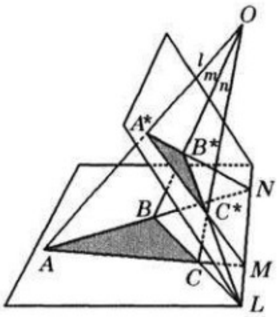


Figure 5.3.3 Third form of Desargues' theorem: noncoplanar case

A and A^* lie on l but not on m nor n,
B and B^* lie on m but not on n nor l,
C and C^* lie on n but not on l nor m,

$L = \overleftrightarrow{BC} \cap \overleftrightarrow{B^*C^*}$, $M = \overleftrightarrow{CA} \cap \overleftrightarrow{C^*A^*}$, $N = \overleftrightarrow{AB} \cap \overleftrightarrow{A^*B^*}$.

Then l, m, and n are copencilar if and only if L, M, and N are collinear.

Proof. If l, m, and n are copencilar, then L, M, and N are collinear because they all lie in the planes of both triangles. See figure 5.3.3 for the concurrent case; you may draw a figure for the parallel case. You may also supply the proof that collinearity of L, M, and N implies copencilarity of l, m, and n. ♦

In 1907, Alfred North Whitehead showed how to use a three-dimensional construction to prove the coplanar case of Desargues' theorem—theorem 1—without using metric concepts.[8] Suppose ΔABC and $\Delta A^*B^*C^*$ lie in the same plane ε, and l, m, and n intersect in a common point O, as in figure 5.3.4. (To enhance the figure's legibility, lines $\overleftrightarrow{CA}$ and $\overleftrightarrow{C^*A^*}$ were omitted.) There's no loss in assuming that A lies between O and A^* as in the figure—otherwise, just relabel the triangles. Select a point P not on ε and a point R between but different from O and P. The plane $\delta = LMR$ intersects $\overleftrightarrow{PA}$, $\overleftrightarrow{PB}$, and $\overleftrightarrow{PC}$ at points A'', B'', and C'' between but different from P and A, B, and C. Lines $\overleftrightarrow{A^*A''}$ and $\overleftrightarrow{OP}$ intersect at a point Q between but different from O and P. Several triples of points are collinear because they lie in two distinct planes:

B'', C'', L in δ and BCP
C'', A'', M in δ and CAP
C^*, C'', Q in $A^*A''M$ and C^*OP
B^*, B'', Q in $C^*C''L$ and B^*OP.

---

[8] Whitehead [1907] 1971, 16–17.

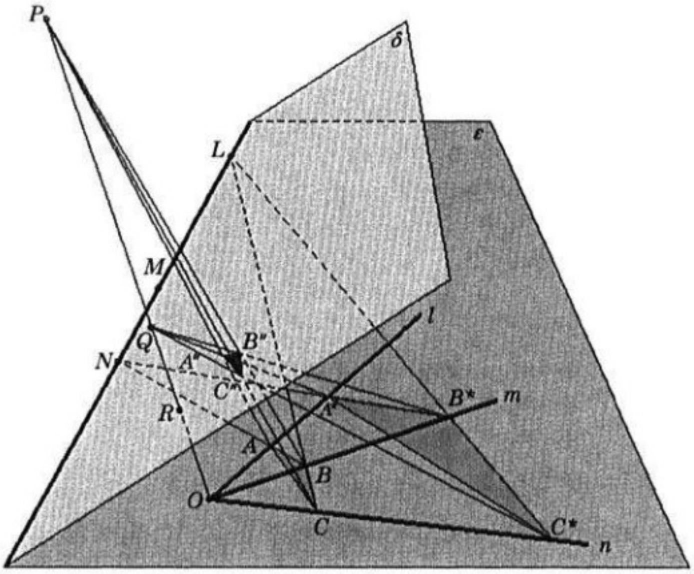

Figure 5.3.4
Third form of Desargues' theorem: coplanar case

By the proof of noncoplanar case of theorem 3, lines $\overleftrightarrow{AB}$ and $\overleftrightarrow{A''B''}$ must be parallel or intersect in a point on $\overleftrightarrow{LM}$, and lines $\overleftrightarrow{A^*B^*}$ and $\overleftrightarrow{A''B''}$ must be parallel or intersect in a point on $\overleftrightarrow{LM}$. One of $\overleftrightarrow{AB} \parallel \overleftrightarrow{A''B''}$ and $\overleftrightarrow{A^*B^*} \parallel \overleftrightarrow{A''B''}$ must fail because $\overleftrightarrow{AB}$ and $\overleftrightarrow{A^*B^*}$ aren't parallel. Assume $\overleftrightarrow{AB}$ and $\overleftrightarrow{A''B''}$ intersect at a point N^* on $\overleftrightarrow{LM}$; you can handle the other possibility similarly. Points A^*, B^*, and N^* are collinear because they all lie in the distinct planes δ and $A''B''Q$. This implies $N = N^*$, hence N lies in $\overleftrightarrow{LM}$. The proof that concurrence of l, m, and n implies collinearity of L, M, and N is complete. You may supply a similar nonmetric proof that L, M, and N are collinear if l, m, and n are parallel. The proof of theorem 1 included a nonmetric argument that in this planar situation, collinearity of L, M, and N implies copencilarity of l, m, and n.

Several years before Whitehead's work, David Hilbert (1899, section 23) had already shown that *every* proof of the plane Desargues theorem requires either metric concepts or a three-dimensional construction.

Alfred North WHITEHEAD was born in 1861 in Ramsgate. His father was a schoolteacher and Anglican clergyman. Alfred's brother became a bishop. In grammar school, Alfred excelled in sports and mathematics. In 1880, he entered Trinity College, Cambridge; all his courses there were in mathematics. Upon graduation he became a fellow of the college, and soon was appointed senior lecturer in mathematics. In 1890 he married Evelyn Wade; they had three children.

Whitehead's early mathematical work had to do with group theory and algebra. He published a book *Universal algebra* that developed in a roundabout way material that would later be included in the theories of linear and multilinear algebra. Around 1900 he began working more in foundations of mathematics, and published two small works on axiom systems for projective and descriptive geometry.

During this period at Cambridge he guided the work of Bertrand Russell as a student, including Russell's dissertation on foundations of geometry. (Whitehead's father had been the Russells' vicar, and in that capacity had been called on to convince the young boy that the earth was round!) Early in the new century they began collaboration on *Principia mathematica*, a monumental work that attempted to demonstrate the *logistic thesis*, that all mathematics can be derived from logical principles alone. A major achievement in mathematical logic, the book provided a framework for much significant research, although Gödel showed later that logicism was inadequate as a philosophy of mathematics. (No system like *Principia* can entail all true arithmetic statements but no false ones.)

By 1910, Whitehead's interests had turned almost entirely to philosophy of science, and he moved to the University of London. During his London period he produced three books on foundations of physics, especially relativity theory. Influenced by the tragedies of World War I, including the death of his son, an aviator, he turned even more to philosophical studies. He crossed the Atlantic in 1924 to become professor of philosophy at Harvard. There he wrote a series of works on philosophy of science, education, and religion, finally retiring in 1937 at age 76. Whitehead died in 1947.

5.4 Ceva's theorem

Concepts

Ceva's theorem
Deriving the medians, altitudes, and angle bisectors theorems
Proving Ceva's theorem by mechanics

A generalization of three of the four concurrence theorems in section 5.1 was found about nineteen centuries after them. It's phrased in terms of Menelaus' product:

.2 7!?

***Theorem 1* (*Ceva's theorem*).** In order to use directed distances, assign scales to the edge lines of ΔABC. If points X, Y, and Z lie on these lines and are distinct from the vertices, then

$$\frac{A \text{ to } Z}{Z \text{ to } B}\,\frac{B \text{ to } X}{X \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} = 1$$

if and only if lines $l = \overleftrightarrow{AX}$, $m = \overleftrightarrow{BY}$, and $n = \overleftrightarrow{CZ}$ are copencilar.

Proof. Each of these statements will be proved in turn:

i. if X, Y, and Z lie within the edges, then l, m, and n aren't all parallel; if they concur, then Menelaus' product equals 1;

ii. if X, Y, and Z lie within the edges and Menelaus' product equals 1, then l, m, and n concur;

iii. if X and Y lie outside the edges and Z within, and l, m, and n concur, then Menelaus' product equals 1;

iv. if X and Y lie outside the edges and Z within, and l, m, and n are parallel, then Menelaus' product equals 1;

v. if X and Y lie outside the edges and Z within, and Menelaus' product equals 1, then l, m, and n are copencilar;

vi. if just one or all three of X, Y, and Z lie within the edges, then Menelaus' product is negative and l, m, and n aren't copencilar.

Parts (*iii*) to (*v*) cover all cases where exactly one of X, Y, and Z lies within an edge of ΔABC; if X or Y instead of Z lies inside, just relabel the triangle.

Part (*i*). Suppose X, Y, and Z lie within the edges, as in figure 5.4.1. You can easily see that l, m, and n can't be all parallel. Suppose they meet at a point W. Then W lies inside the triangle. Apply Menelaus' theorem to the collinear points Z, C, and W on the edge lines of ΔABX:

$$\frac{A \text{ to } Z}{Z \text{ to } B}\,\frac{B \text{ to } C}{C \text{ to } X}\,\frac{X \text{ to } W}{W \text{ to } A} = -1.$$

Apply it again to the collinear points W, B, and Y on the edge lines of ΔAXC:

$$\frac{A \text{ to } W}{W \text{ to } X}\,\frac{X \text{ to } B}{B \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} = -1.$$

Multiply these equations to get

$$\frac{A \text{ to } Z}{Z \text{ to } B}\,\frac{B \text{ to } X}{X \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} =$$

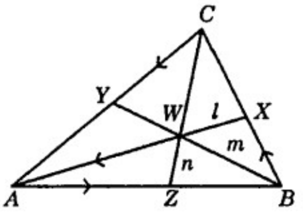

Figure 5.4.1 Ceva's theorem, parts (*i*) and (*ii*)

$$\left[\frac{A\text{ to }Z}{Z\text{ to }B}\,\frac{B\text{ to }C}{C\text{ to }X}\,\frac{X\text{ to }W}{W\text{ to }A}\right]\left[\frac{A\text{ to }W}{W\text{ to }X}\,\frac{X\text{ to }B}{B\text{ to }C}\,\frac{C\text{ to }Y}{Y\text{ to }A}\right]=(-1)(-1)=1.$$

Part (*ii*). Suppose X, Y, and Z lie within the edges, as in figure 5.4.1. Then lines l and m meet at a point W inside the triangle, and line $\overleftrightarrow{CW}$ meets edge $\overline{AB}$ at a point Z'. By part (*i*),

$$\frac{A\text{ to }Z'}{Z'\text{ to }B}\,\frac{B\text{ to }X}{X\text{ to }C}\,\frac{C\text{ to }Y}{Y\text{ to }A}=1.$$

If Menelaus' product equals 1, i.e.

$$\frac{A\text{ to }Z}{Z\text{ to }B}\,\frac{B\text{ to }X}{X\text{ to }C}\,\frac{C\text{ to }Y}{Y\text{ to }A}=1,$$

then

$$\frac{A\text{ to }Z}{Z\text{ to }B}=\frac{A\text{ to }Z'}{Z'\text{ to }B}.$$

This implies $Z=Z'$, so W lies on n as well as l and m.

Part (*iii*). Suppose X and Y lie outside the edges and Z within, and l, m, and n meet at a point W, as in figure 5.4.2. Then W lies outside the triangle. The proof for part (*i*) is valid in this case as well.

Part (*iv*). Suppose X and Y lie outside the edges and Z within, and l, m, and n are parallel, as in figure 5.4.3. Reasoning with similar triangles, you get

$$\frac{A\text{ to }Z}{Z\text{ to }B}\,\frac{B\text{ to }X}{X\text{ to }C}\,\frac{C\text{ to }Y}{Y\text{ to }A}=\frac{A\text{ to }Z}{Z\text{ to }B}\,\frac{B\text{ to }A}{A\text{ to }Z}\,\frac{Z\text{ to }B}{B\text{ to }A}=1.$$

Part (*v*). Suppose X and Y lie outside the edges and Z within, and l, m, and n aren't all parallel. Then at least two of these lines meet; suppose l meets m at a point W. Then W lies outside the triangle, and the lines $\overleftrightarrow{CW}$ and $\overleftrightarrow{AB}$ meet at a point Z'. Proceed as in part (*ii*) to show that $Z=Z'$, hence W lies on n. The arguments for l or m meeting n are similar.

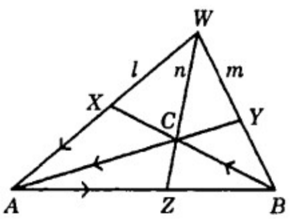

Figure 5.4.2 Ceva's theorem, part (*iii*)

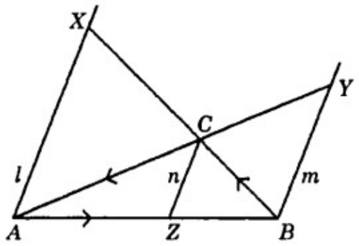

Figure 5.4.3 Ceva's theorem, part (*iv*)

Part (*vi*). If just one or all three of X, Y, and Z lie inside the edges, then Menelaus' product is negative, and you can verify that l, m, and n can't be parallel or concurrent. ♦

Ceva's theorem directly implies concurrence of the medians of ΔABC. Let X, Y, and Z be the edge midpoints A', B', and C', so that

$$\frac{A \text{ to } Z}{Z \text{ to } B}\,\frac{B \text{ to } X}{X \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} = \frac{A \text{ to } C'}{C' \text{ to } B}\,\frac{B \text{ to } A'}{A' \text{ to } C}\,\frac{C \text{ to } B'}{B' \text{ to } A} = 1\cdot 1\cdot 1 = 1.$$

By Ceva's theorem the medians are copencilar. They can't be parallel because the midpoints lie within the edges, so they must concur.

To derive the altitudes' concurrence from Ceva's theorem, first label the vertices of ΔABC so that $\angle A$ and $\angle B$ are acute. Then construct the circle with diameter $\overline{AB}$, as in figure 5.4.4. The feet D and E of the altitudes through A and B lie on this circle. Inscribed angles $\angle CAD$ and $\angle CBE$ are congruent because they subtend the same arc $\widehat{DJE}$, hence $\Delta ADC \sim \Delta BEC$, so

$$\frac{CE}{DC} = \frac{BC}{CA}\,.$$

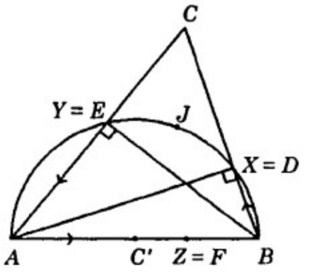

Figure 5.4.4 Deriving the altitudes' concurrence from Ceva's theorem

Giovanni CEVA was born around 1647 in Milan, to a wealthy family. He studied in Pisa, and later in life received a regular stipend from the archduke of Tuscany as a sort of court mathematician. In his 1678 book *De lineis rectis* is found the triangle theorem known by his name, and many elaborations, treated in the framework of mechanics. In several other books, he continued detailed studies in geometrical mechanics, many of which would be supplanted soon by calculus applications. He died in 1734. His Jesuit brother Tomasso was also a mathematician, and a poet.

Similarly,

$$\frac{BD}{FB} = \frac{AB}{BC} \qquad \frac{AF}{EA} = \frac{CA}{AB},$$

where F is the foot of the altitude through C. Now, choose scales for the edge lines as in figure 5.4.4, and let $X, Y, Z = D, E, F$. If $\angle C$ is acute, as in the figure,

$$\frac{A \text{ to } Z}{Z \text{ to } B} \, \frac{B \text{ to } X}{X \text{ to } C} \, \frac{C \text{ to } Y}{Y \text{ to } A} = \frac{AF}{FB} \, \frac{BD}{DC} \, \frac{CE}{EA}$$

$$= \frac{AF}{EA} \, \frac{BD}{FB} \, \frac{CE}{DC} = \frac{CA}{AB} \, \frac{AB}{BC} \, \frac{BC}{CA} = 1.$$

If $\angle C$ is obtuse, then you must place minus signs before two of the fractions in each of these products, but you get the same result. By Ceva's theorem, the altitudes are copencilar. Since they're perpendicular to the edges of a triangle, they can't be parallel, so they must concur.

To derive the concurrence of the angle bisectors of ΔABC from Ceva's theorem, you need a preliminary result. As in figure 5.4.5, the bisector g of $\angle A$ meets the opposite edge at a point X. Let $B^\star$ and $C^\star$ be the feet of the perpendiculars to g through B and C. If $B^\star \neq X \neq C^\star$, then $\Delta XBB^\star \sim \Delta XCC^\star$ and $\Delta ABB^\star \sim \Delta ACC^\star$. From these similarities it follows that

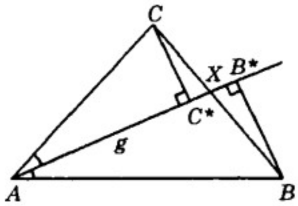

Figure 5.4.5 Deriving the angle bisectors' concurrence from Ceva's theorem

$$\frac{B \text{ to } X}{X \text{ to } C} = \frac{BB^*}{CC^*} = \frac{AB}{CA}\,.$$

On the other hand, if $B^* = X$ or $C^* = X$, then $\overleftrightarrow{BC} \perp g$, ΔABC is isosceles, and you get the same result:

$$\frac{B \text{ to } X}{X \text{ to } C} = 1 = \frac{AB}{CA}\,.$$

By the same argument, the bisectors of $\angle B$ and $\angle C$ meet the opposite edges at points Y and Z such that

$$\frac{C \text{ to } Y}{Y \text{ to } A} = \frac{BC}{AB} \qquad \frac{A \text{ to } Z}{Z \text{ to } B} = \frac{CA}{BC}\,.$$

The previous three equations entail

$$\frac{A \text{ to } Z}{Z \text{ to } B}\,\frac{B \text{ to } X}{X \text{ to } C}\,\frac{C \text{ to } Y}{Y \text{ to } A} = \frac{CA}{BC}\,\frac{AB}{CA}\,\frac{BC}{AB} = 1\,.$$

By Ceva's theorem, the angle bisectors are copencilar. They can't be parallel because X, Y, and Z lie within the edges, so they must concur.

The original derivation of Ceva's theorem was quite different from that given in this section. Ceva didn't base it directly on Euclid; instead, he used some principles governing the center of gravity of a system of weights. Given points X, Y, and Z within the edges of ΔABC opposite angles A, B, and C, Ceva assigned weights to the vertices as follows:

Vertex	*Weight*
A	$CY \cdot BX$
B	$YA \cdot XC$
C	$YA \cdot BX$.

(See figure 5.4.1.) Assuming that the supporting triangle has no mass, he then computed the center of gravity of the system of three weights. In such a computation, you can replace a subsystem of two weights u and v by a single weight $u + v$ at its center of gravity. This is the point P about which the moments of the weights u and v are opposite; they're on opposite sides of P, and the products of u and v by their distances from P are equal. Since $BX \cdot (YA \cdot XC) = XC \cdot (YA \cdot BX)$, the moments about X of the weights at B and C are opposite, so X is their center of gravity. You can replace those two weights by a single one at X. It follows that the center of gravity of the original system coincides with that of the new one consisting of weights at A and X, hence it lies on $\overline{AX}$. Similarly, since $CY \cdot (YA \cdot BX) = YA \cdot (CY \cdot BX)$, you can replace the weights at C and A by a single one at Y, so the center of gravity of the original system lies on $\overline{BY}$. Thus, it's the intersection of $\overline{AX}$ and $\overline{BY}$. Now, Ceva reasoned, segments $\overline{AX}$, $\overline{BY}$, and $\overline{CZ}$ are concurrent if and only if the center of gravity of the original system also falls on $\overline{CZ}$. That happens just in case you can replace the weights at A and B by a single weight at Z, i.e., just when their moments about Z are opposite: $AZ \cdot (CY \cdot BX) = ZB \cdot (YA \cdot XC)$. This condition simply says Menelaus' product equals 1:

$$\frac{A \text{ to } Z}{Z \text{ to } B} \frac{B \text{ to } X}{X \text{ to } C} \frac{C \text{ to } Y}{Y \text{ to } A} = 1.$$

This argument, of course, is not supported by the axiomatic foundation of chapter 3. But that foundation can be extended to describe the behavior of systems of weights, and justify the argument.

If $X, Y, Z = A', B', C'$ in the preceding argument, so that figure 5.4.1 represents the concurrence of the medians of ΔABC, then the weights assigned A, B, and C are all equal. Thus, in that case, Ceva's argument is identical to one used often in mechanics courses to demonstrate the medians' concurrence.

5.5 Trigonometry

Concepts

- Law of sines
- Law of cosines
- Determining other parts of a triangle from ASA, SAS, or SSS data
- Using SSA data
- Cosine and sine sum and difference formulas
- Cosine and sine double and half angle formulas
- SAS and ASA area formulas; Hero's SSS area formula
- Area formulas involving the circumradius
- Inequalities for approximating sine values

This section completes the study of plane trigonometry begun in chapter 3. In addition to the material you'd find in standard trigonometry texts, it presents several striking area formulas that go beyond what you'll find there. The section concludes with a method for approximating sine values, which also plays a major role in applying calculus to trigonometry problems.

Classical trigonometry shows how to determine some parts of ΔABC —measures of $\angle A$, $\angle B$, and $\angle C$ and lengths a, b, and c of the opposite edges—when you're given others. Theorem 3.13.15 and exercise 4.5.4 summarized this for the case where $\angle C$ is right. In that situation, given any two of a, b, c, $m\angle A$, and $m\angle B$, but not just the two angle measures, you can use Pythagoras' theorem, some simple equations involving the trigonometric functions, and computed values of these functions to find the remaining parts. For oblique triangles, you need more sophisticated

Curvature

We have seen, for example in rotating reference frames that the geometry in a space with non-vanishing acceleration of gravity, may be non-Euclidean. It is easy to visualize curves and surfaces in three-dimensional space but it is difficult to grasp visually what curvature means in three-dimensional space, or worse still, in four-dimensional space-time. However the curvature of such spaces may be discussed using the lower dimensional analogues of curves and surfaces. It is therefore important to have a good knowledge of the differential geometry of surfaces. Also the formalism used in describing surfaces may be taken over with minor modifications, when we are going to describe the geometric properties of curved space-time.

7.1 Curves

Let us consider curves in Euclidean three-dimensional space, $\mathbb{E}^3$ and let $\mathbf{r}(s)$ be the position vector of points parametrized by the *arc length* s. The unit tangent vector along the curve is

$$\mathbf{t} = \frac{d\mathbf{r}}{ds} = \frac{dx^i}{ds}\mathbf{e}_i. \tag{7.1}$$

The faster the unit tangent vector changes the direction along the curve the more curved the curve is. The *curvature vector* of the curve is defined by

$$\mathbf{k} = \frac{d\mathbf{t}}{ds}. \tag{7.2}$$

Since $\mathbf{t} \cdot \mathbf{t} = 1$ we have by differentiation $\mathbf{t} \cdot \mathbf{k} = 0$, thus the curvature vector is always orthogonal to the tangent vector. The length of the curvature vector is called the curvature of the curve, and is denoted by κ:

$$\kappa \equiv |\mathbf{k}|. \tag{7.3}$$

A curve with vanishing curvature is a straight line.

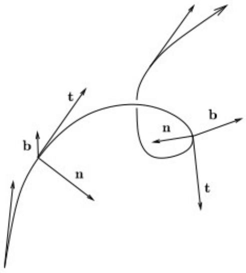

Figure 7.1: A curve in three-dimensional space

Example

Example 7.1 (The curvature of a circle)
Consider a circle of radius R. The tangent vector is

$$\mathbf{t} = \frac{d\mathbf{r}}{ds} = \frac{dr}{ds}\mathbf{e}_r + \frac{d\theta}{ds}\mathbf{e}_\theta = \frac{1}{R}\mathbf{e}_\theta \tag{7.4}$$

since $r = R$ and $s = R\theta$ along the circle. The curvature vector can now be found with

$$\mathbf{k} = \frac{d\mathbf{t}}{ds} = \frac{1}{R^2}\frac{d\mathbf{e}_\theta}{d\theta} = -\frac{1}{R}\mathbf{e}_r. \tag{7.5}$$

Thus the curvature of the circle is $\kappa = \frac{1}{R}$.

The unit vector $\mathbf{n}$ defined by

$$\boxed{\frac{d\mathbf{t}}{ds} = \kappa\mathbf{n}} \tag{7.6}$$

is called the *principal normal vector* of the curve. The vectors $\mathbf{t}$ and $\mathbf{n}$ span a plane which is called the *osculating plane* of the curve. This plane turns as we move along the curve. The unit normal vector $\mathbf{b}$ of this plane, defined by

$$\mathbf{b} = \mathbf{t} \times \mathbf{n} \tag{7.7}$$

is called the *binormal vector* of the curve. The rate of turning of the osculating plane is given by $\frac{d\mathbf{b}}{ds}$. Since $\mathbf{t} \cdot \mathbf{b} = 0$, it follows by differentiation that

$$\frac{d\mathbf{t}}{ds} \cdot \mathbf{b} + \mathbf{t} \cdot \frac{d\mathbf{b}}{ds} = 0. \tag{7.8}$$

Combining this with equations (7.6) and (7.7) it follows that $\frac{d\mathbf{b}}{ds}$ is orthogonal to $\mathbf{t}$. Since $\mathbf{b}$ has constant length, $\frac{d\mathbf{b}}{ds}$ has no component along $\mathbf{b}$ either. Thus $\frac{d\mathbf{b}}{ds}$ points in the $\mathbf{n}$ direction. The *torsion* τ of a curve is defined by the equation

$$\boxed{\frac{d\mathbf{b}}{ds} = -\tau\mathbf{n}.} \tag{7.9}$$

The vectors $\{\mathbf{t}, \mathbf{n}, \mathbf{b}\}$ represent three orthonormal basis vector fields along the curve. They are related by eq. (7.7) together with

$$\mathbf{t} = \mathbf{n} \times \mathbf{b}, \qquad \mathbf{n} = \mathbf{b} \times \mathbf{t}. \tag{7.10}$$

The variation of $\mathbf{n}$ along the curve is now given by

$$\frac{d\mathbf{n}}{ds} = \frac{d\mathbf{b}}{ds} \times \mathbf{t} + \mathbf{b} \times \frac{d\mathbf{n}}{ds} = -\tau\mathbf{n} \times \mathbf{t} + \kappa\mathbf{b} \times \mathbf{n} \tag{7.11}$$

so

$$\boxed{\frac{d\mathbf{n}}{ds} = \tau\mathbf{b} - \kappa\mathbf{t}.} \tag{7.12}$$

Equations (7.6), (7.9) and (7.12) are called the *Serret-Frenet equations*.

7.2 Surfaces

Consider a two-dimensional surface embedded in three-dimensional Euclidean space. Let u and v be coordinates (or parameters) on the surface. Then, at every point on the surface the basis vectors

$$\mathbf{e}_u = \frac{\partial}{\partial u}, \qquad \mathbf{e}_v = \frac{\partial}{\partial v} \tag{7.13}$$

define a tangent plane of the surface.

The line element on the surface is

$$ds^2 = g_{\mu\nu} dx^\mu dx^\nu \tag{7.14}$$

where $x^1 = u$ and $x^2 = v$. This is often called *the first fundamental form* of the surface.

The directional derivative of $\mathbf{e}_\mu$ along $\mathbf{e}_\nu$ has generally one component in the tangent plane of the surface and one component orthogonal to the surface,

$$\boxed{\mathbf{e}_{\mu,\nu} = \Gamma^\alpha_{\ \mu\nu}\mathbf{e}_\alpha + K_{\mu\nu}\mathbf{n}} \tag{7.15}$$

where $\Gamma^\alpha_{\ \mu\nu}$ is the connection coefficients of the u, v system and $\mathbf{n}$ is the unit normal vector field on the surface. The coefficients $K_{\mu\nu}$ are defined by this equation. Since $\mathbf{e}_{\mu,\nu} = \frac{\partial^2}{\partial x^\mu \partial x^\nu} = \frac{\partial^2}{\partial x^\nu \partial x^\mu} = \mathbf{e}_{\nu,\mu}$ these coefficients are symmetric. Note also that the eq. (7.15) provides us with an interpretation of the covariant derivative and the connection coefficients $\Gamma^\alpha_{\ \mu\nu}$. The covariant derivative of a surface embedded in an Euclidean space is the ordinary derivative in Euclidean space, projected onto the tangent space of the surface.

The equation (7.15) is usually called *Gauss' equations*. Using

$$K_{\mu\nu} = \mathbf{e}_{\mu,\nu} \cdot \mathbf{n} \tag{7.16}$$

we can calculate the coefficients $K_{\mu\nu}$. Let now $\mathbf{u}$ be the tangent vector of a curve in the surface, parametrized by λ. Using equation (7.15) we have

$$\frac{d\mathbf{u}}{d\lambda} = u^\mu_{\ ;\nu} u^\nu \mathbf{e}_\mu + K_{\mu\nu} u^\mu u^\nu \mathbf{n}. \tag{7.17}$$

The λ-independent coefficient in front of $\mathbf{n}$, $K_{\mu\nu} dx^\mu dx^\nu$ is called *the second fundamental form* of the surface. Whereas the first fundamental form determines the intrinsic geometry of the surface, the second fundamental form reflects the extrinsic geometry, i.e. how the surface curves in the ambient three-dimensional Euclidean space in which it is embedded.

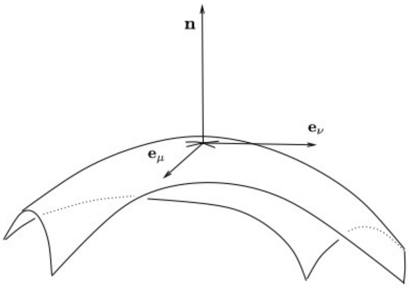

Figure 7.2: A two-dimensional surface embedded in three-dimensional Euclidean space

If λ is the arc-length, we can write equation (7.17) as

$$\frac{d\mathbf{u}}{d\lambda} = \kappa_g \mathbf{e} + \kappa_n \mathbf{n}, \quad \kappa_g \equiv |u^\mu{}_{;\nu} u^\nu \mathbf{e}_\mu|, \quad \kappa_n \equiv K_{\mu\nu} u^\mu u^\nu \tag{7.18}$$

where $\mathbf{e}$ is a unit vector. The quantities κ_g and κ_n are called *the geodesic curvature* and *the normal curvature* of the surface, respectively.

Since $\frac{d\mathbf{u}}{d\lambda}$ is orthogonal to $\mathbf{u}$ and $\mathbf{n}$, the unit vector $\mathbf{e}$ in the surface is given by

$$\mathbf{e} = \pm \mathbf{n} \times \mathbf{u}. \tag{7.19}$$

We see that the normal curvature can also be written

$$\kappa_n = \frac{d\mathbf{u}}{d\lambda} \cdot \mathbf{n}. \tag{7.20}$$

By differentiating $\mathbf{u} \cdot \mathbf{n}$ we get

$$\mathbf{u} \cdot \frac{d\mathbf{n}}{d\lambda} = -\kappa_n = -K_{\mu\nu} u^\mu u^\nu. \tag{7.21}$$

This is *Weingarden's equation*.

The geodesic and normal curvatures, taken separately, characterize the extrinsic geometry of the surface. We shall now find a quantity, called the Gaussian curvature, which is a measure of the intrinsic geometry of the surface.

At an arbitrary point on the surface we consider geodesic curves through the point with tangent vectors $\mathbf{u} = u^\mu \mathbf{e}_\mu$. In order to compare the normal curvature of the geodesics having different directions, we choose tangent vectors of unit length,

$$\mathbf{u} \cdot \mathbf{u} = g_{\mu\nu} u^\mu u^\nu = 1. \tag{7.22}$$

The directions with maximal and minimal values of the normal curvature are found by extremizing κ_n as given by eq. (7.18) with the constraint eq. (7.22). Thus we have to solve the variational problem δF for arbitrary u^μ, where

$$F = K_{\mu\nu} u^\mu u^\nu - k(g_{\mu\nu} u^\mu u^\nu - 1). \tag{7.23}$$

Here k is a Lagrange multiplier. Variation with respect to u^μ gives

$$\delta F = 2(K_{\mu\nu} - k g_{\mu\nu}) u^\nu \delta u^\mu. \tag{7.24}$$

Thus we must have

$$(K_{\mu\nu} - kg_{\mu\nu})u^{\nu} = 0. \tag{7.25}$$

This set of equations has non-trivial solutions whenever

$$\det(K_{\mu\nu} - kg_{\mu\nu}) = 0, \tag{7.26}$$

which yields the following quadratic equation for k

$$k^2 \det(g_{\mu\nu}) - k(g_{11}K_{22} - 2g_{12}K_{12} + g_{22}K_{11}) + \det(K_{\mu\nu}) = 0 \tag{7.27}$$

with solutions k_1 and k_2. These are the extremal values of k.

To see the meaning of k we multiply eq. (7.25) by u^{μ} and use eq. (7.18). This gives

$$k = \kappa_n. \tag{7.28}$$

The extremal values of k are called the *principal curvatures* of the surface. The *Gaussian curvature* of the surface is defined as

$$K = k_1 k_2. \tag{7.29}$$

From eq. (7.27) it follows that

$$\boxed{K = \frac{\det(K_{\mu\nu})}{\det(g_{\mu\nu})}.} \tag{7.30}$$

Let the directions corresponding to the principal curvatures be characterized by the vectors **u** and **v**. From equation (7.25) and the symmetry of $K_{\mu\nu}$ follows

$$(k_1 - k_2)(\mathbf{u} \cdot \mathbf{v}) = 0. \tag{7.31}$$

For $k_1 \neq k_2$ this implies that **u** and **v** are orthogonal. The principal curvatures are found in orthogonal directions.

A positive Gaussian curvature means that the principal curvatures are of the same sign. The surface is locally similar to a distorted sphere, and the geometry is locally elliptic. If the Gaussian curvature vanishes, one of the principal curvatures have to vanish and the geometry is locally planar and the geometry is locally Euclidean. Finally, if the Gaussian curvature is negative the surface is locally saddle-shaped, i.e. like a hyperbolic surface. In this case the geometry is said to be locally hyperbolic.

In the following sections we will show that the Gaussian curvature represents a measure of the intrinsic geometry of the surface. This will be achieved by expressing it in terms of the components of the Riemann tensor, which we will introduce in the next section. Note however that curves have no intrinsic curvature.

7.3 The Riemann Curvature Tensor

In this section we will not restrict ourselves to two-dimensional surfaces, but describe spaces of arbitrary number of dimensions. We will introduce the important concept of curvature in an invariant way, described by the Riemann curvature tensor.

Consider two nearby points Q and P connected by a vector $\delta\lambda\mathbf{v}$ of infinitesimal length. Let $\mathbf{A}$ be a vector field. Then the difference between the vector field at Q, denoted $\mathbf{A}_Q$, and the vector $\mathbf{A}_P$ parallel-transported from P to Q (which is denoted $\mathbf{A}_{PQ}$) is to first order in $\delta\lambda$ given by the directional derivative at Q of $\mathbf{A}$ in the $\mathbf{v}$-direction

$$\delta\lambda\nabla_{\mathbf{v}}\mathbf{A} \approx \mathbf{A}_Q - \mathbf{A}_{PQ} \tag{7.32}$$

Thus

$$\mathbf{A}_{PQ} \approx \left(1 - \delta\lambda\nabla_{\mathbf{v}}\right)\mathbf{A}_Q \tag{7.33}$$

To second order $\mathbf{A}_{PQ}$ is given by the first terms of the Taylor expansion

$$\mathbf{A}_{PQ} \approx \left(1 - \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\mathbf{A}_Q \tag{7.34}$$

We are now going to parallel-transport the vector $\mathbf{A}_P$ around the polygon shown in Fig.7.3. Parallel-transporting $\mathbf{A}_{PQ}$ from Q to R gives

$$\mathbf{A}_{PQR} \approx \left(1 - \delta\lambda\nabla_{\mathbf{u}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\right)\left(1 - \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\mathbf{A}_R. \tag{7.35}$$

Proceeding around the polygon gives

$$\begin{aligned}\mathbf{A}_{PQRSTP} \approx\ & \left(1 + \delta\lambda\nabla_{\mathbf{u}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\right)\left(1 + \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right) \\ \times\ & \left(1 - \delta\lambda^2\nabla_{[\mathbf{u},\mathbf{v}]}\right) \qquad (7.36) \\ \times\ & \left(1 - \delta\lambda\nabla_{\mathbf{u}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\right)\left(1 - \delta\lambda\nabla_{\mathbf{v}} + \frac{1}{2}\delta\lambda^2\nabla_{\mathbf{v}}\nabla_{\mathbf{v}}\right)\mathbf{A}_R.\end{aligned}$$

Thus, to second order, the change of the vector after parallel-transport around the polygon is

$$\delta\mathbf{A} = \mathbf{A}_{PQRSTP} - \mathbf{A}_P = \left([\nabla_{\mathbf{u}}, \nabla_{\mathbf{v}}] - \nabla_{[\mathbf{u},\mathbf{v}]}\right)\delta\lambda^2\mathbf{A}_P \tag{7.37}$$

In flat space there would be no such change of $\mathbf{A}$. This change is due to the curvature of the space. It can be shown that $\delta\mathbf{A}$ as given in eq. (7.37) is a vector which is linear in $\mathbf{A}$, $\mathbf{u}$ and $\mathbf{v}$ (see e.g. [vW81]). Thus $\delta\mathbf{A}$ may be expressed by a tensor of rank $\{^1_3\}$. This tensor $\mathbf{R}$ is called the *Riemann curvature tensor* and is defined by

$$\boxed{\mathbf{R}(\mathbf{u}, \mathbf{v})\mathbf{A} \equiv \left([\nabla_{\mathbf{u}}, \nabla_{\mathbf{v}}] - \nabla_{[\mathbf{u},\mathbf{v}]}\right)\mathbf{A}.} \tag{7.38}$$

The components of this tensor are given by

$$\mathbf{e}_\mu R^\mu{}_{\nu\alpha\beta} = \left([\nabla_\alpha, \nabla_\beta] - \nabla_{[\mathbf{e}_\alpha,\mathbf{e}_\beta]}\right)\mathbf{e}_\nu \tag{7.39}$$

It follows that the Riemann curvature tensor is antisymmetric in $\mathbf{u}$ and $\mathbf{v}$ i.e. in α and β. We can therefore define a matrix of two-forms

$$\boxed{\mathbf{R}^\mu_\nu = \frac{1}{2}R^\mu{}_{\nu\alpha\beta}\boldsymbol{\omega}^\alpha \wedge \boldsymbol{\omega}^\beta} \tag{7.40}$$

$\mathbf{v}(P)$
Q

Figure 7.3: The vector $\mathbf{A}_P$ parallel transported around the polygon $PQRSTP$

which are called the *curvature forms*.

Equation (7.37) may now be written

$$\delta\mathbf{A} = \mathbf{e}_\mu R^\mu{}_{\nu\alpha\beta} A^\nu u^\alpha v^\beta. \tag{7.41}$$

The infinitesimal area of the polygon is to lowest order in $\mathbf{u}$ and $\mathbf{v}$

$$\Delta S^{\alpha\beta} = u^\alpha v^\beta - u^\beta v^\alpha. \tag{7.42}$$

Using the antisymmetry of $R^\mu{}_{\nu\alpha\beta}$ we may then write

$$\delta\mathbf{A} = \frac{1}{2} A^\nu R^\mu{}_{\nu\alpha\beta} \Delta S^{\alpha\beta} \mathbf{e}_\mu. \tag{7.43}$$

This shows that the change of a vector by parallel transport around a closed curve is proportional to the curvature of the space and to the area enclosed by the curve.

We shall now show how $R^\mu{}_{\nu\alpha\beta}$ may be expressed by the connection- and structure coefficients of a given basis. We find

$$\begin{aligned} \mathbf{e}_\mu R^\mu{}_{\nu\alpha\beta} &= \left([\nabla_\alpha, \nabla_\beta] - \nabla_{[\mathbf{e}_\alpha, \mathbf{e}_\beta]}\right)\mathbf{e}_\nu \\ &= \left(\nabla_\alpha\nabla_\beta - \nabla_\beta\nabla_\alpha - c^\rho{}_{\alpha\beta}\nabla_\rho\right)\mathbf{e}_\nu \\ &= \left(\Gamma^\mu{}_{\nu\beta,\alpha} + \Gamma^\rho{}_{\nu\beta}\Gamma^\mu{}_{\rho\alpha} - \Gamma^\mu{}_{\nu\alpha,\beta} - \Gamma^\rho{}_{\nu\alpha}\Gamma^\mu{}_{\rho\beta} - c^\rho{}_{\alpha\beta}\Gamma^\mu{}_{\nu\rho}\right)\mathbf{e}_\mu \end{aligned} \tag{7.44}$$

which implies that

$$\boxed{R^\mu{}_{\nu\alpha\beta} = \Gamma^\mu{}_{\nu\beta,\alpha} - \Gamma^\mu{}_{\nu\alpha,\beta} + \Gamma^\rho{}_{\nu\beta}\Gamma^\mu{}_{\rho\alpha} - \Gamma^\rho{}_{\nu\alpha}\Gamma^\mu{}_{\rho\beta} - c^\rho{}_{\alpha\beta}\Gamma^\mu{}_{\nu\rho}.} \tag{7.45}$$

The connection coefficients and structure coefficients are calculated from a basis vector field in the space considered, without reference to any higher dimensional space. Thus eq. (7.45) shows that the Riemann tensor describes the intrinsic geometry of space.

The curvature forms may now be written in component form as

$$\mathbf{R}^{\mu}{}_{\nu} = \left(\Gamma^{\mu}{}_{\nu\beta,\alpha} - \frac{1}{2} c^{\rho}{}_{\alpha\beta} \Gamma^{\mu}{}_{\nu\rho} + \Gamma^{\rho}{}_{\nu\beta} \Gamma^{\mu}{}_{\rho\alpha} \right) \boldsymbol{\omega}^{\alpha} \wedge \boldsymbol{\omega}^{\beta}. \tag{7.46}$$

Using equations (6.136) and (6.165) we find

$$\boxed{\mathbf{R}^{\mu}{}_{\nu} = \mathbf{d}\boldsymbol{\Omega}^{\mu}{}_{\nu} + \boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \boldsymbol{\Omega}^{\lambda}{}_{\nu}.} \tag{7.47}$$

This is *Cartan's 2nd structural equation.*

We shall now deduce some identities fulfilled by the Riemann tensor. Using eqs. (6.118) and (6.144) we get

$$\begin{aligned} A^{\mu}{}_{;\beta\alpha} \quad = \quad & A^{\lambda} \Gamma^{\mu}{}_{\lambda\beta,\alpha} - A^{\lambda} \Gamma^{\tau}{}_{\lambda\alpha} \Gamma^{\mu}{}_{\tau\beta} - A^{\mu}{}_{;\lambda} \Gamma^{\lambda}{}_{\beta\alpha} + A^{\mu}{}_{,\beta\alpha} \\ & + \left(A^{\lambda}{}_{;\alpha} \Gamma^{\mu}{}_{\lambda\beta} + A^{\lambda}{}_{;\beta} \Gamma^{\mu}{}_{\lambda\alpha} \right). \end{aligned} \tag{7.48}$$

The two latter terms are symmetric in α and β and do not contribute to the antisymmetric combination $A^{\mu}{}_{;\beta\alpha} - A^{\mu}{}_{;\alpha\beta}$. Hence, by using eqs. (7.45) and (6.134), we get

$$A^{\mu}{}_{;\beta\alpha} - A^{\mu}{}_{;\alpha\beta} = A^{\lambda} R^{\mu}{}_{\lambda\alpha\beta} - A^{\mu}{}_{;\lambda} T^{\lambda}_{\alpha\beta}. \tag{7.49}$$

Since this is a tensor equation it is valid in an arbitrary basis. Eq. (7.49) is called the *Ricci identity*. In Riemannian geometry it reduces to

$$\boxed{A^{\mu}{}_{;\beta\alpha} - A^{\mu}{}_{;\alpha\beta} = R^{\mu}{}_{\lambda\alpha\beta} A^{\lambda}.} \tag{7.50}$$

Combining this with eq. (6.163) leads to

$$\mathbf{d}^2 \mathbf{A} = \frac{1}{2} R^{\mu}{}_{\nu\alpha\beta} A^{\nu} \mathbf{e}_{\mu} \otimes \boldsymbol{\omega}^{\alpha} \wedge \boldsymbol{\omega}^{\beta} \tag{7.51}$$

By exterior differentiation of Cartan's first structural equation, eq. (6.180) combined with Cartan's second structural equation and Poincaré's Lemma, we find

$$\mathbf{R}^{\mu}{}_{\nu} \wedge \boldsymbol{\omega}^{\nu} = \mathbf{d}\mathbf{T}^{\mu} + \boldsymbol{\Omega}^{\mu}{}_{\nu} \wedge \mathbf{T}^{\nu}. \tag{7.52}$$

By means of eq. (6.216), this equation takes the form

$$\mathbf{R}^{\mu}{}_{\nu} \wedge \boldsymbol{\omega}^{\nu} = \mathbf{D}\mathbf{T}^{\mu}. \tag{7.53}$$

This is *Bianchi's first identity*. In Riemannian geometry it reduces to

$$\boxed{\mathbf{R}^{\mu}{}_{\nu} \wedge \boldsymbol{\omega}^{\nu} = 0.} \tag{7.54}$$

On component form this equation is

$$\boxed{R^{\mu}{}_{[\nu\alpha\beta]} = 0.} \tag{7.55}$$

By exterior differentiation of Cartan's second structural equation, and using Poincaré's Lemma, we get

$$\mathbf{d}\mathbf{R}^{\mu}{}_{\nu} = \mathbf{d}\boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \boldsymbol{\Omega}^{\lambda}{}_{\nu} - \boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \mathbf{d}\boldsymbol{\Omega}^{\lambda}{}_{\nu} = \mathbf{R}^{\mu}{}_{\lambda} \wedge \boldsymbol{\Omega}^{\lambda}{}_{\nu} - \boldsymbol{\Omega}^{\mu}{}_{\lambda} \wedge \mathbf{R}^{\lambda}{}_{\nu}, \tag{7.56}$$

which is more usually written

$$\mathbf{dR}^{\mu}_{\ \nu} + \mathbf{\Omega}^{\mu}_{\ \lambda} \wedge \mathbf{R}^{\lambda}_{\ \nu} - \mathbf{R}^{\mu}_{\ \lambda} \wedge \mathbf{\Omega}^{\lambda}_{\ \nu} = 0. \tag{7.57}$$

Applying eq. (6.214) to a matrix of two-forms this equation may be written

$$\boxed{\mathbf{DR}^{\mu}_{\ \nu} = 0.} \tag{7.58}$$

This is *Bianchi's second identity*. On component form this identity becomes

$$\boxed{R^{\mu}_{\ \nu[\alpha\beta;\gamma]} = 0.} \tag{7.59}$$

An additional symmetry of the Riemann tensor is most easily found by decomposing it in an orthonormal basis field. Applying eq. (6.169) and Cartan's second structural equation (7.47), we get

$$\boxed{R_{\mu\nu\alpha\beta} = -R_{\nu\mu\alpha\beta}} \tag{7.60}$$

The fourth and last symmetry of the Riemann tensor is found by applying geodesic normal coordinates. From eq. (7.45), (6.110) and (6.232) we then get

$$R_{\mu\nu\alpha\beta} = \frac{1}{2}(g_{\mu\beta,\nu\alpha} - g_{\mu\alpha,\nu\beta} + g_{\nu\alpha,\mu\beta} - g_{\nu\beta,\mu\alpha}). \tag{7.61}$$

It follows that

$$\boxed{R_{\mu\nu\alpha\beta} = R_{\alpha\beta\mu\nu}.} \tag{7.62}$$

The four symmetries of the Riemann tensor reduce its number of independent components in an n-dimensional space from n^4 to $\frac{1}{12}n^2(n^2-1)$, in four-dimensional space-time from 256 to 20.

We shall now construct a curvature tensor of rank $\{^0_2\}$ by contraction of the Riemann tensor. Note first that

$$R^{\alpha}_{\ \alpha\mu\nu} = 0 \tag{7.63}$$

because of the antisymmetry in the first two indices. Furthermore

$$R^{\alpha}_{\ \mu\nu\alpha} = -R^{\alpha}_{\ \mu\alpha\nu}. \tag{7.64}$$

Thus there exists only one independent non-vanishing contraction of the Riemann tensor. This is called the *Ricci tensor* and is usually written

$$\boxed{R_{\mu\nu} = R^{\alpha}_{\ \mu\alpha\nu}.} \tag{7.65}$$

From eq. (7.62) follows that it is symmetrical. It has $\frac{1}{2}n(n+1)$ independent components in an n-dimensional space; 10 components in four-dimensional space-time.

Contraction of the Ricci tensor gives the *Ricci scalar*

$$\boxed{R = R^{\mu}_{\ \mu}.} \tag{7.66}$$

Let us calculate the divergence of the Ricci tensor. Contraction of Bianchi's second identity eq.(7.58) (μ with α), yields

$$\begin{aligned} R^{\mu}_{\ \nu\mu\beta;\gamma} + R^{\mu}_{\ \nu\gamma\mu;\beta} + R^{\mu}_{\ \nu\beta\gamma;\mu} &= \\ R_{\nu\beta;\gamma} - R_{\nu\gamma;\beta} + R^{\mu}_{\ \nu\beta\gamma;\mu} &= 0. \end{aligned} \tag{7.67}$$

Raising the index ν and contracting with γ leads to

$$R^{\nu}{}_{\beta;\nu} - R_{;\beta} + R^{\mu}{}_{\beta;\mu} = 0. \tag{7.68}$$

Hence the divergence of the Ricci tensor is

$$R^{\nu}{}_{\mu;\nu} = \frac{1}{2}\left(\delta^{\nu}{}_{\mu}R\right)_{;\nu}. \tag{7.69}$$

Thus the tensor

$$E^{\nu}{}_{\mu} = R^{\nu}{}_{\mu} - \frac{1}{2}\delta^{\nu}{}_{\mu}R \tag{7.70}$$

is divergence free. This is *Einstein's curvature tensor*. Its covariant components are

$$\boxed{E_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu}.} \tag{7.71}$$

It follows immediately that this tensor is symmetric.

In an n-dimensional space the vanishing of the divergence of the Einstein tensor represents n equations. Thus the Einstein tensor has $\frac{1}{2}n(n-1)$ independent components in general, and 6 independent components in four-dimensional space-time.

The Weyl Curvature Tensor

Let us now focus on the case where the dimension of the manifold is 4, like our four-dimensional spacetime. The symmetries of the Riemann tensor imply that the Riemann tensor has 20 independent components in four dimensions. The Ricci tensor, on the other hand, has only 10 independent components. The components of the Riemann tensor which is not captured in the Ricci part form what is called the *Weyl curvature tensor*.

In four dimensions the Weyl curvature tensor is defined by

$$C_{\alpha\beta\gamma\delta} = R_{\alpha\beta\gamma\delta} - g_{\alpha[\gamma}R_{\delta]\beta} + g_{\beta[\gamma}R_{\delta]\alpha} + \frac{1}{3}Rg_{\alpha[\gamma}g_{\delta]\beta}. \tag{7.72}$$

It possesses the same symmetries as the Riemann tensor,

$$C_{\alpha\beta\gamma\delta} = C_{\gamma\delta\alpha\beta}, \quad C_{\alpha\beta\gamma\delta} = -C_{\beta\alpha\gamma\delta}, \quad C_{\alpha[\beta\gamma\delta]} = 0,$$

and in addition, *contraction over any pair of indices yields zero*:

$$C^{\alpha}{}_{\beta\alpha\delta} = 0. \tag{7.73}$$

Hence, when contracting the Riemann tensor over two indices only the Ricci part of it will survive. This gives, as we will see later, a physical interpretation of the Weyl tensor. Einstein's equations, which will be introduced in the next chapter, will only involve the Ricci tensor and hence the Weyl tensor represents the *free gravitational field*. Thus even if the Ricci tensor is zero, there can be a free gravitational field encoded in the Weyl tensor. This property gives rise to many interesting phenomena; many of which will be discussed in this book. Two important examples are gravitational waves, and the Schwarzschild vacuum solution.

The definition of the Weyl tensor in any dimension, see section 18.4. This section also discusses some further properties of the Weyl tensor.

7.4 Extrinsic and Intrinsic Curvature

From eq. (7.45) it is seen that the components of the Riemann tensor may be calculated from the components of the metric tensor. They are defined in terms of basis-vectors in a space which has a curvature specified by the Riemann tensor. Thus the specification of the metric does not presuppose any embedding of the curved space in a higher-dimensional flat space. The Riemann curvature tensor represents intrinsic geometric properties of space, which may be measured by inhabitants of that space. (Such inhabitants are always assumed to be creatures with the same number of dimensions as that of the space they inhabit.) Therefore one says that the Riemann tensor is a measure of the *intrinsic* curvature of space.

In the case of a two-dimensional surface, say a balloon, the intrinsic geometry is measured by two-dimensional creatures on the surface, "flatlanders". In general, if the Riemann tensor in a space vanishes, the space is flat. For a two-dimensional surface this means that the surface may be rolled onto an Euclidean plane without any local changes of the geometry. If the surface is an elastic membrane, no stresses or strains are introduced by this "rolling out" of it. The intrinsic geometry of a cylindrical surface for example, is Euclidean, and has no intrinsic curvature.

However, as seen from an external Euclidean three-dimensional space, the cylindrical surface looks curved. The surface has external curvature. We shall now introduce a tensor measuring the external curvature of a space, which is embedded in a space of one more dimension.

In the following we shall consider a curved n-dimensional space $\mathcal{M}^n$ embedded in an $(n+1)$-dimensional space $\mathcal{M}^{n+1}$ which also may be curved. Such a space embedded in an space with one dimensional higher, is called a *hypersurface*. Furthermore, Greek indices are associated with $\mathcal{M}^{n+1}$ and Latin indices with $\mathcal{M}^n$.

A measure of the extrinsic curvature of a space is obtained by considering how the direction of the unit normal vector $\mathbf{N}$ to the hypersurface changes with position on the hypersurface. *The extrinsic curvature tensor* $\mathbf{K}$ is a tensor on $\mathcal{M}^n$ of rank $\left\{ {0 \atop 2} \right\}$ defined up to a sign ambiguity by

$$\boxed{K_{ab} = -\mathbf{e}_b \cdot \nabla_a \mathbf{n}} \tag{7.74}$$

where the covariant derivative is taken in the ambient space $\mathcal{M}^{n+1}$. Since $\mathbf{N}$ is orthogonal to the basis vectors $\mathbf{e}_b$ on $\mathcal{M}^n$, so that $\nabla_a(\mathbf{e}_b \cdot \mathbf{n}) = 0$ we get

$$K_{ab} = \mathbf{n} \cdot \nabla_a \mathbf{e}_b = \mathbf{n} \cdot \mathbf{e}_\alpha \Gamma^{\alpha}_{\ ba} = n^\alpha g_{\alpha\beta} \Gamma^{\beta}_{\ ba} = n_\alpha \Gamma^{\alpha}_{\ ba}, \tag{7.75}$$

where $\mathbf{n} = n^\alpha \mathbf{e}_\alpha$. We introduce an orthonormal basis $\{\mathbf{e}_{\hat{a}}\}$ on $\mathcal{M}^n$ and a normal unit vector $\mathbf{n} = \mathbf{e}_{\hat{n}}$. By defining $\mathbf{n} \cdot \mathbf{n} = \epsilon = \pm 1$ we get

$$K_{\hat{a}\hat{b}} = \Gamma^{\hat{n}}_{\ \hat{a}\hat{b}}\,, \qquad g_{\hat{n}\hat{n}} = \epsilon. \tag{7.76}$$

Equation (7.75) shows that the extrinsic curvature is symmetric.

Let us now deduce the relation between the Riemann tensors of $\mathcal{M}^{n+1}$ and $\mathcal{M}^n$ and the extrinsic curvature of $\mathcal{M}^n$.

We will calculate the Riemann tensors using orthonormal frames. The Riemann tensor in $\mathcal{M}^{n+1}$ projected onto $\mathcal{M}^n$ is given by

$$\left(\mathbf{d}^2 \mathbf{e}_{\hat{b}}\right)_\perp = \left(\frac{1}{2} {}^{(n+1)}R^{\hat{\lambda}}_{\ \hat{b}\hat{\alpha}\hat{\beta}} \mathbf{e}_{\hat{\lambda}} \otimes \boldsymbol{\omega}^{\hat{\alpha}} \wedge \boldsymbol{\omega}^{\hat{\beta}}\right)_\perp = \frac{1}{2} {}^{(n+1)}R^{\hat{a}}_{\ \hat{b}\hat{c}\hat{d}} \mathbf{e}_{\hat{a}} \otimes \boldsymbol{\omega}^{\hat{c}} \wedge \boldsymbol{\omega}^{\hat{d}}. \tag{7.77}$$

We can also write this in another way, using instead the Riemann tensor in $\mathcal{M}^n$

$$\begin{aligned}\left(\mathbf{d}^2\mathbf{e}_{\hat{b}}\right)_\perp &= \left(\mathbf{d}\left[\mathbf{e}_{\hat{\alpha}}\otimes\mathbf{\Omega}^{\hat{\alpha}}{}_{\hat{b}}\right]\right)_\perp = \left(\mathbf{d}\mathbf{e}_{\hat{\alpha}}\otimes\mathbf{\Omega}^{\hat{\alpha}}{}_{\hat{b}}\right)_\perp + \left(\mathbf{e}_{\hat{\alpha}}\otimes\mathbf{d}\mathbf{\Omega}^{\hat{\alpha}}{}_{\hat{b}}\right)_\perp \\ &= \mathbf{e}_{\hat{a}}\otimes\left(\mathbf{d}\mathbf{\Omega}^{\hat{a}}{}_{\hat{b}} + \mathbf{\Omega}^{\hat{a}}{}_{\hat{\alpha}}\wedge\mathbf{\Omega}^{\hat{\alpha}}{}_{\hat{b}}\right)_\perp . \end{aligned} \tag{7.78}$$

We can now use Cartan's second structural equation in $\mathcal{M}^n$ by decomposing the wedge product

$$\begin{aligned}\left(\mathbf{d}^2\mathbf{e}_{\hat{b}}\right)_\perp &= \mathbf{e}_{\hat{a}}\otimes\left(\mathbf{d}\mathbf{\Omega}^{\hat{a}}{}_{\hat{b}} + \mathbf{\Omega}^{\hat{a}}{}_{\hat{\lambda}}\wedge\mathbf{\Omega}^{\hat{\lambda}}{}_{\hat{b}} + \mathbf{\Omega}^{\hat{a}}{}_{\hat{n}}\wedge\mathbf{\Omega}^{\hat{n}}{}_{\hat{b}}\right)_\perp \\ &= \mathbf{e}_{\hat{a}}\otimes\left({}^{(n)}\mathbf{R}^{\hat{a}}{}_{b} + \left[\mathbf{\Omega}^{\hat{a}}{}_{\hat{n}}\wedge\mathbf{\Omega}^{\hat{n}}{}_{\hat{b}}\right]_\perp\right) \\ &= \frac{1}{2}\left({}^{(n)}R^{\hat{a}}{}_{\hat{b}\hat{c}\hat{d}} + \Gamma^{\hat{a}}{}_{\hat{n}\hat{c}}\Gamma^{\hat{n}}{}_{\hat{b}\hat{d}}\right)\mathbf{e}_{\hat{a}}\otimes\boldsymbol{\omega}^{\hat{c}}\wedge\boldsymbol{\omega}^{\hat{d}} \\ &= \frac{1}{2}\left({}^{(n)}R^{\hat{a}}{}_{\hat{b}\hat{c}\hat{d}} \pm K^{\hat{a}}{}_{\hat{c}}K_{\hat{b}\hat{d}}\right)\mathbf{e}_{\hat{a}}\otimes\boldsymbol{\omega}^{\hat{c}}\wedge\boldsymbol{\omega}^{\hat{d}}. \end{aligned} \tag{7.79}$$

From equations (7.77) and (7.79) it follows that

$${}^{(n)}R^{\hat{a}}{}_{\hat{b}\hat{c}\hat{d}} = {}^{(n+1)}R^{\hat{a}}{}_{\hat{b}\hat{c}\hat{d}} \pm 2K^{\hat{a}}{}_{[\hat{c}}K_{\hat{d}]\hat{b}}. \tag{7.80}$$

This is an expression of *Gauss' Theorema Egregium*, which says that an inhabitant of, say, a three-dimensional space, may perform measurements, within the three-dimensional space, which reveals to him the curvature of that space. It is not necessary to embed the space in a higher-dimensional one.

Let us write equation (7.80) in a covariant manner. The Riemann tensor on the right side in eq. (7.80) is the projected Riemann tensor of the ambient space $\mathcal{M}^{n+1}$. If we split the metric tensor $g_{\alpha\beta}$ into

$$g_{\alpha\beta} = h_{\alpha\beta} + \epsilon n_\alpha n_\beta, \tag{7.81}$$

where n_α are the components of the unit normal vector $\mathbf{n}$, then the tensor $h_{\alpha\beta}$ will act as a projection tensor onto the space $\mathcal{M}^n$. In addition, the tensor $h_{\alpha\beta}$ will be the metric tensor of the space $\mathcal{M}^n$ for vectors on $\mathcal{M}^n$. Since the exterior curvature and the Riemann tensor in $\mathcal{M}^n$ already are projected we have

$$h^{\lambda}{}_{\alpha}K_{\lambda\beta} = K_{\alpha\beta} \tag{7.82}$$

i.e. they are eigentensors to the projection map $h^{\lambda}{}_{\alpha}$. The equation (7.80) can now be written covariantly as

$$\boxed{{}^{(n)}R^{\alpha}{}_{\beta\mu\nu} = {}^{(n+1)}R^{\lambda}{}_{\gamma\sigma\rho}h^{\alpha}{}_{\lambda}h^{\gamma}{}_{\beta}h^{\sigma}{}_{\mu}h^{\rho}{}_{\nu} + \epsilon\left(K^{\alpha}{}_{\mu}K_{\beta\nu} - K^{\alpha}{}_{\nu}K_{\beta\mu}\right).} \tag{7.83}$$

Similarly, we can show that

$$\boxed{{}^{(n)}\nabla_\alpha K_{\beta\mu} - {}^{(n)}\nabla_\mu K_{\beta\alpha} = {}^{(n+1)}R^{\lambda}{}_{\sigma\rho\delta}n_\lambda h^{\sigma}{}_{\beta}h^{\rho}{}_{\alpha}h^{\delta}{}_{\mu}} \tag{7.84}$$

where ${}^{(n)}\nabla_\alpha = h^{\beta}{}_{\alpha}\nabla_\beta$ is the n-dimensional connection. The derivation of this is left as a problem (see problem 7.4). This equation is called the *Codazzi equation*.

In the special case where $\mathcal{M}^{n+1}$ is flat, eq. (7.80) reduce to

$${}^{(n)}R_{\hat{a}\hat{b}\hat{c}\hat{d}} = \pm\left(K_{\hat{a}\hat{c}}K_{\hat{d}\hat{b}} - K_{\hat{a}\hat{d}}K_{\hat{c}\hat{b}}\right). \tag{7.85}$$

For a two dimensional surface $\mathcal{M}^2$ these equations reduce to the single equation

$$R_{\hat{1}\hat{2}\hat{1}\hat{2}} = K_{\hat{1}\hat{1}} K_{\hat{1}\hat{2}} - (K_{\hat{1}\hat{2}})^2 = \det(K_{\hat{a}\hat{b}}). \tag{7.86}$$

Comparing with eq. (7.30) of a surface (with $\det(g_{\hat{a}\hat{b}}) = 1$) we obtain

$$K = R_{\hat{1}\hat{2}\hat{1}\hat{2}}. \tag{7.87}$$

Thus, the Gaussian curvature represents the *intrinsic* geometry of the surface.

Example 7.2 (The curvature of a straight circular cone) **Example**

From the figure 7.4 it is seen that the line element on the conical surface is

$$ds^2 = dl^2 + r^2 d\theta^2 = dl^2 + \left(\frac{R}{H}\right)^2 l^2 d\theta^2. \tag{7.88}$$

Here are l and θ coordinates on the surface, and r a coordinate normal to the axis of the cone.

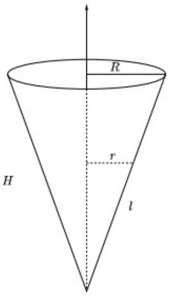

Figure 7.4: A cone is intrinsically flat

We introduce an orthonormal basis on the surface

$$\boldsymbol{\omega}^{\hat{l}} = \mathbf{dl}, \quad \boldsymbol{\omega}^{\hat{\theta}} = \left(\frac{R}{H}\right) \mathbf{d}\boldsymbol{\theta}. \tag{7.89}$$

Exterior differentiation yields

$$\mathbf{d}\boldsymbol{\omega}^{\hat{l}} = 0, \quad \mathbf{d}\boldsymbol{\omega}^{\hat{\theta}} = \frac{1}{l}\boldsymbol{\omega}^{\hat{l}} \wedge \boldsymbol{\omega}^{\hat{\theta}}. \tag{7.90}$$

Cartan's first structural equation now give the non-vanishing connection forms

$$\boldsymbol{\Omega}^{\hat{\theta}}{}_{\hat{l}} = -\boldsymbol{\Omega}^{\hat{l}}{}_{\hat{\theta}} = \frac{1}{l}\boldsymbol{\omega}^{\hat{\theta}}. \tag{7.91}$$

Thus

$$\mathbf{d}\boldsymbol{\Omega}^{\hat{\theta}}{}_{\hat{l}} = \left(\mathbf{d}\frac{1}{l}\right)\boldsymbol{\omega}^{\hat{\theta}} + \frac{1}{l}\mathbf{d}\boldsymbol{\omega}^{\hat{\theta}} = 0. \tag{7.92}$$

and Cartan's second structural equation gives

$$\mathbf{R}^{\hat{\theta}}{}_{\hat{l}} = \mathbf{R}^{\hat{l}}{}_{\hat{\theta}} = 0 \tag{7.93}$$

which shows that the intrinsic geometry of the conical surface is Euclidean.

The extrinsic curvature is given by eq. (7.75). In the present case the single non-vanishing component of this tensor is

$$K_{\hat{\theta}\hat{\theta}} = \Gamma^{\hat{n}}{}_{\hat{\theta}\hat{\theta}}. \tag{7.94}$$

In example 6.9 we found that $\Gamma^{\hat{r}}{}_{\hat{\theta}\hat{\theta}} = -\frac{1}{r}$, so

$$\mathbf{d}\mathbf{e}_{\hat{\theta}} = -\frac{1}{r}\mathbf{e}_{\hat{r}} \otimes \boldsymbol{\omega}^{\hat{\theta}} \tag{7.95}$$

From Fig.7.4 we see that

$$\mathbf{e}_{\hat{r}} = \frac{H}{L}\mathbf{e}_{\hat{n}} + \frac{R}{L}\mathbf{e}_{\hat{l}}, \quad L = (H^2 + L^2)^{\frac{1}{2}} \tag{7.96}$$

This yields

$$\mathbf{d}\mathbf{e}_{\hat{\theta}} = -\frac{H}{Lr}\mathbf{e}_{\hat{n}} \otimes \boldsymbol{\omega}^{\hat{\theta}} - \frac{R}{Lr}\mathbf{e}_{\hat{l}} \otimes \boldsymbol{\omega}^{\hat{\theta}} \tag{7.97}$$

which shows that

$$\Gamma^{\hat{n}}{}_{\hat{\theta}\hat{\theta}} = -\frac{H}{Lr} \tag{7.98}$$

Hence, the conical surface has a non-vanishing extrinsic curvature given by

$$K_{\hat{\theta}\hat{\theta}} = -\left(1 + \frac{R^2}{H^2}\right)^{-\frac{1}{2}} \cdot \frac{1}{r} \tag{7.99}$$

The limit $H \longrightarrow \infty, r \longrightarrow R$ represents a straight cylinder with $K_{\hat{\theta}\hat{\theta}} = -\frac{1}{R}$. The limit $H \longrightarrow 0$ represents a plane with $K_{\hat{\theta}\hat{\theta}} = 0$.

7.5 The equation of geodesic deviation

Consider two nearby geodesic curves, both parametrised by a parameter λ. Let s be a vector connecting points on the two curves with the same value of λ. The connecting vector s is said to measure the *geodesic deviation* of the curves.

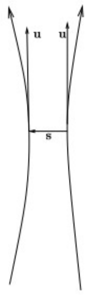

Figure 7.5: The two solid lines are neighbouring geodesics. They are connected by an infinitesimal vector s that obeys the equation of geodesic deviation

In order to deduce an equation describing how the geodesic deviation varies along the curves, we consider the covariant directional derivative of s along the curve $\nabla_{\mathbf{u}}\mathbf{s}$ where $\mathbf{u}$ is the tangent vector to the curve.

Let $\mathbf{u}$ and s be coordinate basis vectors of a coordinate system. Then $[\mathbf{s},\mathbf{u}] = 0$, so that

$$\nabla_{\mathbf{u}}\mathbf{s} = \nabla_{\mathbf{s}}\mathbf{u} \tag{7.100}$$

giving

$$\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\mathbf{s} = \nabla_{\mathbf{u}}\nabla_{\mathbf{s}}\mathbf{u}. \tag{7.101}$$

Furthermore

$$\begin{aligned}\mathbf{R}(\mathbf{u},\mathbf{s})\mathbf{u} &= \left([\nabla_{\mathbf{u}},\nabla_{\mathbf{s}}] - \nabla_{[\mathbf{u},\mathbf{s}]}\right)\mathbf{u} \\ &= [\nabla_{\mathbf{u}},\nabla_{\mathbf{s}}]\,\mathbf{u}.\end{aligned} \tag{7.102}$$

Thus

$$\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\mathbf{s} = \nabla_{\mathbf{s}}\nabla_{\mathbf{u}}\mathbf{u} + \mathbf{R}(\mathbf{u},\mathbf{s})\mathbf{u}. \tag{7.103}$$

Since the curves are geodesics $\nabla_{\mathbf{u}}\mathbf{u} = 0$, and the equation reduces to

$$\boxed{\nabla_{\mathbf{u}}\nabla_{\mathbf{u}}\mathbf{s} + \mathbf{R}(\mathbf{s},\mathbf{u})\mathbf{u} = 0} \tag{7.104}$$

where we have used the antisymmetry of the Riemann tensor. Equation (7.104) is called the *equation of geodesic deviation*. The component form of the equation is

$$\left(\frac{d^2\mathbf{s}}{d\lambda^2}\right)^{\mu} + R^{\mu}{}_{\alpha\nu\beta}u^{\alpha}s^{\nu}u^{\beta} = 0. \tag{7.105}$$

This equation shows that the Riemann tensor can be determined entirely from measurements of geodesic deviation.

In comoving geodesic normal coordinates with $\mathbf{u} = (1,0,0,0)$ the equation reduces to

$$\left(\frac{d^2\mathbf{s}}{d\lambda^2}\right)^{i} + R^{i}{}_{0j0}s^{j} = 0. \tag{7.106}$$

7.6 Spaces of constant curvature

We have in section 6.11 seen how important Killing vectors may be for the solvability of the equations that govern particle motion. Highly symmetric spaces are therefore important both in mathematics and in physics. We will study maximally symmetric spaces with a Riemannian metric, S^n, $\mathbb{P}^n$, $\mathbb{E}^n$ and $\mathbb{H}^n$. The first 2 of these differ only at a global scale, that is they are locally the same but their topology is different. Maybe the mathematically most interesting one is the hyperbolic space $\mathbb{H}^n$. We will start out with the most familiar one, the Euclidean space $\mathbb{E}^n$.

The Euclidean space, $\mathbb{E}^n$

We are all familiar with this space. The metric can be written

$$ds^2 = g_{ab}\mathbf{dx}^a \otimes \mathbf{dx}^b \tag{7.107}$$

where $g_{ab} = \delta_{ab}$. We can easily generalize this to the Minkowskian case by letting the components of the metric tensor be of either sign, $g_{ab} = \pm\delta_{ab}$. As claimed, this is a maximally symmetric space, thus having $\frac{1}{2}n(n+1)$ linearly independent Killing vectors. We should stress that when we say linearly independent in this context, we mean linearly independent *solutions* of Killing's equations. The Killing vectors are not linearly independent in the space itself. Killing's equations do in this case reduce to

$$\xi_{i,j} + \xi_{j,i} = 0 \tag{7.108}$$

because the connection coefficients all vanish identically. We can easily find n linearly independent solutions to this equation,

$$\boldsymbol{\xi}_{(a)} = \frac{\partial}{\partial x^b}. \tag{7.109}$$

Another set of solutions are[1]

$$\boldsymbol{\xi}_{(ab)} = x^b\frac{\partial}{\partial x^a} - x^a\frac{\partial}{\partial x^b} \tag{7.110}$$

The solutions $\boldsymbol{\xi}_{(ab)}$ are antisymmetric in the indices so they represent $\frac{1}{2}n(n-1)$ linearly independent solutions. Thus all in all we have found $n + \frac{1}{2}n(n-1) = \frac{1}{2}n(n+1)$ linearly independent solutions of Killing's equation. Hence, as claimed, the Euclidean spaces admit $\frac{1}{2}n(n+1)$ linearly independent Killing vectors and is therefore maximally symmetric.

The one-parameter group of diffeomorphisms associated to these Killing vectors can be found by solving the equations

$$\frac{d}{dt}\phi_t = \boldsymbol{\xi}. \tag{7.111}$$

Representing ϕ_t by a vector $\mathbf{V}$, the equations for $\boldsymbol{\xi}_{(a)}$ can be written

$$\frac{d}{dt}\mathbf{V}_{(a)} = \mathbf{e}_a. \tag{7.112}$$

It has solutions

$$\mathbf{V}_{(a)} = \mathbf{V}_0 + t\mathbf{e}_a \tag{7.113}$$

where $\mathbf{V}_0$ is a constant vector corresponding to the initial condition. These mappings are mere translations a distance t in the a-direction. The Euclidean spaces have translation invariance.

Defining $\mathsf{J}_{(ab)}$ as the antisymmetric matrix with indices

$$\left(\mathsf{J}_{(ab)}\right)_{ij} = \delta_{ai}\delta_{bj} - \delta_{bi}\delta_{aj} \tag{7.114}$$

---

[1] Since we use Cartesian coordinates we have $x_i \equiv g_{ij}x^j = x^i$. Hence, the position of the index does not matter.

we can write for the Killing vectors $\boldsymbol{\xi}_{(ab)}$

$$\frac{d}{dt}\mathbf{V}_{(ab)} = \mathsf{J}_{(ab)}\mathbf{V}_{(ab)}. \tag{7.115}$$

This equation have solutions

$$\mathbf{V}_{(ab)} = e^{t\mathsf{J}_{(ab)}} \cdot \mathbf{V}_0 \tag{7.116}$$

where

$$e^{t\mathsf{J}_{(ab)}} = 1 + t\mathsf{J}_{(ab)} + \frac{1}{2}t^2\mathsf{J}^2_{(ab)} + ... = \mathsf{R}_{(ab)}(t) \tag{7.117}$$

is the rotation matrix through an angle t with respect to the (ab)-plane. Showing this is left as an exercise, see the problems in the end of this chapter. Thus, the Euclidean spaces are also rotationally symmetric. The three-dimensional Euclidean space has 6 linear independent Killing vectors, representing translation and rotational invariance. There is one significant difference between these operations. While the translations move "the whole space", the rotations leave an axis fixed. For a point p, the subgroup of the isometry group that leaves p fixed, is called *the isotropy subgroup*. In the case of $\mathbb{E}^3$, the isotropy subgroup of any point is the group of rotations with respect to this point. We will come back to these concepts in a later chapter, where we will define these groups more rigorously.

The elliptic spaces, S^n and $\mathbb{P}^n$

Let us first start out by defining the spheres S^n. Consider the $(n+1)$-dimensional Euclidean space and look at the hypersurface

$$(x^1)^2 + (x^2)^2 + ... + (x^{n+1})^2 = 1. \tag{7.118}$$

This hypersurface with the induced metric is the sphere S^n. We claim now

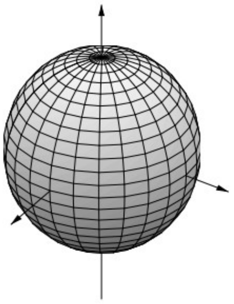

Figure 7.6: The two-dimensional sphere embedded in a Euclidean space

that the Killing vectors of the sphere is the Killing vectors from the Euclidean space that generate maps that map the sphere onto itself. These are the rotations with respect to the origin, with corresponding Killing vectors

$$\boldsymbol{\xi}_{(\alpha\beta)} = x^{\beta}\frac{\partial}{\partial x^{\alpha}} - x^{\alpha}\frac{\partial}{\partial x^{\beta}} \tag{7.119}$$

where Latin indices run from 1 to $(n+1)$. Here we have $\frac{1}{2}n(n+1)$ of them, and when constrained to the sphere, they form the Killing vectors of the sphere. Thus this space is maximally symmetric. Let us use Gauss' Theorema Egregium to calculate its curvature properties. Given a point on the sphere, then for one of the coordinates $x^a \neq 0$. Assume that $x^{n+1} \neq 0$. Then we can define the following basis vectors

$$\mathbf{e}_a = \boldsymbol{\xi}_{(a(n+1))} = x^{n+1}\frac{\partial}{\partial x^a} - x^a\frac{\partial}{\partial x^{n+1}} \tag{7.120}$$

where Greek indices run from 1 to n. The metric in this basis is

$$\begin{aligned} g_{ab} &= \mathbf{e}_a \cdot \mathbf{e}_b = \left(x^{n+1}\frac{\partial}{\partial x^a} - x^a\frac{\partial}{\partial x^{n+1}}\right)\cdot\left(x^{n+1}\frac{\partial}{\partial x^b} - x^b\frac{\partial}{\partial x^{n+1}}\right) \\ &= x^a x^b + \left(x^{n+1}\right)^2\delta_{ab}. \end{aligned} \tag{7.121}$$

The radial vector

$$\mathbf{e}_r = x^\alpha\frac{\partial}{\partial x^\alpha} \tag{7.122}$$

has unit length on the sphere. Using this we can calculate the components of the extrinsic curvature

$$\begin{aligned} K_{ab} &= \mathbf{e}_r \cdot (\mathbf{d}\mathbf{e}_a(\mathbf{e}_b)) = \mathbf{e}_r \cdot \left[\frac{\partial}{\partial x^a}\left(\mathbf{d}\mathbf{x}^{n+1}(\mathbf{e}_b)\right) - \frac{\partial}{\partial x^{n+1}}\left(\mathbf{d}\mathbf{x}^a(\mathbf{e}_b)\right)\right] \\ &= \mathbf{e}_r \cdot \left[x^b\frac{\partial}{\partial x^a} + \delta_{ab}(x^{n+1})\frac{\partial}{\partial x^{n+1}}\right] = x^a x^b + \left(x^{n+1}\right)^2\delta_{ab}. \end{aligned} \tag{7.123}$$

Thus we have

$$K_{ab} = g_{ab}. \tag{7.124}$$

The Gauss' Theorema Egregium now gives us the Riemann tensor

$$R_{abcd} = g_{ac}g_{bd} - g_{ad}g_{bc}. \tag{7.125}$$

Contracting once,

$$R_{bd} = (n-1)g_{bd} \tag{7.126}$$

we see that the Ricci tensor is proportional to the metric[2]. Thus in an orthonormal frame, the Ricci tensor will be everywhere positive and constant. Contracting once more to obtain the Ricci scalar

$$R = n(n-1). \tag{7.127}$$

The projective space $\mathbb{P}^n$ can now be obtained by identifying opposite points on the sphere S^n. The projective space is therefore basically half of the sphere. There is a pathology however, for n even, the projective space is *non-orientable*. That means there is no globally defined unit normal vector field on the space. However, for n odd (including therefore dimension 3), the space is orientable, and no problem of such kind exists.

---

[2] More generally, spaces for which the Ricci tensor can be written $R_{ab} = \lambda g_{ab}$ where λ is a constant, are called *Einstein spaces*. All the constant curvature spaces are Einstein spaces.

Let us derive a useful form of the metric of the sphere. We introduce a radial coordinate r by

$$r^2 = \sum_a (x^a)^2 \tag{7.128}$$

so that

$$x^{n+1} = \pm\sqrt{1-r^2}. \tag{7.129}$$

Hence,

$$\left(dx^{n+1}\right)^2 = \frac{r^2dr^2}{1-r^2}. \tag{7.130}$$

Assuming now that $d\Omega_{n-1}$ is the metric on the $(n-1)$-dimensional sphere, S^{n-1}, then

$$\sum_a (dx^a)^2 = dr^2 + r^2 d\Omega_{n-1}^2 \tag{7.131}$$

which is just the expression for the Euclidean metric in spherical coordinates. The metric on the sphere, S^n, is now

$$ds^2 = \left(dx^{n+1}\right)^2 + \sum_a (dx^a)^2 = \frac{dr^2}{1-r^2} + r^2 d\Omega_{n-1}^2. \tag{7.132}$$

Note that this metric only covers half of the sphere. For the case $\mathbb{P}^n$ it covers the whole space, except for the points on the equator which forms a set of measure zero.

The Hyperbolic spaces, $\mathbb{H}^n$

As for the sphere, the hyperbolic space can be viewed upon as a hypersurface in a flat $(n+1)$-dimensional space. But now we have to use the flat $(n+1)$-dimensional Minkowski space with metric

$$ds^2 = \eta_{\alpha\beta}\mathbf{dx}^\alpha \otimes \mathbf{dx}^\beta = -\mathbf{dx}^{n+1} \otimes \mathbf{dx}^{n+1} + \sum_a \mathbf{dx}^a \otimes \mathbf{dx}^a. \tag{7.133}$$

The hyperbolic space is defined as the hyperboloid

$$-(x^{n+1})^2 + (x^1)^2 + ... + (x^n)^2 = -1, \quad x^{n+1} > 0. \tag{7.134}$$

This surface is space-like and has a Riemannian metric. Its symmetries can be found by using the same argument as for the sphere. The symmetries for the Minkowski space that leave the hyperboloid invariant, are the Lorentz transformations in $(n+1)$ dimensions. The Killing vectors for the Lorentz transformations come in two classes, boosts

$$\boldsymbol{\xi}_{(a)} = x^{n+1}\frac{\partial}{\partial x^a} + x^a\frac{\partial}{\partial x^{n+1}} \tag{7.135}$$

and rotations

$$\boldsymbol{\xi}_{(ab)} = x^b\frac{\partial}{\partial x^a} - x^a\frac{\partial}{\partial x^b}. \tag{7.136}$$

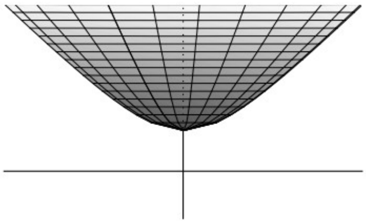

Figure 7.7: The Hyperbolic plane embedded in three-dimensional Minkowski space

As for the sphere we can now choose a set of basis vectors by

$$\mathbf{e}_a = \boldsymbol{\xi}_{(a)} \tag{7.137}$$

but these will now be globally defined since $x^{n+1} \geq 1$. The metric in this basis is

$$\begin{aligned} g_{ab} &= \mathbf{e}_a \cdot \mathbf{e}_b = \left(x^{n+1} \frac{\partial}{\partial x^a} + x^a \frac{\partial}{\partial x^{n+1}} \right) \cdot \left(x^{n+1} \frac{\partial}{\partial x^b} + x^b \frac{\partial}{\partial x^{n+1}} \right) \\ &= -x^a x^b + \left(x^{n+1} \right)^2 \delta_{ab} \end{aligned} \tag{7.138}$$

since $\frac{\partial}{\partial x^{n+1}} \cdot \frac{\partial}{\partial x^{n+1}} = -1$. The radial vector

$$\mathbf{e}_r = x^\alpha \frac{\partial}{\partial x^\alpha} \tag{7.139}$$

has on the hyperboloid a length

$$\mathbf{e}_r \cdot \mathbf{e}_r = -(x^{n+1})^2 + \sum_a (x^a)^2 = -1. \tag{7.140}$$

Following an almost identical procedure to the case of the sphere, we can calculate the extrinsic curvature

$$\begin{aligned} K_{ab} &= \mathbf{e}_r \cdot (\mathbf{d}\mathbf{e}_a(\mathbf{e}_b)) \\ &= g_{ab}. \end{aligned} \tag{7.141}$$

The Gauss's Theorema Egregium now turns into (we have to choose the negative sign due to the negative length of the normal unit vector)

$$R_{abcd} = -(g_{ac} g_{bd} - g_{ad} g_{bc}). \tag{7.142}$$

Contracting once,

$$R_{bd} = -(n-1) g_{bd}. \tag{7.143}$$

This space has negative curvature, and basically just the same curvature properties as for the sphere, just with an opposite sign of the curvature. A metric on the hyperbolic space can written by the following. Introduce spherical coordinates,

$$r^2 = \sum_a (x^a)^2 \tag{7.144}$$

and following the procedure as for the sphere, the metric can be written

$$ds^2 = \frac{dr^2}{1+r^2} + r^2 d\Omega_{n-1}^2 \tag{7.145}$$

where $d\Omega_{n-1}^2$ is the metric on the $(n-1)$-dimensional sphere. In this case the metric covers the whole of $\mathbb{H}^n$.

As we see, this space has infinite volume in contrast to the sphere. Note that there exist (and a lot of them) compact hyperbolic spaces as well, but these breaks the isometries for the $\mathbb{H}^n$ at a global scale. Locally, however, they have a hyperbolic metric and are locally isometric to $\mathbb{H}^n$.

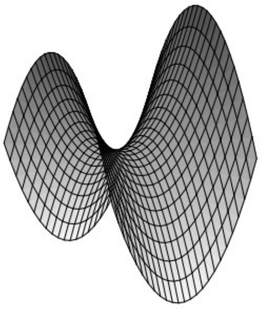

Figure 7.8: The hyperbolic plane can be seen upon as a saddle-surface

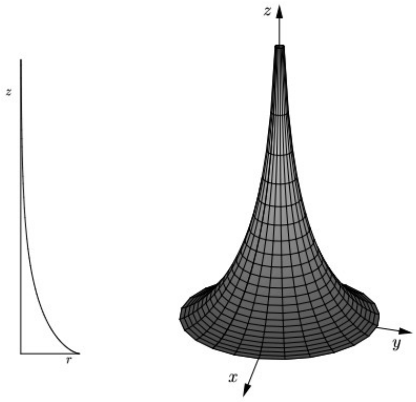
A more intuitive view of the hyperbolic plane is by considering it as the surface of a saddle, Fig. 7.8. A saddle surface in Euclidean three-space has a negative curvature and has therefore much of the same properties of the constantly curved hyperbolic plane. We should emphasize that the whole hyperbolic plane given by eq. (7.134) for $n = 2$ cannot be embedded in the three-dimensional Euclidean space. So the surface in Fig. 7.8 has not a constant curvature.

We can find a constant negatively curved space in Euclidean space. Consider the surface generated by the rotation around the z-axis of the *tractrix*

$$z = \ln\left|\frac{1 \pm \sqrt{1-r^2}}{r}\right| \mp \sqrt{1-r^2} \tag{7.146}$$

where $r^2 = x^2 + y^2$. This space will have constant negative curvature and are sometimes called a *pseudo-sphere*. The tractrix and the pseudo-sphere are depicted in Fig.7.9.

The name tractrix is due to the fact that this is the curve which is traced out by an object on the end of a rope of unit length held by a running child along the z-axis. If the object and the child start in the xz-plane at $(1, 0)$ and $(0, 0)$, respectively, then the curve is precisely the curve eq. (7.146) with $y = 0$. The points along the circle $r = 1$ correspond to a singular line, and hence, this cannot be the whole hyperbolic space.



(a) The tractrix (b) The pseudo-sphere

Figure 7.9: The tractrix and the pseudo-sphere. The pseudo-sphere is obtained by rotating the tractrix around the z-axis.

Problems

7.1. *Rotation matrices*
Show that

$$e^{t\mathsf{J}_{(ab)}} = 1 + t\mathsf{J}_{(ab)} + \frac{1}{2}t^2\mathsf{J}_{(ab)}^2 + \dots = \mathsf{R}_{(ab)}(t), \tag{7.147}$$

i.e. verify eq. (7.117).

7.2. *Inverse metric on S^n*
In this problem we will use the basis vectors $\mathbf{e}_a$ defined in eq. (7.120):

$$\mathbf{e}_a = \boldsymbol{\xi}_{(a(n+1))} = x^{n+1}\frac{\partial}{\partial x^a} - x^a\frac{\partial}{\partial x^{n+1}}. \tag{7.148}$$

(a) Assume that the basis forms on the sphere S^n has the form

$$\boldsymbol{\omega}^a = C^a_{\ \mu}\mathbf{dx}^\mu \tag{7.149}$$

Find the coefficients $C^a_{\ \mu}$.

(b) Find g^{ab}, and verify that $g^{ab}g_{bc} = \delta^a_{\ c}$.

7.3. *The curvature of a curve*
Consider a curve $y = y(x)$ in a two-dimensional plane. Utilize that the differential of the arc length is $ds = \left(1+y'^2\right)^{1/2}dx$ and show that the tangent vector, the curvature vector and the curvature of the curve are given by

$$\begin{aligned} \mathbf{t} &= \left(1+y'^2\right)^{-1/2}\left(\mathbf{e}_x + y'\mathbf{e}_y\right), \\ \mathbf{k} &= \left(1+y'^2\right)^{-2}y''\left(y'\mathbf{e}_x + \mathbf{e}_y\right), \\ \kappa &= \left(1+y'^2\right)^{-3/2}y'', \end{aligned} \tag{7.150}$$

respectively.

7.4. *The Gauss-Codazzi equations*
The Gauss-Codazzi equations are of great importance and tells us much about the geometry of hypersurfaces. We will need these equations for a later chapter, and in this problem we will show an important relation between the Ricci curvatures in the ambient space and on the hypersurface.

(a) We will first show that the projection operator $h^{\alpha}_{\ \beta}$, defined by eq. (7.81) is what it is claimed to be. We define $h_{\alpha\beta}$ with eq. (7.81):

$$g_{\alpha\beta} = h_{\alpha\beta} + \epsilon n_{\alpha} n_{\beta} \tag{7.151}$$

where $g_{\alpha\beta}$ is the metric in the ambient space, and n_{α} is the components of the unit normal vector. The operator $h^{\alpha}_{\ \beta}$ is now defined by $h^{\alpha}_{\ \beta} = g^{\alpha\lambda} h_{\lambda\beta}$. Show the following:

$$\begin{aligned} h_{\alpha\beta} &= h_{\beta\alpha} \\ h^{\alpha}_{\ \lambda} h^{\lambda}_{\ \beta} &= h^{\alpha}_{\ \beta}. \end{aligned}$$

These properties defines a projection map. We now have to show that it projects onto the space that is orthogonal to n^{α}. Hence, if v^{β} is a vector, we have to show that

$$\begin{aligned} h^{\alpha}_{\ \beta} v^{\beta} &= 0, && \text{iff } v^{\beta} \text{ is parallel to } n^{\beta}. \\ h^{\alpha}_{\ \beta} v^{\beta} &= v^{\alpha}, && \text{iff } v^{\beta} \text{ is orthogonal to } n^{\beta}. \end{aligned}$$

Prove this. Explain now we can define the projection of an arbitrary tensor by projection the tensor, index by index.

(b) Verify the Codazzi equation, eq. (7.84). (Hint: Calculate $\left(\mathbf{d}^2\mathbf{e}_{\hat{b}}\right) \cdot \mathbf{n}$.)

(c) Show that

$$^{(n+1)}R = {}^{(n)}R - \epsilon\left(K^2 - K^{\alpha\beta}K_{\alpha\beta}\right) + 2\epsilon^{(n+1)}R_{\alpha\beta}n^{\alpha}n^{\beta}, \tag{7.152}$$

which can be written

$$-2\epsilon^{(n+1)}E_{\alpha\beta}n^{\alpha}n^{\beta} = {}^{(n)}R - \epsilon\left(K^2 - K^{\alpha\beta}K_{\alpha\beta}\right). \tag{7.153}$$

7.5. *The Poincaré half-space*
Consider half of $\mathbb{R}^3$, $z > 0$ with metric

$$ds^2 = \frac{1}{z^2}\left(dx^2 + dy^2 + dz^2\right) \tag{7.154}$$

(a) Calculate the connection forms and the curvature forms using the structural equations of Cartan.

(b) Calculate the Riemann tensor, the Ricci tensor and the Ricci scalar.

(c) Show that

$$R_{abcd} = -(g_{ac}g_{bd} - g_{ad}g_{bc}) \tag{7.155}$$

Compare this with the three-dimensional hyperbolic space. Are there any way we can differentiate between these two cases? Are they different manifestations of the same space?

7.6. *The pseudo-sphere*
Show that the tractrix, eq. (7.146), obeys the differential equation

$$\left(\frac{dr}{dz}\right)^2 = \frac{r^2}{1-r^2}. \tag{7.156}$$

Substitute this into the line-element for flat space, do the substitution $r = \sin\theta$, and show that the metric on the pseudo-sphere can be written

$$ds^2 = d\theta^2 + \sinh^2\theta d\phi^2. \tag{7.157}$$

Show that this metric has constant negative curvature.

7.7. *A non-Cartesian coordinate system in two dimensions*
Consider the following metric on a two-dimensional surface:

$$ds^2 = v^2 du^2 + u^2 dv^2. \tag{7.158}$$

We will show, in two different ways, that this is only the flat Euclidean plane in disguise.

(a) Use the orthonormal frame approach and find the connection one-forms $\mathbf{\Omega}^{\hat{a}}_{\ \hat{b}}$. Find also the curvature two-forms $\mathbf{R}^{\hat{a}}_{\ \hat{b}}$ and show that they are identically zero.

(b) Show that the metric can be put onto the form

$$ds^2 = dx^2 + dy^2$$

by finding a transformation matrix $\mathsf{M} = \left(M^i_{\ a}\right)$ connecting the basis vectors $\mathbf{e}_u$ and $\mathbf{e}_v$, and $\mathbf{e}_x$ and $\mathbf{e}_y$. This can be done using the following relations

$$\begin{aligned} g_{ab} &= g_{ij} M^i_{\ a} M^j_{\ b} \\ \frac{\partial M^i_{\ a}}{\partial x^b} &= \frac{\partial M^i_{\ b}}{\partial x^a}. \end{aligned} \tag{7.159}$$

Where do these relations come from?

7.8. *The curvature tensor of a sphere*
Introduce an orthonormal basis on the sphere, S^2, and use Cartan's structural equations to find the physical components of the Riemann curvature tensor.

7.9. *The curvature scalar of a surface of simultaneity*
The spatial line-element of a rotating disc is

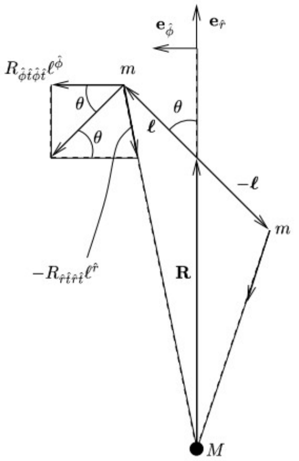
$$d\ell^2 = dr^2 + \frac{r^2}{1 - \frac{\omega^2 r^2}{c^2}} d\phi^2. \tag{7.160}$$

Introduce an orthonormal basis on this surface and use Cartan's structural equations to find the Ricci scalar.

7.10. *The tidal force pendulum and the curvature of space*
We will again consider the tidal force pendulum from Example 1.3. Here we shall use the equation for geodesic deviation, eq. (7.104), to find the period of the pendulum.

(a) Why can the equation for geodesic equation be used to find the period of the pendulum in spite of the fact that the particles do not move along geodesics? Explain also why the equation can be used even though the centre of the pendulum does not follow a geodesic.

(b) Assume that the centre of the pendulum is fixed at a distance R from the centre of mass of the Earth. Introduce an orthonormal basis $\{\mathbf{e}_{\hat{a}}\}$ with the origin at the centre of the pendulum (see Fig.7.10).



$\mathbf{e}_{\hat{\phi}}$

Figure 7.10: The tidal force pendulum

Show that, to first order in v/c and ϕ/c^2, where v is the three-velocity of the masses and ϕ the gravitational potential at the position of the pendulum, that the equation of geodesic equation takes the form

$$\frac{d^2\ell_{\hat{i}}}{dt^2} + R_{\hat{i}\hat{0}\hat{j}\hat{0}}\ell^{\hat{j}} = 0. \tag{7.161}$$

(c) Find the period of the pendulum expressed in terms of the components of Riemann's curvature tensor.

7.11. *The Weyl tensor vanishes for spaces of constant curvature*
Use the definition eq. (7.72) to show that the constant curvature spaces S^4, $\mathbb{E}^4$, and $\mathbb{H}^4$ all have zero Weyl tensor.

The Equation of geodesic deviation

( )
+,- * *. ! * "9' " 9' 1#
) &" '

Somit gilt

$$ax^2 + bx + c = a\left[\left(x + \frac{b}{2a}\right)^2 - \left(\frac{b}{2a}\right)^2\right] + c = a\left(x + \frac{b}{2a}\right)^2 - a\left(\frac{b}{2a}\right)^2 + c$$

und folglich

$$d = \frac{b}{2a} \quad \text{sowie} \quad e = -a \cdot \left(\frac{b}{2a}\right)^2 + c = c - ad^2 \,.$$

Damit haben wir die Idee des folgenden Algorithmus erklärt.

Algorithmus 1.2 (Quadratische Ergänzung II)
Überführung des Terms

$$ax^2 + bx + c$$

in die Form

$$a(x+d)^2 + e$$

1. Berechne

$$d = \frac{b}{2a} \,.$$

2. Berechne

$$e = c - ad^2 \,.$$

Beispiel 1.14
Wir überführen den Term

$$ax^2 + bx + c = 9x^2 + 36x + 12$$

in die Form $a(x+d)^2 + e$. Gemäß Algorithmus 1.2 berechnen wir mit $a = 9$, $b = 36$ und $c = 12$

$$d = \frac{b}{2a} = \frac{36}{2 \cdot 9} = 2 \quad \text{und} \quad e = c - ad^2 = 12 - 9 \cdot 2^2 = -24 \,.$$

Damit ist

$$9x^2 + 36x + 12 = 9(x+2)^2 - 24 \,.$$

■

1.6 Die irrationalen Zahlen π und e

In diesem Abschnitt beschäftigen wir uns mit zwei irrationalen Zahlen, die in der Mathematik eine besonders große Rolle spielen. Dies sind die Kreiszahl

$$\pi = 3.141592653589793238\ldots \tag{1.79}$$

und die Eulersche Zahl

$$\mathrm{e} = 2.718281828459045235\ldots \qquad (1.80)$$

Die Zahl π tritt beispielsweise bei der Definition des Bogenmaßes von Winkeln (siehe Abschnitt 3.2), bei der Berechnung des Flächeninhalts ebener Flächen und Flächen im Raum, bei Volumenberechnungen von Körpern sowie der Berechnung der Länge von Kurven auf. Aus der Schulmathematik sind sicher noch die Formeln zur Berechnung des Flächeninhalts F und des Umfangs U eines Kreises mit dem Durchmesser d bekannt, nämlich

$$F = \frac{\pi}{4}\,d^2 \quad \text{und} \quad U = \pi d\,.$$

Die Zahl e benötigt man im Zusammenhang mit der sogenannten e-Funktion, mit welcher man z. B. Wachstumsprozesse mathematisch beschreiben kann (siehe Beispiel 3.29 im Abschnitt 3.2). Sie tritt auch auf, wenn man den Durchhang eines nur durch sein Eigengewicht belasteten Seils (siehe Beispiel 3.30) berechnet oder spiralförmige Kurven mathematisch beschreibt.

Ausgehend von der Formel für den Umfang eines Kreises mit dem Radius d kann man einen Näherungswert für π folgendermaßen ermitteln. Man markiert auf einem Kreis mit dem Durchmesser $d = 1$, der eine Gerade berührt, den Punkt in welchem die Berührung erfolgt. Dann lässt man den Kreis auf dieser Geraden solange abrollen bis der Markierungspunkt auf dem Kreis wieder Berührungspunkt des Kreises mit der Geraden ist (siehe Abbildung 1.1). Der Abstand zwischen den beiden Berührungspunkten auf der Geraden ist gleich π, denn bei einem Kreis mit dem Durchmesser $d = 1$ ist der Umfang U gleich π.

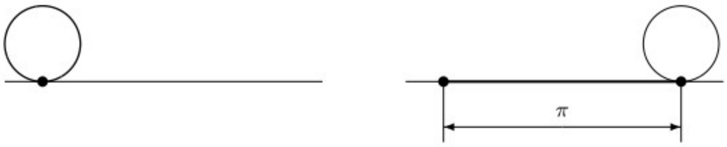

Abb. 1.1 Bestimmung von π

Im Folgenden geben wir einige Möglichkeiten an, wie man Näherungswerte für π und e berechnen kann. Unser Ziel ist es dabei, Näherungswerte auf 15 Stellen (14 Nachkommastellen) genau anzugeben. Dies ist die Genauigkeit in der Zahlendarstellung, welche man hat, wenn man in den üblichen Programmiersprachen wie z. B. der Programmiersprache C doppelt genaue Zahlen (double precision) nutzt (siehe auch Bemerkung 5.4 im Abschnitt 5.2).

Archimedes[3] ermittelte Näherungswerte für π, indem er Vielecke (6-Eck, 12-Eck, …, 96-Eck) in einen Kreis einbeschrieb bzw. den Kreis mit den Vielecken umschrieb. Dabei erhielt er mittels der Umfänge der Vielecke die Einschachtelung

$$\boxed{3+\frac{10}{71}=\frac{223}{71}\approx 3.140845<\pi<3+\frac{10}{70}=\frac{22}{7}\approx 3.142857\,.}$$

Ein Vergleich mit (1.79) zeigt, dass man so die Zahl π mit zwei Nachkommastellen Genauigkeit erhält.

Im Jahr 1593 entwickelte Viète[4] die folgende Formel mit unendlich vielen Faktoren zur Darstellung von $\frac{2}{\pi}$.

$$\frac{2}{\pi}=\frac{\sqrt{2}}{2}\cdot\frac{\sqrt{2+\sqrt{2}}}{2}\cdot\frac{\sqrt{2+\sqrt{2+\sqrt{2}}}}{2}\cdot\frac{\sqrt{2+\sqrt{2+\sqrt{2+\sqrt{2}}}}}{2}\cdot\ldots\,. \tag{1.81}$$

Berechnet man nur das Produkt der ersten n Faktoren (n eine natürliche Zahl, welche man sich vorgibt), dann erhält man einen Näherungswert für $\frac{2}{\pi}$ und daraus einen Näherungswert für π. In der folgenden Tabelle 1.1 geben wir an, wieviele Faktoren man im obigen Produkt benötigt, um einen Näherungswert für π mit k exakten Stellen zu bestimmen:

Tab. 1.1 Unter Nutzung der Formel von Viète berechnete Näherungswerte für π

Näherungswert für π	Anzahl n der Faktoren in (1.81)	Anzahl k der exakten Stellen
3.061467458920718	2	1
3.121445152258051	3	2
3.140331156954752	5	3

[3] Archimedes von Syrakus, geb. um 287 v. Chr., gest. 212 v. Chr. vermutlich in Syrakus (Sizilien), griechischer Mathematiker, Physiker und Ingenieur

[4] François Viète, latinisiert Franciscus Vieta, geb. 1540 in Fontenay-le-Comte, gest. 1603 in Paris, französischer Advokat und Mathematiker

Wallis[5] entwickelte 1655 die folgende Darstellungsformel für $\frac{\pi}{2}$:

$$\boxed{\frac{\pi}{2} = \prod_{k=1}^{\infty} \frac{2k}{2k-1} \cdot \frac{2k}{2k+1} = \frac{2}{1} \cdot \frac{2}{3} \cdot \frac{4}{3} \cdot \frac{4}{5} \cdot \frac{6}{5} \cdot \frac{6}{7} \cdot \dots \,. \qquad (1.82)}$$

Nutzt man nur die ersten n Faktoren im obigen Produkt erhält man Näherungswerte für $\frac{\pi}{2}$ und damit für π (siehe Tabelle 1.2).

Tab. 1.2 Unter Nutzung der Formel von Wallis berechnete Näherungswerte für π

Näherungswert für π	Anzahl n der Faktoren in (1.82)	Anzahl k der exakten Stellen
3.555555555555555	3	1

3.141592653589700	387418192	14
3.141592653589790	387418826	15

Im Jahr 1674 veröffentlichte Leibniz[6] die folgende Darstellungsformel für $\frac{\pi}{4}$:

$$\boxed{\frac{\pi}{4} = \sum_{k=1}^{\infty} (-1)^{k-1} \cdot \frac{1}{2k-1} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots + (-1)^{n-1} \cdot \frac{1}{2n-1} \dots \,. \quad (1.83)}$$

Berechnen wir nur die Summe der ersten n Summanden, ergibt sich ein Näherungswert für $\frac{\pi}{4}$ und somit für π. Diese Näherungswerte sind in der Tabelle 1.3 angegeben.

---

[5] John Wallis, geb. 3.12.1616 in Ashford, Kent, gest. 8.11.1703 in Oxford, englischer Mathematiker

[6] Gottfried Wilhelm Leibniz, geb. 1.7.1646 in Leipzig, gest. 14.11.1716 in Hannover, Philosoph, Mathematiker, Physiker, Historiker, 1672/73 Konstruktion einer Rechenmaschine für die vier Grundrechenarten, Entwickler der Differential- und Integralrechnung

Tab. 1.3 Unter Nutzung der Formel von Leibniz berechnete Näherungswerte für π

Näherungswert für π	Anzahl n der Summanden in (1.83)	Anzahl k der exakten Stellen
3.466666666666666	3	1
3.194187909231942	19	2
3.149995866593469	119	3
3.141000236580159	1688	4

3.141592653000000	1700659132	10

Wie aus der Tabelle ersichtlich ist, benötigt man ungefähr 1.7 Milliarden Summanden, damit man wenigstens zehn exakte Ziffern erhält. Mit dieser Formel ist es also extrem aufwändig, sehr genaue Näherungswerte für π zu bestimmen.

Euler[7] publizierte im Jahr 1748 eine Reihe von Darstellungsformeln für π, z. B. die Formel

$$\frac{\pi^2}{6} = \sum_{k=1}^{\infty} \frac{1}{k^2} = 1 + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \cdots + \frac{1}{n^2} + \cdots . \tag{1.84}$$

Berechnet man nur die Summe aus den ersten n Summanden, dann erhält man einen Näherungswert für $\frac{\pi^2}{6}$ und daraus einen Näherungswert für π. Derartige Näherungswerte sind in der Tabelle 1.4 angegeben.

Tab. 1.4 Unter Nutzung der Formel von Euler (1.84) berechnete Näherungswerte für π

Näherungswert für π	Anzahl n der Summanden in (1.84)	Anzahl k der exakten Stellen

---

[7] Leonhard Euler, geb. 15.4.1707 in Basel, gest. 18.9.1783 in Sankt Petersburg, Mathematiker und Physiker

Auch bei dieser Formel benötigt man sehr viele Summanden, um einen recht genauen Näherungswert für π zu erhalten. Da die Summanden für große Werte von n sehr klein sind, haben sie ab einem gewissen n keinen Einfluss mehr bei der Addition in der Computerarithmetik (siehe Abschnitt 5.2, insbesondere auch Beispiel 5.11), so dass sich der Näherungswert für π auch nicht mehr verbessern lässt.

Eine weitere von Euler veröffentlichte Darstellungsformel für π ist die Formel

$$\boxed{\frac{\pi^2}{8} = \sum_{k=1}^{\infty} \frac{1}{(2k-1)^2} = 1 + \frac{1}{3^2} + \frac{1}{5^2} + \frac{1}{7^2} + \cdots + \frac{1}{(2n-1)^2} + \cdots . \qquad (1.85)}$$

Näherungswerte für π, welche man bei Nutzung dieser Formel erhält, sind in der Tabelle 1.5 ersichtlich.

Tab. 1.5 Unter Nutzung der Formel von Euler (1.85) berechnete Näherungswerte für π

Näherungswert für π	Anzahl n der Summanden in (1.85)	Anzahl k der exakten Stellen
3.034615113797611	3	1
3.101600903283900	8	2
3.140000704127709	200	3
3.141000943973225	538	4
3.141500012560330	3436	5
3.141590000011233	119955	6
3.141592000000234	487018	7
3.141592600000000	5939849	8
3.141592659240904	4801919418	9

Wie wir aus dieser Tabelle erkennen können, ist es ebenfalls schwierig mittels der Formel (1.85) sehr genaue Näherungswerte für π zu bestimmen. Die folgende Formel von Euler ist wesentlich besser zur Bestimmung von Näherungswerten für π geeignet.

$$\boxed{\begin{aligned} \frac{\pi - 3}{4} &= \sum_{k=1}^{\infty} (-1)^{k-1} \cdot \frac{1}{2k \cdot (2k+1) \cdot (2k+2)} \\ &= \frac{1}{2 \cdot 3 \cdot 4} - \frac{1}{4 \cdot 5 \cdot 6} + \frac{1}{6 \cdot 7 \cdot 8} - \cdots (-1)^{n-1} \cdot \frac{1}{2n \cdot (2n+1) \cdot (2n+2)} \cdots \\ & \qquad (1.86) \end{aligned}}$$

Die Tabelle 1.6 enthält Näherungswerte für π, welche man unter Nutzung der obigen Formel erhält.

Tab. 1.6 Unter Nutzung der Formel von Euler (1.86) berechnete Näherungswerte für π

Näherungswert für π	Anzahl n der Summanden in (1.86)	Anzahl k der exakten Stellen

Von Bailey[8], Borwein[9] und Plouffe[10] wurde 1995 die folgende Formel (BBP-Formel) zur Berechnung von π entwickelt (siehe auch Bailey et al. [1997]).

$$\boxed{\begin{aligned} \pi &= \sum_{k=0}^{\infty} \frac{1}{16^k}\left(\frac{4}{8k+1} - \frac{2}{8k+4} - \frac{1}{8k+5} - \frac{1}{8k+6}\right) \\ &= \left(4 - \frac{2}{4} - \frac{1}{5} - \frac{1}{6}\right) + \frac{1}{16}\left(\frac{4}{9} - \frac{2}{12} - \frac{1}{13} - \frac{1}{14}\right) \qquad (1.87) \\ &\quad + \cdots + \frac{1}{16^n}\left(\frac{4}{8n+1} - \frac{2}{8n+4} - \frac{1}{8n+5} - \frac{1}{8n+6}\right) + \cdots . \end{aligned}}$$

Wie die Tabelle 1.7 zeigt, erhält man schon mit sehr wenigen Summanden dieser Summe sehr genaue Näherungswerte für π.

Nachdem wir verschiedene Möglichkeiten zur Berechnung von Näherungswerten für π vorgestellt haben, diskutieren wir im Folgenden die näherungsweise Berechnung der Eulerschen Zahl e. Die Eulersche Zahl wird als Grenzwert der Zahlenfolge

$$(a_n)_{n=1}^{\infty} = \left(\left(1 + \frac{1}{n}\right)^n\right)_{n=1}^{\infty} \tag{1.88}$$

---

definiert (siehe auch Papula [2014], Jung [2021b], d. h.

$$\mathrm{e} = \lim_{n\to\infty}\left(1+\frac{1}{n}\right)^n$$

Man kann zeigen, dass für wachsende Werte von n die sogenannten Folgeglieder $a_n = \left(1+\frac{1}{n}\right)^n$ immer größer werden, aber die Zahl e nicht überschreiten (siehe z. B. Meyberg und Vachenauer [2001a], Jung [2021b]). Deshalb kann man erwarten, dass man für hinreichend große Werte von n gute Näherungswerte für e erhält. Dieser Idee sind aber auf jedem Computer Grenzen gesetzt. Ab einem gewissen n^* führt eine weitere Vergrößerung von n zu keinem genaueren Näherungswert für die Eulersche Zahl e (siehe Beispiel 5.11 im Abschnitt 5.2). Wie groß man n wählen muss, damit man einen Näherungswert für e mit k exakten Stellen erhält, ist in der Tabelle 1.8 ersichtlich.

Eine andere Möglichkeit zur näherungsweisen Berechnung von e ist die Nutzung der Summe

$$\begin{aligned} \mathrm{e} &= \sum_{k=0}^{\infty}\frac{1}{k!} = \frac{1}{0!}+\frac{1}{1!}+\frac{1}{2!}+\frac{1}{3!}+\cdots+\frac{1}{n!}+\cdots \\ &= 1+1+\frac{1}{2}+\frac{1}{6}+\cdots+\frac{1}{1\cdot 2\cdot\cdots\cdot(n-1)\cdot n}+\cdots \end{aligned} \tag{1.89}$$

(siehe auch Papula [2014], Meyberg und Vachenauer [2001a], Jung [2021b] bezüglich der Taylorentwicklung der e-Funktion). In der Tabelle 1.9 geben wir an, wie groß n

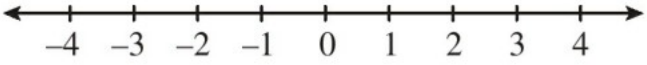
$$B = \{x : 2x^3 - x^2 - 3x = 0\},$$



Chapter 1

Preliminaries

1.1 Numbers and Sets

The numbers we will use in this book are the *real numbers*. These are all the numbers that can be written in decimal notation. We often think of them as corresponding to points on a number line (see Figure 1.1). The simplest real numbers are the *integers*: the numbers 0, 1, −1, 2, −2, 3, −3, and so on. A real number is said to be *rational* if it can be written as an integer divided by an integer; for example, 2/3 and −13/5 are rational numbers. Notice that every integer is also a rational number, since, for example, we can write 3 as 3/1. Real numbers that are not rational are called *irrational*. For example, it can be shown that $\sqrt{2} = 1.41421\ldots$ and $\pi = 3.14159\ldots$ are irrational. Both rational and irrational numbers are spread throughout the number line; in fact, between any two real numbers there are infinitely many rational numbers and also infinitely many irrational numbers.

We will also often work with collections of numbers. In mathematics, a collection of objects is called a *set*, and the objects in the collection are called *elements* of the set. The simplest way to specify a set is to list the elements of the set between braces. For example, $\{-1, 0, 3/2\}$ is the set whose elements are the three numbers −1, 0, and 3/2. If we let the letter A stand for this set, then we write $3/2 \in A$ to say that 3/2 is an element of A, while $4 \notin A$ means that 4 is not an element of A.

Another way to specify a set is to give a rule for determining which objects belong to the set and which do not. For example, if we write

$$B = \{x : 2x^3 - x^2 - 3x = 0\}, \tag{1.1}$$

Figure 1.1: The number line.

then this means that B is the set whose elements are all values of x that satisfy the equation $2x^3 - x^2 - 3x = 0$. Equation (1.1) is read "B is equal to the set of all x such that $2x^3 - x^2 - 3x = 0$." The equation $2x^3 - x^2 - 3x = 0$ that appears in the definition of B is a statement that is true for some values of x and false for others. You should think of it as an elementhood test for the set B; those values of x that make the equation true pass the test and are elements of B, while those that make the equation false are not. To determine which numbers belong to B we simply have to solve the equation, which we can do by factoring the left-hand side. We have

$$2x^3 - x^2 - 3x = x(x + 1)(2x - 3),$$

so the equation can be rewritten $x(x + 1)(2x - 3) = 0$, and the solutions are 0, -1, and 3/2. These are the elements of the set B. Notice that these are exactly the same as the elements of the set A defined earlier. Thus $B = A$; they are both the same collection of numbers, described in two different ways.

Although we will usually use the letter x when writing an elementhood test to define a set, as we did in the definition of B, in fact any letter can be used. For example, the set $C = \{y : 2y^3 - y^2 - 3y = 0\}$ is the set of all values of y that satisfy the equation $2y^3 - y^2 - 3y = 0$. Of course, this is the same equation that we used in the definition of B, but with x replaced by y. The values of y that satisfy the equation are therefore once again the numbers 0, -1, and 3/2. Therefore $C = B = A$; we have the same set of numbers described in yet another way.

Here is another example of a set defined by an elementhood test: $I = \{x : 2 < x < 5\}$. This time the elementhood test is $2 < x < 5$, which is a shorthand way of saying that $2 < x$ and $x < 5$. In this case $3 \in I$, since the statement $2 < 3 < 5$ is true, but $5 \notin I$, since the statement $2 < 5 < 5$ is false. The elements of I are all the numbers strictly between 2 and 5. There are infinitely many numbers in this range, so we cannot list all the elements of I, as we did for A. But we can mark them on a number line, as in Figure 1.2.

Figure 1.2: $I = \{x : 2 < x < 5\}$. The open circles indicate that 2 and 5 are not elements of I, while the thick line shows that all numbers between 2 and 5 are elements.

The set I is an example of a kind of set called an *open interval*. For any numbers a and b with $a < b$, the set of all numbers strictly between a and b is an open interval, and it is denoted (a, b). In other words,

$$(a, b) = \{x : a < x < b\}.$$

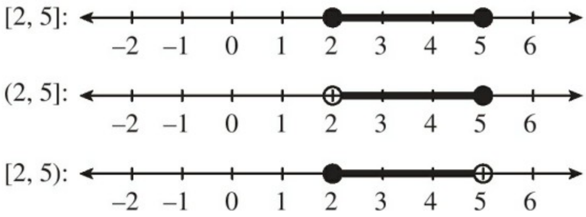


Figure 1.3: The closed interval [2, 5], and the half-open intervals (2, 5] and [2, 5). Black dots indicate points that are included in a set.

The numbers a and b are called the *endpoints* of the interval. Thus $I = (2, 5)$; it is the open interval with endpoints 2 and 5.

The endpoints of an open interval are not elements of the interval. But sometimes we will want to include the endpoints, so we define

$$[a, b] = \{x : a \leq x \leq b\}.$$

This set is called a *closed interval*. For example, $[2, 5] = \{x : 2 \leq x \leq 5\}$. This set is exactly the same as the open interval (2, 5) considered earlier, except that it includes the endpoints 2 and 5 as elements. If we include only one endpoint, we get a *half-open interval*. As you might guess, we write half-open intervals like this:

$$(a, b] = \{x : a < x \leq b\},$$
$$[a, b) = \{x : a \leq x < b\}.$$

In general, we use a square bracket to indicate that an endpoint is included in an interval, and a parenthesis to indicate that it is not. Figure 1.3 shows examples of closed and half-open intervals.

The *interior* of an interval is the set containing all numbers in the interval except the endpoints. Thus, the interior of the closed interval [2, 5] is the open interval (2, 5). The interiors of (2, 5] and [2, 5) are also (2, 5), and we will even say that the interior of (2, 5) is (2, 5).

Finally, we sometimes want to consider intervals that extend infinitely far in some direction, so we introduce the notation:

$$(a,\infty) = \{x : x > a\},$$
$$[a,\infty) = \{x : x \geq a\},$$
$$(-\infty, b) = \{x : x < b\},$$
$$(-\infty, b] = \{x : x \leq b\}.$$

Some examples of infinite intervals are shown in Figure 1.4. The interior of $[a,\infty)$ is (a,∞), and the interior of $(-\infty, b]$ is $(-\infty, b)$. The set of all real numbers is often denoted R, but we could also think of it as the interval $(-\infty,\infty)$. We consider any interval that does not include its endpoints to be an open interval. Thus, the intervals (a,∞), $(-\infty, b)$, and $(-\infty,\infty)$ are open intervals, and the interior of any interval is an open interval.

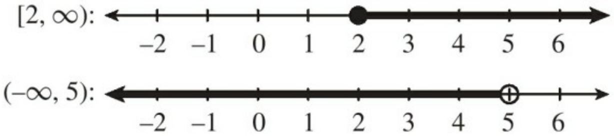

Figure 1.4: Infinite intervals.

Since this is our first use of the infinity symbol∞, it might be worthwhile to pause at this point to explain what this symbol means. The most important thing to understand about the infinity symbol is that *there is no such number as infinity*. You might wonder, then, how it can be correct to use this symbol in mathematical notation like (a,∞). The answer is that, according to the definition we have given, this notation is simply a shorthand for $\{x : x > a\}$, and this last expression makes no mention of infinity. Every time we make a statement using the symbol ∞, it will be a similar shorthand for a statement that makes no mention of infinity. We will never use the symbol ∞ as if it stood for a number. Thus, for example, wewould never set x equal to ∞in some formula, and we would never talk about the “closed interval” $[2,\infty]$.

There are two ways of combining sets that we will sometimes make use of. If A and B are sets, then the *intersection* of A and B, denoted $A \cap B$, is the set whose elements are those objects that belong to both A and B. Thus

$$A \cap B = \{x : x \in A \text{ and } x \in B\}.$$

For example,

$$\begin{aligned}[2,\infty) \cap (-\infty, 5) &= \{x : x \in [2,\infty) \text{ and } x \in (-\infty, 5)\}\\ &= \{x : 2 \leq x \text{ and } x < 5\} = [2, 5).\end{aligned}$$

Looking at Figure 1.4, you can see that the elements of $[2,\infty) \cap (-\infty, 5)$ are those numbers that are in the overlap of the sets $[2,\infty)$ and $(-\infty, 5)$. In general, you can think of $A \cap B$ as the overlap of A and B.

The *union* of A and B, denoted $A \cup B$, is the set whose elements are all those objects that are elements of either A or B (or both). That is,

$$A \cup B = \{x : x \in A \text{ or } x \in B\}.$$

You could think of $A \cup B$ as the set you get if you take all the elements of A, and all the elements of B, and throw them together into one set. For example, if we take all the numbers in the intervals $(2, 4]$ and $[4, 5]$ and put them together into one set, we get the interval $(2, 5]$. That is,

$$\begin{aligned}(2, 4] \cup [4, 5] &= \{x : x \in (2, 4] \text{ or } x \in [4, 5]\}\\ &= \{x : 2 < x \leq 4 \text{ or } 4 \leq x \leq 5\} = \{x : 2 < x \leq 5\} = (2, 5].\end{aligned}$$

If A and B are sets, then A is called a *subset* of B if every element of A is also an element of B. We write $A \subseteq B$ to indicate that A is a subset of B. For example, $(2, 4) \subseteq [2, 4]$, and $[2, 4] \subseteq (1, 5)$.

One reason that intervals are important in calculus is that they often come up as solution sets of inequalities. In particular, we will often be concerned with inequalities involving absolute values. Recall that the *absolute value* of a number x is defined as follows:

$$|x| = \begin{cases} x, & \text{if } x \geq 0,\\ -x, & \text{if } x < 0.\end{cases}$$

This notation means that if $x \geq 0$ then $|x| = x$, and if $x < 0$ then $|x| = -x$. For example, $|3| = 3$ and $|-4| = -(-4) = 4$.

The fact that $|x|$ is defined by cases, with one formula when $x \geq 0$ and a different formula when $x < 0$, suggests a method that can be used when solving any problem involving absolute values: reasoning by cases. As a simple example of this kind of reasoning, notice that if $x \geq 0$ then we have $|x| = x \geq 0$, and if $x < 0$ then $|x| = -x > 0$. In both cases the statement $|x| \geq 0$ is true, so we conclude that for every number x, $|x| \geq 0$. You can also use reasoning by cases to show that for every number x, $\sqrt{x^2} = |x|$ (see Exercise 15).

Here's an example of how reasoning by cases can be used to solve an inequality involving absolute values:

Example 1.1.1. Solve:

$$|x| < 3.$$

Solution. Motivated by the definition of $|x|$, we will consider $x \geq 0$ and $x < 0$ separately.

Case 1. $x \geq 0$. In this case, according to the definition of absolute value we have $|x| = x$, so the inequality $|x| < 3$ means $x < 3$.

Case 2. $x < 0$. Now the definition of absolute value says that $|x| = -x$, and substituting this into our inequality $|x| < 3$ gives us $-x < 3$. Multiplying by -1 (and remembering that when multiplying an inequality by a negative number, we must reverse the direction of the inequality) we get $x > -3$.

So what's the solution to our inequality? Is it $x < 3$, as we found in case 1, or $x > -3$, as in case 2? To answer this question, we must think about what it means to solve an inequality. To solve the inequality $|x| < 3$ means to determine which values of x make the inequality true. Our reasoning in case 1 shows that, for $x \geq 0$, the inequality means $x < 3$. Thus the inequality is true if $0 \leq x < 3$ and false if $x \geq 3$. We can't tell from this reasoning whether the inequality is true or false when $x < 0$; that's the purpose of case 2. Case 2 tells us that, for $x < 0$, the inequality will be true precisely when $x > -3$. Thus, the inequality is true if $-3 < x < 0$ and false if $x \leq -3$. Putting all this information together, we conclude that the inequality is true if $-3 < x < 3$ and false if either $x \geq 3$ or $x \leq -3$, as shown in Figure 1.5. This means that the *solution set* of the inequality is an open interval:

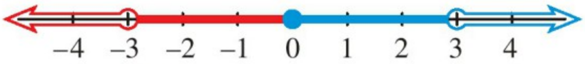

Figure 1.5: The solution to Example 1.1.1.The parts of the number line marked with solid lines are in the solution set, and outlined areas are not. The blue lines were determined in case 1 of the solution, and the red lines in case 2.

$$\{x : |x| < 3\} = \{x : -3 < x < 3\} = (-3, 3).$$

Notice that in case 1 we determined that all numbers in the interval $[0, 3)$ are in the solution set, and in case 2 we determined that the numbers in $(-3, 0)$ are also in the solution set. The solution set is therefore the union of these two intervals: $[0, 3) \cup (-3, 0) = (-3, 3)$.

Here's another way of describing the answer to Example 1.1.1. Our reasoning shows that the statements $|x| < 3$ and $-3 < x < 3$ are true for exactly the same values of x; the two statements are equivalent. In other words, for any number x, if $|x| < 3$, then $-3 < x < 3$, and if $-3 < x < 3$, then $|x| < 3$. Mathematicians usually describe this situation by saying that $|x| < 3$ is true *if and only if* $-3 < x < 3$. The phrase "if and only if" comes up often in mathematics, and we will see it many times later in this book.

Of course, there is nothing special about the number 3 in this example. Similar reasoning, using the variable y in place of the number 3, can be used to establish the following theorem. Parts 3 and 4 of the theorem follow directly from parts 1 and 2, by negating the statements involved.

Theorem 1.1.2. *For any numbers x and y, the following statements are true:*

1. $|x| < y$ *if and only if* $-y < x < y$.
2. $|x| \leq y$ *if and only if* $-y \leq x \leq y$.
3. $|x| \geq y$ *if and only if either* $x \leq -y$ *or* $x \geq y$.
4. $|x| > y$ *if and only if either* $x < -y$ *or* $x > y$.

The most important use of absolute values in calculus is to compute distances between numbers on the number line. To find the distance between two numbers, we subtract the smaller number from the larger. For example, the distance from -4 to 3 on the number line is $3-(-4) = 7$. In general, if $a \leq b$ then the distance from a to b is $b-a$. But if $a > b$ then the distance is $a - b$. Is there a single formula that gives the distance from a to b no matter which of the numbers is larger?

It turns out that the formula $|b-a|$ does the trick. We can see this by once again using reasoning by cases.

Case 1. $a \leq b$. Then $b-a \geq 0$, so $|b-a| = b-a$, which, in this case, is the distance from a to b on the number line.

Case 2. $a > b$. Now $b-a < 0$, so $|b-a| = -(b-a) = a - b$, which is, once again, the distance from a to b in this case.

Thus, no matter which of the numbers a and b is larger, we have

$$|b-a| = \text{the distance from } a \text{ to } b \text{ on the number line.}$$

This fact provides a nice way to see why our solution to Example 1.1.1 makes sense. We have

$$|x| = |x - 0| = \text{distance from 0 to } x \text{ on the number line.}$$

With this interpretation for $|x|$, the inequality $|x| < 3$ can be thought of as saying

$$(\text{distance from 0 to } x \text{ on the number line}) < 3.$$

It is clear geometrically that the values of x for which this statement is true are the numbers in the open interval $(-3, 3)$, exactly as we found in our solution to Example 1.1.1.

Example 1.1.3. Solve:

$$|3t + 2| \leq 4.$$

Solution. By part 2 of Theorem 1.1.2, the inequality to be solved is equivalent to

$$-4 \leq 3t + 2 \leq 4.$$

Subtracting 2 all the way through the inequality gives us

$$-6 \leq 3t \leq 2,$$

and then dividing by 3 we get

$$-2 \leq t \leq 2/3.$$

Thus the solution set for this inequality is a closed interval:

$$\{t : |3t + 2| \leq 4\} = \{t : -2 \leq t \leq 2/3\} = [-2, 2/3].$$

Sometimes it is useful to be able to simplify absolute values of complicated expressions. In such situations, the following theorem can be helpful.

Theorem 1.1.4. *For any numbers x and y, the following statements are true:*

1. $|xy| = |x||y|$.
2. *If* $y \neq 0$ *then* $\left|\frac{x}{y}\right| = \frac{|x|}{|y|}$.

Proof. We will just prove part 1; the proof of part 2 is similar. First note that if either x or y is 0 then both sides of the equation $|xy| = |x||y|$ are 0, so the equation is true.
If neither of them is 0, then each is either positive or negative. This leaves us with four cases to consider:

Case 1. $x > 0, y > 0$. Then by the definition of absolute value, $|x| = x$ and $|y| = y$. Also, since the product of two positive numbers is positive, $xy > 0$. Therefore $|xy| = xy = |x||y|$.

Case 2. $x > 0, y < 0$. Then $|x| = x$ and $|y| = -y$. Since a positive number times a negative number is negative, $xy < 0$. Thus $|xy| = -xy = x(-y) = |x||y|$.

Case 3. $x < 0, y > 0$. Then $|x| = -x$, $|y| = y$, and $xy < 0$, so $|xy| = -xy = |x||y|$.

Case 4. $x < 0, y < 0$. Then $|x| = -x$ and $|y| = -y$. Since a negative times a negative is positive, we have $xy > 0$, so $|xy| = xy = (-x)(-y) = |x||y|$.

To illustrate the use of Theorem 1.1.4, we briefly revisit Example 1.1.3. Notice that $|3t + 2| = |3(t + 2/3)| = |3||t + 2/3| = 3|t - (-2/3)|$, where we have used part 1 of Theorem 1.1.4 in the second step. Thus, the inequality in Example 1.1.3 can be rewritten

$$3|t - (-2/3)| \leq 4.$$

Dividing through by 3, this is equivalent to

$$|t - (-2/3)| \leq 4/3,$$

which can be interpreted as meaning

$$\text{(distance from } t \text{ to } -2/3 \text{ on the number line)} \leq 4/3.$$

Thus the solution set of the inequality is

$$[-2/3-4/3, -2/3+4/3] = [-2, 2/3],$$

exactly as we found in Example 1.1.3.

Theorem 1.1.4 tells us how to simplify an absolute value of a product or a quotient. What about the absolute value of a sum? Is it always true that $|x+y| = |x| + |y|$? A little experimentation shows that, unfortunately, this equation is not always true. For example, $|5+(-3)| = 2$, but $|5| + |-3| = 8$. However, we do have the following important fact, which is known as the *triangle inequality*.

Theorem 1.1.5 (Triangle Inequality). *For all numbers x and y,* $|x+y| \leq |x| + |y|$.

Proof. According to part 2 of Theorem 1.1.2, the triangle inequality is equivalent to the statement

$$-(|x|+|y|) \leq x+y \leq |x|+|y|, \tag{1.2}$$

so it will suffice to prove this inequality. We will leave it to you to verify (using reasoning by cases) that

$$-|x| \leq x \leq |x|$$

and

$$-|y| \leq y \leq |y|$$

(see Exercise 18). Adding these two inequalities gives inequality (1.2).

The theorems we have proven about absolute values could be regarded as shortcuts that allow us to solve problems more easily. For example, using Theorem 1.1.2 we were able to solve Example 1.1.3 without having to resort to reasoning by cases. This is a pattern that we will see repeated many times in this book. When a new concept is introduced, we will initially rely on the definition to tell us how to solve problems involving that concept. But often solutions based on the definition will be long and complicated, so we will develop theorems that provide shortcuts that allow us to solve problems more easily.

You may wonder, why bother learning the definitions? Why not just learn the shortcuts, if they provide easier ways of solving problems? One answer is that shortcuts, while helpful, are also often somewhat limited. They usually allow us to solve only a restricted range of problems. Sometimes you come across a problem for which the shortcuts are not helpful, and then you have no choice but to return to the definitions of the relevant concepts to solve the problem.

As an illustration of this, we close this section by solving an inequality involving absolute values for which our various shortcuts don't seem to be very helpful.

Example 1.1.6. Solve:

$$2|x|-3 \geq |x-1|.$$

Solution. Although it is possible to use Theorem 1.1.2 to solve this inequality (see Exercise 16), the solution is not easy. Here we use the more straightforward approach of working from the definition of absolute value, which suggests reasoning by cases. Since we need to work with both $|x|$ and $|x-1|$, we are led to consider three cases: $x < 0$, $0 \leq x < 1$, and $x \geq 1$.

Case 1. $x < 0$. In this case we also have $x-1 < 0$, so according to the definition of absolute value, $|x| = -x$ and $|x-1| = -(x-1) = 1-x$. Substituting into our inequality, we find that we must solve

$$-2x-3 \geq 1-x.$$

Adding $2x$ to both sides and subtracting 1, we get $-4 \geq x$. Thus, for negative values of x, the inequality is true if and only if $x \leq -4$. In other words, it is true if $x \leq -4$ and false if $-4 < x < 0$.

Case 2. $0 \leq x < 1$. We have $x \geq 0$, so $|x| = x$, and $x < 1$, so $x-1 < 0$ and therefore $|x-1| = 1-x$. Thus in this case the inequality means

$$2x-3 \geq 1-x,$$

which can be simplified to $x \geq 4/3$. But this inequality is false for all values of x in the range $0 \leq x < 1$. Thus, none of the numbers in the interval $[0, 1)$ will be included in the solution set of our inequality.

Case 3. $x \geq 1$. Then $x \geq 0$ and $x-1 \geq 0$, and therefore $|x| = x$ and $|x-1| = x-1$. Filling in these formulas in our inequality we get

$$2x - 3 \geq x - 1,$$

and simplifying leads to $x \geq 2$. Thus, the inequality is true for $x \geq 2$ and false for $1 \leq x < 2$.

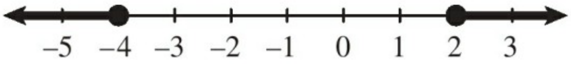

Figure 1.6: The solution set for Example 1.1.6 is $(-\infty,-4] \cup [2,\infty)$.

Combining the information from all three cases, we find that the solution set is the set containing all numbers in the interval $(-\infty,-4]$ and also all numbers in the interval $[2,\infty)$. In other words,

$$\{x : 2|x| - 3 \geq |x - 1|\} = \{x : \text{either } x \leq -4 \text{ or } x \geq 2\} = (-\infty,-4] \cup [2,\infty).$$

Exercises 1.1

1–13: Solve the inequality. If possible, write the solution set as an interval or a union of intervals.

1. $|x - 5| < 7$.
2. $|4x + 2| \leq 6$.
3. $|5 - 2t| \geq 4$.
4. $|x - 4| < x$.
5. $2|x - 4| < x$.
6. $|x + 4| < x$.
7. $|x + 4| < 2x$.
8. $|6 - 2u| - 3 < u$.
9. $|3y| \leq |y| + 10$.
10. $|x - 3| \geq |x| - 1$.
11. $|2x - 3| \geq |x| - 1$.
12. $|2x - 2| > |x| - 1$.
13. $|3x - 6| \leq |3 - 6x|$.
14. Write the following sets as intervals or unions of intervals. Use

interval notation.

(a) $\{x : x^2 < 64\}$.

(b) $\{x : x^3 < 64\}$.

(c) $\{x : 4 \le x^2 < 9\}$.

(d) $(-\infty, 5] \cap (3, \infty)$.

(e) $(-3, 5] \cup (3, 7]$.

15. Use reasoning by cases to prove that for every number x, $\sqrt{x^2} = |x|$.
16. Solve Example 1.1.6 by using Theorem 1.1.2.
17. Prove part 1 of Theorem 1.1.2. (Hint: Treat the cases $y > 0$ and $y \le 0$ separately.)
18. Prove that for every number x, $-|x| \le x \le |x|$. (This fact is used in the proof of Theorem 1.1.5.)
19. Prove that for all numbers x and y, $|x - y| \ge |x| - |y|$. (Hint: Start by applying the triangle inequality to $|(x - y) + y|$.)
20. Use the triangle inequality to show that for every number x, if $|x| \le 2$ then $|x^3 - 7x + 3| \le 25$.
21. Show that for every number x, if $|x| \le 2$ then $\left|\frac{x^3 - 7x + 3}{9 - x^2}\right| \le 5$. (Hint: Use

    Exercise 19 to show that $|9 - x^2| \ge 5$.)

1.2 Graphs in the Plane

In Section 1.1 we considered statements involving a single variable, usually x, and we illustrated these statements by marking on a number line the values of the variable for which the statement is true. Often in calculus we will work with statements involving two variables, usually x and y. To illustrate such statements we use the coordinate plane. Each point in the plane represents an ordered pair of numbers (x, y), as illustrated in Figure 1.7.[1]

For example, consider the statement

$$1 < x \le 3 \text{ and } -2 \le y < 1. \tag{1.3}$$

+,- * *. ! * + (# 1 4 + ! 0
! # / 0 + ! ! ! ! 0 1#
) '

Multiplying both sides by -1 and using 2) yields

$$0 = (-1)0 = (-1)(1 + (-1)) = (-1)1 + (-1)^2 = -1 + (-1)^2.$$

Thus $(-1)^2$ is an additive inverse to -1; of course 1 also is. By the uniqueness of additive inverses, we see that $(-1)^2 = 1$. The proof of 4) is similar. Start with $0 = 1 + (-1)$ and multiply by x to get $0 = x + (-1)x$. Thus $(-1)x$ is an additive inverse of x and the result follows by uniqueness of additive inverses. Finally, to prove 5), we assume that $xy = 0$. If $x = 0$, the conclusion holds. If $x \neq 0$, we can multiply by $\frac{1}{x}$ to obtain

$$y = (\frac{1}{x}x)y = \frac{1}{x}(xy) = \frac{1}{x}0 = 0.$$

Thus, if $x \neq 0$, then $y = 0$, and the conclusion also holds. □

We note a point of language, where mathematics usage may differ with common usage. For us, the phrase "either $x = 0$ or $y = 0$" allows the possibility that **both** $x = 0$ and $y = 0$.

Example 2.1. A field with two elements. Let $\mathbf{F}_2$ consist of the two elements 0 and 1. We put $1 + 1 = 0$, but otherwise we add and multiply as usual. Then $\mathbf{F}_2$ is a field.

This example illustrates several interesting things. For example, the object 2 (namely $1 + 1$), can be 0 in a field. This possibility will prevent the quadratic formula from holding in a field for which $2 = 0$. In Theorem 2.1 we will derive the quadratic formula when it is possible to do so.

First we make a simple observation. We have shown that $(-1)^2 = 1$. Hence, when $-1 \neq 1$, it follows that 1 has two square roots, namely ± 1. Can an element of a field have more than two square roots? The answer is no.

Lemma 2.1. *In a field, an element t can have at most two square roots. If x is a square root of t, then so is $-x$, and there are no other possibilities.*

Proof. If $x^2 = t$, then $(-x)^2 = t$ by 3) and 4) of Proposition 2.1. To prove that there are no other possibilities, we assume that both x and y are square roots of t. We then have

$$0 = t - t = x^2 - y^2 = (x - y)(x + y). \tag{2}$$

By 5) of Proposition 2.1, we obtain either $x - y = 0$ or $x + y = 0$. Thus $y = \pm x$ and the result follows. □

The difference of two squares law stating that $x^2 - y^2 = (x - y)(x + y)$ is a gem of elementary mathematics. For example, suppose you are asked to multiply 88 times 92 in your head. You imagine $88 * 92 = (90 - 2)(90 + 2) = 8100 - 4 = 8096$ and impress some audiences. One can also view this algebraic identity for positive integers simply by removing a small square of dots from a large square of dots and rearranging the dots to form a rectangle. The author once used this kind of method when doing volunteer teaching of multiplication to third graders. See Figure 1.1 for a geometric interpretation of the identity in terms of area.

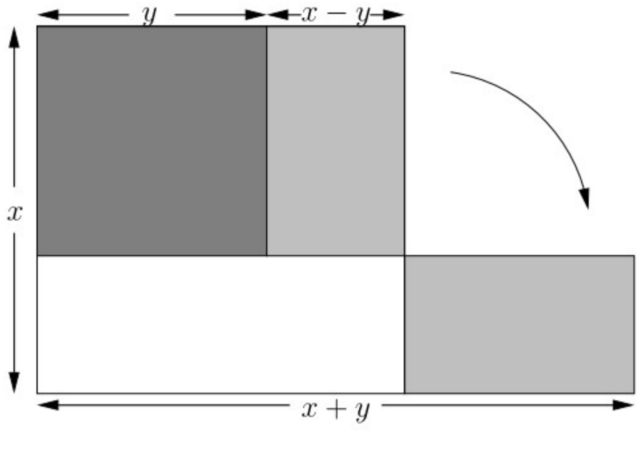

Figure 1.1. Difference of two squares.

We pause to make several remarks about square roots. The first remark concerns a notational convention; the discussion will help motivate the notion of ordered field defined below. The real number system will be defined formally below, and we will prove that positive real numbers have square roots. Suppose $t > 0$. We write $\sqrt{t}$ to denote the *positive* x for which $x^2 = t$. Thus both x and $-x$ are square roots of t, but the notation $\sqrt{t}$ means the positive square root. For the complex numbers, things will be more subtle. We will prove that each nonzero complex number z has two square roots, say $\pm w$, but there is no sensible way to prefer one to the other. We emphasize that the existence of square roots depends on more than the field axioms. Not all positive rational numbers have rational square roots, and hence it must be proved that each positive real number has a square root. The proof requires a limiting process. The quadratic formula, proved next, requires that the expression $b^2 - 4ac$ be a square. In an arbitrary field, the expression $\sqrt{t}$ usually means any x for which $x^2 = t$, but the ambiguity of signs can cause confusion. See Exercise 1.4.

Theorem 2.1. *Let* $\mathbf{F}$ *be a field. Assume that* $2 \neq 0$ *in* $\mathbf{F}$. *For* $a \neq 0$ *and arbitrary* b, c *we consider the quadratic equation*

$$ax^2 + bx + c = 0. \tag{3}$$

Then x *solves* (3) *if and only if*

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}. \tag{4}$$

If $b^2 - 4ac$ *is not a square in* $\mathbf{F}$, *then* (3) *has no solution.*

Proof. The idea of the proof is to *complete the square*. Since both a and 2 are nonzero elements of $\mathbf{F}$, they have multiplicative inverses. We therefore have

$$ax^2 + bx + c = a(x^2 + \frac{b}{a}x) + c = a(x^2 + \frac{b}{a}x + \frac{b^2}{4a^2}) + c - \frac{b^2}{4a}$$

$$= a(x + \frac{b}{2a})^2 + \frac{4ac - b^2}{4a}. \tag{5}$$

We set (5) equal to 0 and we can easily solve for x. After dividing by a, we obtain

$$(x + \frac{b}{2a})^2 = \frac{b^2 - 4ac}{4a^2}. \tag{6}$$

The square roots of $4a^2$ are of course $\pm 2a$. Assuming that $b^2 - 4ac$ has a square root in $\mathbf{F}$, we solve (6) for x by first taking the square root of both sides. We obtain

$$x + \frac{b}{2a} = \pm\frac{\sqrt{b^2 - 4ac}}{2a}. \tag{7}$$

After a subtraction and simplification we obtain (4) from (7). □

The reader surely has seen the quadratic formula before. Given a quadratic polynomial with real coefficients, the formula tells us that the polynomial will have no real roots when $b^2 - 4ac < 0$. For many readers the first exposure to complex numbers arises when we introduce square roots of negative numbers in order to use the quadratic formula.

► **Exercise 1.3.** Show that additive and multiplicative inverses in a field are unique.

► **Exercise 1.4.** A subtlety. Given a field, is the formula

$$\sqrt{u}\sqrt{v} = \sqrt{uv}$$

always valid? In the proof of the quadratic formula, did we use this formula implicitly? If not, what did we use?

Example 2.2. One can completely analyze quadratic equations with coefficients in $\mathbf{F}_2$. The only such equations are $x^2 = 0$, $x^2 + x = 0$, $x^2 + 1 = 0$, and $x^2 + x + 1 = 0$. The first equation has only the solution 0. The second has the two solutions 0 and 1. The third has only the solution 1. The fourth has no solutions. We have given a complete analysis, even though Theorem 2.1 cannot be used in this setting.

Before introducing the notion of ordered field, we give a few other examples of fields. Several of these examples use modular (clock) arithmetic. The phrases *add modulo p* and *multiply modulo p* have the following meaning. Fix a positive integer p, called the *modulus*. Given integers m and n, we add (or multiply) them as usual and then take the remainder upon division by p. The remainder is called the sum (or product) modulo p. This natural notion is familiar to everyone; five hours after nine o'clock is two o'clock; we added modulo twelve. The subsequent examples can be skipped without loss of continuity.

Example 2.3. Fields with finitely many elements. Let p be a prime number, and let $\mathbf{F}_p$ consist of the numbers $0, 1, ..., p-1$. We define addition and multiplication modulo p. Then $\mathbf{F}_p$ is a field.

In Example 2.3, p needs to be a prime number. Property 5) of Proposition 2.1 fails when p is not a prime. We mention without proof that the number of elements in a finite field must be a power of a prime number. Furthermore, for each prime p and positive integer n, there exists a finite field with p^n elements.

► **Exercise 1.5.** True or false? Every quadratic equation in $\mathbf{F}_3$ has a solution.

Fields such as $\mathbf{F}_p$ are important in various parts of mathematics and computer science. For us, they will serve only as examples of fields. The most important examples of fields for us will be the real numbers and the complex numbers. To define these fields rigorously will take a bit more effort. We end this section by giving an example of a field built from the real numbers. We will not use this example in the logical development.

Example 2.4. Let K denote the collection of rational functions in one variable x with real coefficients. An element of K can be written $\frac{p(x)}{q(x)}$, where p and q are polynomials, and we assume that q is not the zero polynomial. (We allow $q(x)$ to equal 0 for some x, but not for all x.) We add and multiply such rational functions in the usual way. It is tedious but not difficult to verify the field axioms. Hence K is a field. Furthermore, K contains $\mathbf{R}$ in a natural way; we identify the real number c with the constant rational function $\frac{c}{1}$. As with the rational numbers, many different fractions represent the same element of K. To deal rigorously with such situations, one needs the notion of equivalence relation, discussed in Section 5.

3. Inequalities and ordered fields

Comparing the sizes of a pair of integers or of a pair of rational numbers is both natural and useful. It does not make sense however to compare the sizes of elements in an arbitrary ring or field. We therefore introduce a crucial property shared by the integers $\mathbf{Z}$ and the rational numbers $\mathbf{Q}$. For x, y in either of these sets, it makes sense to say that $x > y$. Furthermore, given the pair x, y, one and only one of three things must be true: $x > y$, $x < y$, or $x = y$. We need to formalize this idea in order to define the real numbers.

Definition 3.1. A field $\mathbf{F}$ is called *ordered* if there is a subset $P \subset \mathbf{F}$, called the *set of positive elements* of $\mathbf{F}$, satisfying the following properties:

1) For all x, y in P, we have $x + y \in P$ and $xy \in P$ (closure).

2) For each x in $\mathbf{F}$, one and only one of the following three statements is true: $x = 0$, $x \in P$, $-x \in P$ (trichotomy).

► **Exercise 1.6.** Let $\mathbf{F}$ be an ordered field. Show that $1 \in P$.

► **Exercise 1.7.** Show that the trichotomy property can be rewritten as follows. For each x, y in $\mathbf{F}$, one and only one of the following three statements is true: $x = y$, $x - y \in P$, $y - x \in P$.

The rational number system is an ordered field; a fraction $\frac{p}{q}$ is positive if and only if p and q have the same sign. Note that q is never 0 and that a rational number is 0 whenever its numerator is 0. It is of course elementary to check in

This equivalence relation partitions the set $\mathbf{R}[t]$ into equivalence classes; the situation is strikingly similar to modular arithmetic. Given a polynomial $p(t)$, we use the division algorithm to write $p(t) = q(t)(1+t^2) + r(t)$, where the remainder r has degree at most one. Thus $r(t) = a + bt$ for some a, b, and this r is the unique first-degree polynomial equivalent to p. In the case of modular arithmetic we used the remainder upon division by the modulus; here we use the remainder upon division by $t^2 + 1$.

► **Exercise 1.31.** Verify the transitivity property of equivalence modulo I.

Standard notation in algebra writes $\mathbf{R}[t]/(1+t^2)$ for the set of equivalence classes. We can add and multiply in $\mathbf{R}[t]/(1+t^2)$. As usual, the sum (or product) of equivalence classes P and Q is defined to be the equivalence class of the sum $p+q$ (or the product pq) of members; the result is independent of the choice. An equivalence class then can be identified with a polynomial $a+bt$, and the sum and product of equivalence classes satisfies (15) and (16). In this setting we define $\mathbf{C}$ as the collection of equivalence classes with this natural sum and product:

$$\mathbf{C} = \mathbf{R}[t]/(1+t^2). \tag{25}$$

Definition (25) allows us to set $t^2 = -1$ whenever we encounter a term of degree at least two. The irreducibility of t^2+1 matters. If we form $\mathbf{R}[t]/(p(t))$ for a reducible polynomial p, then the resulting object will not be a field. The reason is precisely parallel to the situation with modular arithmetic. If we consider $\mathbf{Z}/(n)$, then we get a field (written $\mathbf{F}_n$) if and only if n is prime.

► **Exercise 1.32.** Show that $\mathbf{R}[t]/(t^3+1)$ is not a field.

► **Exercise 1.33.** A polynomial $\sum_{k=0}^{d} c_k t^k$ in $\mathbf{R}[t]$ is equivalent to precisely one polynomial of the form $A + Bt$ in the quotient space. What is $A + Bt$ in terms of the coefficients c_k?

► **Exercise 1.34.** Prove the division algorithm in $\mathbf{R}[t]$. In other words, given polynomials p and g, with g not the zero polynomial, show that one can write $p = qg + r$ where either $r = 0$ or the degree of r is less than the degree of g. Show that q and r are uniquely determined by p and g.

► **Exercise 1.35.** For any polynomial p and any x_0, show that there is a polynomial q such that $p(x) = (x - x_0)q(x) + p(x_0)$.

6. A glimpse at metric spaces

Both the real number system and the complex number system provide intuition for the general notion of a metric space. This section can be omitted without impacting the logical development, but it should appeal to some readers.

Definition 6.1. Let X be a set. A *distance function* on X is a function $\delta : X \times X \to \mathbf{R}$ such that the following hold:

1) $\delta(x, y) \geq 0$ for all $x, y \in X$ (distances are nonnegative).

2) $\delta(x, y) = 0$ if and only if $x = y$ (distinct points have positive distance between them; a point has 0 distance to itself).

3) $\delta(x, y) = \delta(y, x)$ for all $x, y \in X$ (the distance from x to y is the same as the distance from y to x).

4) $\delta(x, w) \leq \delta(x, y) + \delta(y, w)$ for all $x, y, w \in X$ (the triangle inequality).

Definition 6.2. Let X be a set, and let δ be a distance function on X. The pair (X, δ) is called a *metric space*.

Mathematicians sometimes write that "the distance function δ makes the set X into a metric space". That statement is not completely precise. It ignores a somewhat pedantic point: the set X is not the metric space; a metric space consists of the set and the distance function. Many different distance functions are possible for most sets X.

Sometimes we use the word *metric* on its own to mean the distance function on a metric space. The most intuitive example is the real number system; putting $\delta(x, y) = |x - y|$ makes $\mathbf{R}$ into a metric space. There are many other possibilities for metrics on $\mathbf{R}$; for example, putting $\delta(x, y)$ equal to 1 whenever $x \neq y$ gives another possible distance function. In Chapter 2 we formally define the absolute value function for complex numbers. Then $\mathbf{C}$ becomes a metric space when we put $\delta(z, w) = |z - w|$. Again, many other distance functions exist. We mention these ideas now for primarily one reason. The basic concepts involving sequences and limits can be developed in the metric space setting. The concept of completeness is then based upon Cauchy sequences; a metric space (X, δ) is *complete* if and only if every Cauchy sequence in X has a limit in X. Given a metric space that is not complete in this sense, it is possible to enlarge it by including all limits of Cauchy sequences. This approach provides one method for defining the real numbers in terms of the rational numbers. Recall that our development assumes the existence of the real numbers and defines the rational numbers as a particular subset of the real numbers.

In a metric space there are notions of *open* and *closed* balls. Given $p \in X$, we write $B_r(p)$ for the set of points whose distance to p is less than r; we call $B_r(p)$ the open ball of radius r about p. The closed ball also includes points whose distance to p equals r. Depending on the metric δ, these sets might not resemble our usual geometric picture of balls. A subset S of a metric space is *open* if, for each $p \in S$, there is an $\epsilon > 0$ such that $B_\epsilon(p) \subset S$. In most situations what counts is the collection of open subsets of a metric space. It is possible and also appealing to define all the basic concepts (limit, continuous function, bounded, compact, connected, etc.) in terms of the collection of open sets. The resulting subject is called *point set topology*. In order to keep this book at an elementary level, we will not do so; instead we rely on the metric in $\mathbf{C}$ defined by $\delta(z, w) = |z - w|$. The distance between points in this metric equals the usual Euclidean distance between them.

Occasionally we will require that an open set be connected, and hence we give the definition here. In Definition 6.3 and a few other times in this book, the symbol $\varnothing$ denotes the empty set. The empty set is open; there are no points in $\varnothing$, and hence the definition of open is satisfied, albeit vacuously.

Definition 6.3. Let (X, δ) be a metric space. A subset S of X is called connected if the following holds: whenever $S = A \cup B$, where A and B are open and $A \cap B = \varnothing$, then either $A = \varnothing$ or $B = \varnothing$.

In Chapter 6 we will use the following fairly simple result. In it and in the subsequent comment we assume **C** is equipped with the usual metric.

Theorem 6.1. *An open subset Ω of* **C** *is connected if and only if each pair of points $z, w \in \Omega$ can be joined by a polygonal path whose sides are parallel to the axes.*

Proof. (Sketch.) The result holds (and is uninteresting) when Ω is the empty set. We therefore first assume Ω is connected and nonempty. Choose $z \in \Omega$. Consider the set S of points that can be reached from z by such a polygonal path. Then S is not empty, as $z \in S$. Also, S is open; if we can reach w, then we can also reach points in a ball about w. On the other hand, the set T of points we cannot reach from z is also open. By the definition of connectedness, Ω is not the union of disjoint open subsets unless one of them is empty. Thus, as S is nonempty, T must be empty. Hence $S = \Omega$ and the conclusion holds.

The proof of the converse statement is similar; we prove its contrapositive. Assume Ω is not connected and nonempty. Then $\Omega = A \cup B$, where A and B are open, $A \cap B = \varnothing$, but neither A nor B is empty. One then checks that no polygonal path in Ω connects points in A to points in B. Hence the contrapositive of the converse statement holds. □

We pause to state the intuitive characterization of connected subsets of the real line. A subset of **R** (in the usual metric) is connected if and only if it is an interval. By convention, the word interval includes the entire real line, the empty set, and semi-infinite intervals. We leave the proof as an exercise, with the following hints. Given a bounded connected set S, let α be its greatest lower bound and let β be its least upper bound. We claim that S must be the interval between α and β, perhaps including one or both of these end points. To check this assertion, suppose $\alpha < x_0 < \beta$. If x_0 is not in S, then $\{x \in S : x < x_0\}$ and $\{x \in S : x > x_0\}$ are open nonempty subsets of S violating the definition of connectedness. The same idea works when S is unbounded below or above. The converse (an interval is connected) proceeds by writing the interval as $A \cup B$, where A and B are nonempty *closed* sets. (Their complements are open.) Choosing points in each and successively bisecting the interval between them creates two monotone sequences with a common limit, which must then be in both sets. Hence $A \cap B$ is nonempty.

► **Exercise 1.36.** Complete the proof that a subset of **R** is connected if and only if it is an interval.

Finally we mention one more concept, distinct from *connectedness*, but with a similar name. Roughly speaking, an open and connected subset S of **C** is called *simply connected* if it has no holes. Intuitively speaking, S has a hole if there is a closed curve in S which surrounds at least one point not in S. For example, the complement of a point is open and connected, but it is not simply connected. The set of z for which $1 < |z| < 2$ is open and connected but not simply connected. In

Chapter 8 we will define the *winding number* of a closed curve about a point. At that time we give a precise definition of simple connectivity.

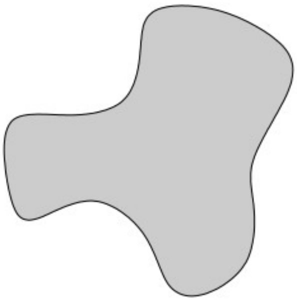

Figure 1.6. A connected and simply connected set.

3. Ramanujan's Notebooks

The history of the notebooks, in brief, is the following: Ramanujan had noted down the results of his researches, without proofs, (as in *A Synopsis of Elementary Results, a book on pure Mathematics,* by G.S. Carr), in three notebooks, between the years 1903 - 1914, before he left for England. These were the notebooks which he showed to his benefactors to convince them about his abilities as a mathematician. The results in these notebooks were organized by him. The first notebook has 16 chapters in 134 pages. The second is a revised, enlarged version of the first, containing 21 chapters in 252 pages. The third notebook contains 33 pages of unorganized material (included at the end of volume 2 of the facsimile edition [VII]). Ramanujan took these notebooks with him to Cambridge. But, in one of his letters to a friend, he wrote that he had no time to look into them and most probably he did not put them to use during his five year stay abroad.

The Preface to the *Collected Papers of Srinivasa Ramanujan* ([III], p.ix) contains the following appraisal of the work in the notebooks:

> *There is still a large mass of unpublished material. None of the contents of Ramanujan's notebooks has been printed, unless incorporated in later papers, except that one chapter, on generalized hypergeometric series, was analyzed by Hardy* [37] *in the Proceedings of the Cambridge Philosophical Society. This chapter is sufficient to show that, while the notebooks are naturally unequal in quality, they contain much which should certainly be published. It would be a very formidable task to work through them systematically, select particular passages, and edit these with adequate comment, and it is impossible to print the notebooks as they stand without further monetary assistance. The singular quality of Ramanujan's work and the romance which surrounds his career, encourage us to hope that this volume may enjoy sufficient success to make possible the publication of another.*

Hardy tried to persuade the University of Madras to undertake such a task and in turn, Prof. G.N. Watson was requested by the Madras University, in 1931, to edit the notebooks in a suitable form for publication. This was a formidable task since the notebooks contained about 4000 theorems.

Prof. Watson gave a lecture [39] on Ramanujan's notebooks at the London Mathematical Society in 1931, and published several papers between 1928–36, motivated by Ramanujan's work. Watson's Presidential address to the London Mathematical Society, in 1935, was on *mock-theta functions*, discovered by Ramanujan during the period when he was terminally ill (March 1919 – April 1920) after his return to India. Watson undertook the task of editing the notebooks with Prof. B.M. Wilson and

> *they focussed their attention on the second notebook. Chapters 2–13 were to be edited by Wilson, and Watson was to examine chapters 14–21. Unfortunately, Wilson passed away prematurely in 1935 at the age of 38.* (Berndt [40]).

This possibly put an end to the joint effort of Watson and Wilson to edit the notebooks.

In 1957, with monetary assistance from Sir Dadabai Naoroji Trust, at the instance of Prof. Homi J. Bhabha and Prof. K. Chandrasekaran of the Tata Institute of Fundamental Research, the Tata Institute published a facsimile edition of the notebooks of Ramanujan in two volumes. The reproduction is thoroughly faithful to the original. About a thousand copies were made then and in the centenary year of Ramanujan's birth, 1987, Springer - Narosa reprinted the same.

The formidable task of truly editing the notebooks –*viz.* to either prove each of the results or provide references to the literature where the proofs may be found – which was started by G. N. Watson and B. M. Wilson but never completed, was taken up in right earnest by Prof. Bruce C. Berndt, who has been publishing a series of papers, since 1981, by himself or in collaboration with others, including Indian Mathematicians Padmini T. Joshi, C. Adiga and S. Bhargava. He has also utilized the earlier work of G.N. Watson and B.M. Wilson on the notebooks with the Trinity College. This dedicated work of Berndt, published by Springer-Verlag [VIII], is now available in five parts, the first of which appeared in 1985 and the fifth, in 1997.

At the beginning of his work, in Part I, Berndt [34] points out:

> *The notebooks were originally intended primarily for Ramanujan's own personal use and not for publication ... Some of Ramanujan's incorrect 'theorems' in number theory found in his letters to*

> *Hardy have been well publicized. Thus, perhaps, some think that Ramanujan was prone to making errors. However, such thinking is erroneous. The notebooks contain scattered errors. Especially if one takes into account the roughly hewn nature of the material and his frequently formal arguments, Ramanujan's accuracy is amazing.*

Resurgence of interest

After Ramanujan returned to India, though he was seriously ill and bedridden for most of the time, he was working continuously. His life-long habit had been to work on a slate and transfer the final results to the notebook or sheets of paper. His brother-in-law has stated [59] that *a vast quantity of papers containing his notes was handed over to the University after his death.* Three days after Ramanujan died, his brother S. Lakshminarasimhan, in a letter to Prof. Hardy, dated 29th April 1920, informing him about his demise, wrote :

> *All his Mss that were in his trunk were handed over on the day of his death to Mr. Ramachandra Row's son in law, since the former is at Nilgiris. Not only those but also the journals, magazines - all he possessed except the books which he had, were taken away by them.*

In a letter to Prof. Hardy, dated 3 Dec. 1920, Mr. R. Ramachandra Row, wrote:

> *Ramanujan's M.S.S whatever they are are with me and will be handed over intact to the University of Madras who I understand is already in correspondence with you regarding the methods of publication.*

These papers reached Prof. Hardy, who should have passed them on to Prof. G.N. Watson and hence to their final destination – viz. the estate of Prof. Watson, in the underground cellar of Trinity College – after he wrote several papers inspired Ramanujan's results, until their discovery in 1976 by George E. Andrews.

Prof. Watson died in Feb. 1965. A decade later, in the spring of 1976, when Prof. George Andrews [53] of the Pennsylvania State University was going through the estate of Watson, he discovered a box of papers.

> *The most interesting item in this box was a manuscript of more*

> *than one hundred pages in Ramanujan's distinctive handwriting which contains over six hundred mathematical formulae listed one after the other without proof. It is my contention that this manuscript, or notebook, was written during the last year of Ramanujan's life after his return to India from England. My evidence for this assertion is all indirect; in the words of Stephen Leacock, 'It is what we call circumstantial evidence — the same that people are hanged for'* .

These are now referred to as the contents of the *Lost* notebook of Ramanujan. Andrews assessed ([101], p.xii):

> *While it is impossible to categorize the various formulas completely, a rough approximation of its contents is the following:*
>
> *q-series and related topics including mock θ-functions: 60%*
> *Modular equations and relation, singular moduli: 30%*
> *Integrals, Dirichlet series, congruences, asymptotics, misc.: 10%*
>
> *I give only this rough break down because of the chaotic nature of this manuscript. On many pages there are fragments of numerical computations and infinite series running off in all directions. It may be possible eventually to make sense out of some of these pages; if so, the above percentage breakdown may change. ...*
> *In any event it is clear that q-series investigations make up the bulk of the work in in the Lost Notebook. Indeed I count about 380 formulae that I consider to belong more to q-series than to modular relations or other topics.*

Sixty-seven years after the death of Ramanujan, due to the discovery of the 'lost' notebook by Prof. George Andrews, in 1976, and the editing of the three Notebooks of Ramanujan by Prof. Bruce Berndt, there has been a resurgence of interest in the work of Ramanujan. These notebooks of Ramanujan have formed the basis for numerous papers by many mathematicians, who gave proofs of the theorems and conjectures of Ramanujan obtained by him through his intuition and sheer brilliance. This is a singular and unparalleled phenomenon in the annals of mathematics. In the centenary year of his birth, 1987, several conferences were held in many countries to focus attention on his work and the recent developments. Mystery still surrounds *some of his* *work, mostly in the theory of elliptic functions*, wherein

> *it is not possible, after all the work of Watson and Mordell, to draw the line between what he may have picked up somehow and what he must have found for himself.* ([IV], p.10).

Hardy [60] regretted that he could easily have but did not find out all the details from Ramanujan himself since he

> *was quite able and willing to give a straight answer to a straight question, and not in the least disposed to make a mystery of his achievements.*

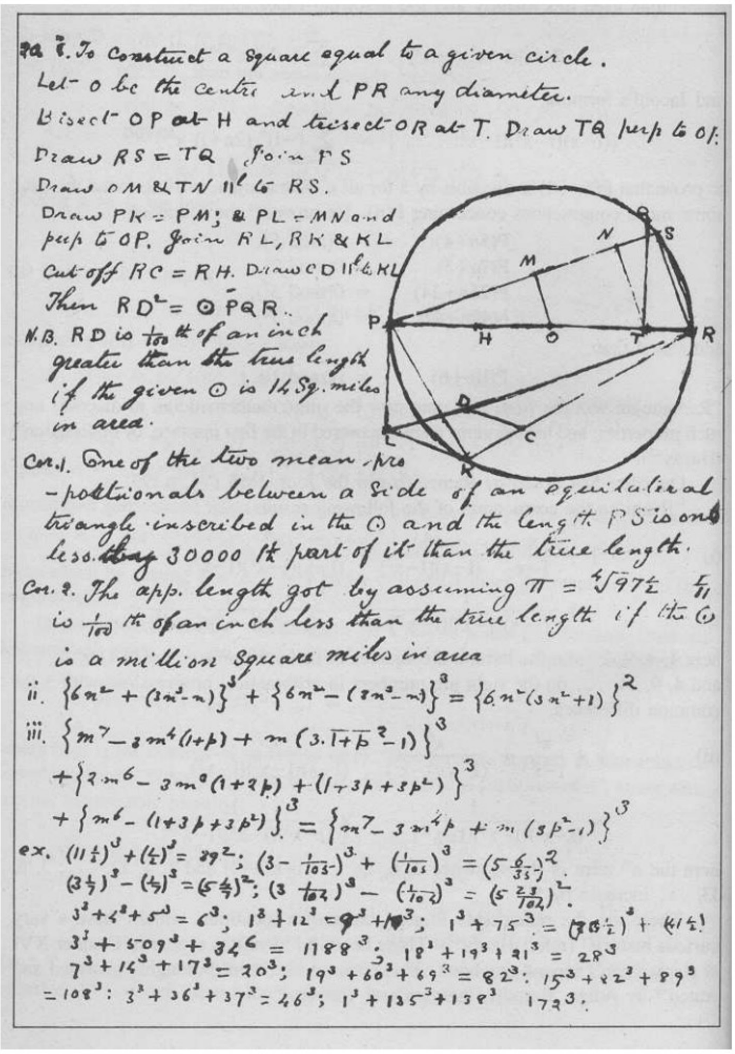
However, Hardy [60] argues that Ramanujan

> *was not particularly interested in his own history or psychology; he was a mathematician anxious to get on with the job. And after all I too was a mathematician, and a mathematician meeting Ramanujan had more interesting things to think about than historical research. It seemed ridiculous to worry him about how he had found this or that known theorem, when he was showing me half a dozen new ones almost every day.*

A Page from the second Notebook

To provide a feeling for Ramanujan's notebooks, we reproduce here a page [61] from his second Notebook, Chapter XVIII. There is no particular reason for choosing this page except that it contains an entry which has become a 'folklore' which illustrates the attachment Ramanujan had to numbers prompting Littlewood to state that to Ramanujan every number is a *personal friend.*

There are 2 parts shown in this page. The first part is concerning the geometrical construction of a square whose area is equal to that of a given circle. This is a rare piece of Ramanujan's work in geometry, since he did very little work in geometry and perhaps did not have much interest in it. Several attempts on this problem have been made from early times by (ancient Greek and Hindu) mathematicians and it has been shown that it is impossible



7a i. To construct a square equal to a given circle.
Let O be the centre and PR any diameter.
Bisect OP at H and trisect OR at T. Draw TQ perp to OP.
Draw RS = TQ Join PS
Draw OM & TN $\|^{l}$ to RS.
Draw PK = PM; & PL = MN and perp to OP. Join RL, RK & KL
Cut off RC = RH. Draw CD $\|^{l}$ to KL
Then $RD^2 = \odot PQR$.
N.B. RD is $\frac{1}{100}$th of an inch greater than the true length if the given $\odot$ is 14 Sq. miles in area.
Cor. 1. One of the two mean proportionals between a side of an equilateral triangle inscribed in the $\odot$ and the length PS is one ~~than~~ less. 30000th part of it than the true length.
Cor. 2. The app. length got by assuming $\pi = \sqrt[4]{97\tfrac{1}{2} - \tfrac{1}{11}}$ is $\frac{1}{100}$th of an inch less than the true length if the $\odot$ is a million square miles in area

ii. $\{6n^2 + (3n^3 - n)\}^3 + \{6n^2 - (3n^3 - n)\}^3 = \{6n^2(3n^2+1)\}^2$

iii. $\{m^7 - 3m^4(1+p) + m(3\cdot\overline{1+p}^2 - 1)\}^3$
$+ \{2m^6 - 3m^3(1+2p) + (1+3p+3p^2)\}^3$
$+ \{m^6 - (1+3p+3p^2)\}^3 = \{m^7 - 3m^4 p + m(3p^2-1)\}^3$

ex. $(11\tfrac{1}{2})^3 + (\tfrac{1}{2})^3 = 39^2$; $(3 - \tfrac{1}{105})^3 + (\tfrac{1}{105})^3 = (5\tfrac{6}{35})^2$.
$(3\tfrac{1}{7})^3 - (\tfrac{4}{7})^3 = (5\tfrac{4}{7})^2$; $(3\tfrac{1}{102})^3 - (\tfrac{1}{102})^3 = (5\tfrac{23}{102})^2$.
$3^3 + 4^3 + 5^3 = 6^3$; $1^3 + 12^3 = 9^3 + 10^3$; $1^3 + 75^3 = (38\tfrac{1}{2})^3 + (41\tfrac{1}{2})$
$3^3 + 509^3 + 34^6 = 1188^3$; $18^3 + 19^3 + 21^3 = 28^3$
$7^3 + 14^3 + 17^3 = 20^3$; $19^3 + 60^3 + 69^3 = 82^3$: $15^3 + 82^3 + 89^3$
$= 108^3$: $3^3 + 36^3 + 37^3 = 46^3$; $1^3 + 135^3 + 138^3$ 172^3.

Fig. caption: The last three lines of p. 224 and the p. 225 from the second notebook of Ramanujan, chapter XVIII. ([61]).

to *square the circle*, in the Euclidian sense[1]. Hardy has commented that he found in Ramanujan's collection of books in Cambridge some books by 'quacks' on this theme.

Ramanujan published a paper [62] entitled, "*Squaring the circle*" in the Jour. of the I.M.S. in 1913, in which he gives a geometrical construction for finding the length of the side of a square whose area equals that of the circle. He also reproduced this and another geometrical construction for π in his later paper [63] on "*Modular equations and approximations to* π". In this paper, he deduced several formulae[2] for π like:

$$\frac{63}{25}\frac{17+15\sqrt{5}}{7+15\sqrt{5}} = 3.14159265380...$$

$$\pi = \frac{24}{\sqrt{142}} log \left\{ \sqrt{\left(\frac{10+11\sqrt{2}}{4}\right)} + \sqrt{\left(\frac{10+7\sqrt{2}}{4}\right)} \right\}$$

$$\pi = 12\sqrt{190}\ log\left\{(2\sqrt{2}+\sqrt{10})(3+\sqrt{10})\right\}$$

formulae correct to 9, 16 and 18 decimal places; and

$$\frac{1}{\pi} = 2\sqrt{2}\left\{\frac{1103}{99^2} + \frac{27493}{99^6}\cdot\frac{1}{2}\cdot\frac{1.3}{4^2} + \frac{53883}{99^10}\cdot\frac{1.3}{2.4}\cdot\frac{1.3.5.7}{4{\cdot}8^2} + \cdots\right\}$$

$$= 2\sqrt{2}\sum_{n=0}^{\infty}\frac{(1/4)_n(1/2)_n(3/4)_n}{(1)_n(1)_n(1)_n}(1103+26390n)(\frac{1}{99})^{4n+2},$$

which he asserted would be "*rapidly convergent*", for the first term itself gives the sum to 8 decimal places. In 1986, Borwein and Borwein [64], two computer scientists used a version of Ramanujan's formula to calculate π to

---

[1] It is the ancient Greeks who set-up the circle-squaring problem with the following two conditions [83]: the solution should use only a straightedge and compass, so that the proofs can be reduced to Euclid's theorems and the solution must use only a finite number of steps. If, in fact, $\pi r^2 = a^2$, where r is the radius of the circle and a is the length of the side of a square, then it follows that $\pi = (a/r)^2$, or that π is rational. In fact, π has been shown to be not only an *irrational number* but also, proved by Ferdinand von Lindermann, in 1882, to be a *transcendental* number. Furthermore, the phrase 'squaring the circle' in common usage suggests a project doomed to failure!

[2] Note that Ramanujan has used the equality sign for his approximations to π even though he states explicitly that the formulae are correct only to a certain number of decimal places.

17 million places and found that the formula converges on the exact value with far greater efficiency than any previous method[3]. This success proved that Ramanujan's insight was correct.

The next entries on this page in Ch. XVIII of his second note book are solutions of Diophantine equations:

$$\begin{aligned} X^3+Y^3 &= U^2 \\ \text{and} \qquad X^3+Y^3+Z^3 &= U^3 \quad \text{(Euler's equation).} \end{aligned}$$

which are followed by numerical examples for these equations – 6 solutions for the first and 12 solutions for the Euler's equation and one which looks like but is not a solution of the Euler's equation. Characteristically, Ramanujan does not give the values of the parameters for the examples (ref. [VIII], part III, p.199 for the examples with the values of the parameters appended).

Ramanujan's solution of Euler's equation in rational numbers given here is:

$$\begin{aligned} X &= m^7 - 3m^4(1+p) + m(2+6p+3p^2), \\ Y &= 2m^6 - 3m^3(1+2p) + 1 + 3p + 3p^2, \\ Z &= m^6 - 1 - 3p - 3p^2, \\ U &= m^7 - 3m^4 p + m(3p^2-1), \end{aligned}$$

where m and p denote arbitrary numbers. He has also given another solution of this equation elsewhere (see Question 441 which follows) but neither of these two parameter solutions is the general solution[4] which contains three parameters, prompting Hardy [65] to comment that

> *Diophantine equations should have suited him, but he did comparatively little with them, and what he did was not his best.*

The second of the 12 examples given for the Euler equation on this page:

$$1^3 + 12^3 = 9^3 + 10^3 \quad (= \ 1729)$$

---

[3] David and Gregory Chudnovsky are two mathematicians who hold several world records for calculating the highest number of digits of π: first up to 450 million digits, then 1 billion and then 2 billion digits. The current record is over 51 billion digits (cf. For a brief history of π, [83]).

[4] The last of the examples $1^3 + 6^3 + 8^3 = 9^3$ does not belong to this class of solutions, since no values of m and p yield this solution to the Euler's equation. So, its presence reveals that perhaps, Ramanujan was aware that his solution was not the most general for Euler's equation.

corresponds to ($m = 2$, $p = 3$). This has been made famous by the following anecdote associated with it, due to Hardy [66]:

> *He could remember the idiosyncrasies of numbers in an almost uncanny way. It was Littlewood who said that every positive integer was one of Ramanujan's personal friends. I remember going to see him once when he was lying ill in Putney. I had ridden in taxi-cab number 1729, and remarked that the number seemed to me rather a dull one, and that I hoped that it was not an unfortunate omen. 'No', he replied, 'it is a very interesting number, it is the smallest number expressible as a sum of two cubes in two different ways'. I asked him, naturally, whether he could tell me the solution of the corresponding problem for fourth powers; and he replied, after a moment's thought, that he knew no obvious example, and supposed that the first such number must be very large.*

The simplest known solution of:

$$x^4 + y^4 = z^4 + t^4$$

is Euler's: $59^4 + 158^4 = 133^4 + 134^4 = 635318657.$
Euler gave a solution involving two parameters, but no 'general' solution is known.

The anecdote reveals Ramanujan's remarkable feeling for numbers and his sharp memory which made him recall one entry out of several thousands he had made in his notebook just like that and the fact that he had not recorded in his notebook the observation he made about 1729 which came from him only when Prof. Hardy made an innocuous statement regarding the taxi number.

Though the number 1729 itself finds no explicit mention in the notebooks, the Euler's equation and/or its solution: $1^3 + 12^3 = 9^3 + 10^3$ finds mention[5] in three Questions to the Journal of the I.M.S. ([III], p.331) and in two places in his notebooks ([VII], Vol. 2, p.266 and 387). These are indicated below:

---

[5] I am thankful to Mr. P.K. Srinivasan for drawing my attention to these and his publications [81].

- **Question 441** (V, 39)[6]:
Shew that

$$(6a^2-4ab+4b^2)^3=(3a^2+5ab-5b^2)^3+(4a^2-4ab+6b^2)^3+(5a^2-5ab-3b^2)^3,$$

and find other quadratic expressions satisfying similar relations.
[*Solution* by S. Narayanan, VI, 226.]

- **Question 661** (VII, 119):
Solve in integers $x^3+y^3+z^3=u^6$,
and deduce the following:

$$\begin{array}{rclrcl} 6^3-5^3-3^3 &=& 2^6, & 8^3+6^3+1^3 &=& 3^6,\\ 12^3-10^3+1^3 &=& 3^6, & 46^3-37^3-3^3 &=& 6^6,\\ 174^3+133^3-45^3 &=& 14^6, & 1188^3-509^3-3^3 &=& 34^6. \end{array}$$

[*Solutions by* N.B. Mitra, XIII, 15 – 17. Additional solution and remarks by N.B. Mitra, XIV, 73 – 77.]

- **Question 681** (VII, 160):
Solve in integers $x^3+y^3+z^3=1$,
and deduce the following:

$$\begin{array}{rclrcl} 6^3+8^3 &=& 9^3-1, & 9^3+10^3 &=& 12^3+1,\\ 135^3+138^3 &=& 172^3-1, & 791^3+812^3 &=& 1010^3-1,\\ 11161^3+11468^3 &=& 14258^3+1, & 65601^3+67402^3 &=& 83802^3+1. \end{array}$$

[*Partial solution by* N.B. Mitra, XIII, 17. See also N.B. Mitra, XIV, 73–77 (76–77).]

- If p,q,r are quantities so taken that $p+3a^2=q+3ab=r+3b^2=(a+b)^2$ and m and n are any two quantities, then

$$n(mp+nq)^3+m(mq+nr)^3=m(np+mq)^3+n(nq+mr)^3.$$

A particular case of the above theorem is:

$$(3a^2+5ab-5b^2)^3+(4a^2-4ab+6b^2)^3+(5a^2-5ab-3b^2)^3=(6a^2-4ab+4b^2)^3.$$

([VIII], Vol.2, p.266)

---

[6] J. of the IMS, vol. V, p.39.

- If $\alpha^2 + \alpha\beta + \beta^2 = 3\lambda\gamma^2$, then

$$(\alpha + \lambda^2\gamma)^3 + (\lambda\beta + \gamma)^3 = (\lambda\alpha + \gamma)^3 + (\beta + \lambda^2\gamma)^3.$$

([VIII], Vol.2, p.387)

Note that in the above 4-parameter solution for the Euler's equation, it has been observed (cf. [95] (c), p.43) that for $\alpha = 3, \beta = 0, \lambda = 3$ and $\gamma = 1$, we get $12^3 + 1^3 = 10^3 + 9^3 = 1729$. The fact that Ramanujan could come out spontaneously with the statement that 1729 in the smallest number which could be expressed as the sum of two cubes in two different ways, something which he had not jotted down in his notebooks, proves that every integer is a 'personal friend' of Ramanujan as remarked by Prof. Littlewood.

Hardy's statement that two thirds of Srinivasan Ramanujan's work in India, (contained in the notebooks), consisted of rediscoveries, is refuted by Prof. Bruce C. Berndt, who states after his extensive studies that Hardy's estimate is too high. Berndt's main goal was: "*To prove each of Ramanujan's theorems*" and for known results refer to literature where proofs may be found. Tables of the contents of "Ramanujan's Notebooks", Parts I to V, edited by Prof. Berndt are given here in the following pages. The titles of the chapters gives the reader an idea about the nature and range of problems and the number of results Ramanujan had recorded in each chapter.

In the Introduction to Part V, Berndt states:

> *This volume, however, should not be regarded as the closing chapter on Ramanujan's notebooks. Instead, it is just the first milestone on our journey to understanding Ramanujan's ideas. ... It is our fervent wish that these volumes will serve as springboards for further investigations by mathematicians intrigued by Ramanujan's remarkable ideas. ... Ramanujan remarked that several of his series arose from alternative theories of elliptic functions ... The first of the three alternative theories is the most interesting and the most important, and we feel that a large body of work remains to be discovered here.*

Ramanujan's Note Books, Part I, Bruce C. Berndt ([VIII], 1985):

Ch.	Subject	# of Results
1.	Magic Squares	43
2.	Sums Related to the Harmonic series or the Inverse Tangent Function	68
3.	Combinatorial Analysis and Series Inversions	86
4.	Iterates of the Exponential Function and an Ingenius Formal Technique	50
5.	Eulerian Polynomials and Numbers, Bernoulli Numbers and the Riemann Zeta-Function	94
6.	Ramanujan's Theory of Divergent series	61
7.	Sums of Powers, Bernoulli Numbers and the Γ Function	110
8.	Analogues of the Gamma Function	108
9.	Infinite Series Identities, Transformations, and Evaluations	139
	Ramanujan's Quarterly Reports	

Ramanujan's Note Books, Part II, Bruce C. Berndt ([VIII], 1989):

Ch.	Subject	# of Results
10.	Hypergeometric Series I	116
11.	Hypergeometric Series II	103
12.	Continued Fractions	113
13.	Integrals and Asymptotic Expansions	92
14.	Infinite Series	87
15.	Asymptotic Expansions Modular Forms	94

Ramanujan's work on hypergeometric series, contained in chapters X and XI of his second notebook was edited by Hardy, as stated earlier. In chapter 4 of this book, we take a closer look at some of the beautiful work of Ramanujan on hypergeometric series.

Ramanujan's Notebooks, Part III, Bruce C. Berndt ([VIII], 1991):

Ch.	Subject	# of Results
16.	q-Series and Theta Functions	134
17.	Fundamental Properties of Elliptic Functions	162
18.	The Jacobian Elliptic Functions	135
19.	Modular Equations of Degrees 3, 5 and 7 and Associated Theta Function Identities	185
20.	Modular Equations of Higher & Composite Degrees	173
21.	Eisenstein series	45

The 100 Pages of Unorganized material after Chapter 21 of Srinivasa Ramanujan's second Notebook and the 33 Pages of his third Notebook were organized into chapters 22 to 31 by Berndt.

Ramanujan's Notebooks, Part IV, Bruce C. Berndt ([VIII], 1994):

Ch.	Subject	# of Results
22	Elementary results	47
23.	Number Theory	108
24.	Theory of Prime numbers	24
25.	Theta Function and Modular Equations	86
26.	Inversion Formulas for Lemniscate & other functions.	10
27.	Q series	9
28.	Integrals	63
29.	Special Functions	39
30.	Partial Fraction Expansions	15
31.	Elementary and miscellaneous analysis	36
	16 Chapters of first Notebook	54

In the concluding part V, Berndt examines the unorganized pages in all the three notebooks of Ramanujan on continued fractions, alternative theories of elliptic functions, class invariants and singular moduli, explicit values of theta-functions, modular equations, infinite series, approximations and asymptotic expansions, etc. Berndt points out that *very few claims in this volume pertain to Ramanujan's published papers and problems.*

Ramanujan‘s Notebooks, Part V, Bruce C. Berndt ([VIII], 1997)[7]:

Ch.	Subject	# of Results
32.	Continued Fractions	73
33.	Ramanujan's Theories of Elliptic Functions to Alternative Bases	62
34.	Class Invariants and Singular Moduli	196
35.	Values of Theta-Functions	24
36.	Modular Equations and Theta-Function Identities in Notebook 1	87
37.	Infinite Series	53
38.	Approximations and Asymptotic Expansions	46
39.	Miscellaneous Results in the First Notebook	24

Many theorems communicated by Ramanujan to Hardy in his Jan.16, Feb. 27, 1913 letters are found in Chapters.22 – 31. In all, $759+605+834+491+565 = 3254$ theorems have been studied in the parts I–V by Prof. Berndt. Hardy had estimated that the notebooks of Ramanujan contained approximately 3000 – 4000 statements of theorems and besides editing one chapter of Ramanujan's second Notebook, in 1923, he tried to get them edited. His intentions have at long last been fulfilled by the tireless efforts of the indefatigable Bruce C. Berndt. For the motivated student of Mathematics, this five part publication will provide a plethora of results for further studies. As stated elsewhere [XV], it is no exaggeration to say that as long as people do mathematics, the work of Ramanujan and the stupendous effort of Prof. Bruce C. Berndt in editing the Ramanujan notebooks will be appreciated.

---

[7] The author thanks Prof. Berndt for readily communicating the Preface and the Contents pages of Part V, by e-mail, on request.

R.P. Agarwal's work on the notebooks

Prof. Ratan P. Agarwal is the founder of a school of ordinary and basic hypergeometric series in India. In recent times, he has consolidated a part of his work in a publication entitled: *Resonance of Ramanujan's Mathematics* [82]. This two volume work concerns some of the results of Srinivasa Ramanujan (1887 - 1920), the renowned Indian Mathematician, recorded in his notebooks, which continue to be a perennial source of inspiration for generations of Mathematicians.

Volume I has five chapters. Chapter 1 concerns certain summation and asymptotic formulae for generalized (ordinary and basic) hypergeometric series. Chapter 2 is on Rogers-Ramanujan identities. Chapters 3 - 5 deal with certain definite Integrals of interest to Ramanujan.

Prof. Agarwal opines, like Hardy, that *a major part of Ramanujan's systematic work on ordinary hypergeometric series has been in the nature of a rediscovery of the work already done by previous authors* – the ${}_7F_6(1)$ summation formula of Dougall (1907) and particular cases of this sum, such as, Pfaff (1797) - Saalschütz (1890) theorem for the ${}_3F_2(1)$ and the Gauss and Kummer summation theorems for the ${}_2F_1(1)$ and the ${}_2F_1(-1)$, respectively, and Dixon's summation theorem for a well-poised ${}_3F_2(1)$. These and Ramanujan's entries in his notebooks concerning the deep results on the asymptotic relations for a finite number of terms of a variety of ordinary hypergeometric series, which center around the behaviour of the logarithmic solutions of the hypergeometric differential equation are presented in Chapter 1.

Chapter 2 deals with the derivations of the celebrated Rogers–Ramanujan identities[8], their combinatorial interpretations, their generalizations and their applications in Statistical Mechanics for the solution of the two-dimensional hard-hexagonal model (by R.J. Baxter). Several proofs of these identities and the interesting mathematical developments have been described very well in this cogently written chapter.

---

[8] Refer chapter 2 of this work for a discussion about these famous identities.

The next three chapters of Volume I deal with some of the integrals studied by Ramanujan. Prof. Agarwal presents definite integrals associated with Fourier transforms in the second Notebook and self-reciprocal functions given in his 'lost' Notebook in Chapter 3. He has shown how some of Ramanujan's results on integrals in his Notebook can be established with the help of other entries of his

> *that every entry given in the notebooks by him has a purpose, although sometimes a particular entry may look out of context at the first instance. ... We have advocated elsewhere also that it may be interesting many a time to try to prove 'unproven' entry of Ramanujan with the help of some other entry given by him earlier or later on.*

Chapter 4 is focused on Ramanujan's Master Theorem for the evaluation of definite integrals, viz.:

$$\int_0^\infty x^{n-1}F(x)dx = \Gamma(n)\phi(-n), \qquad \text{where } F(x) = \sum_{k=0}^{\infty} \frac{\phi(k)(-x)^k}{k!},$$

in some neighbourhood of $x = 0$ and for n not necessarily a positive integer. The three Quarterly Reports submitted by Ramanujan to the Madras University, as a requirement stipulated by the University for awarding him the *First Research Scholarship in Mathematics*, contain various applications of this theorem to the *evaluation of a huge variety of integrals* and expansion formulae. The appropriate conditions of convergence for its validity have been provided by Hardy in his lectures contained in *Ramanujan* [IV]. The q-extension of the Master Theorem by Jackson (1951) and its extension to two variables by R.P. Agarwal (1974) are presented. The fundamental gamma and beta functions of mathematical analysis have been ingeniously extended by Ramanujan and these are related to the 'incomplete' gamma and beta functions (in which the upper limit of the integrals is finite and not ∞). The q-extensions of these works by several mathematicians including

Thomae (1879), F.H. Jackson (1904), R. Askey (1978), G.E. Andrews and R. Askey (1981), A. Verma and V.K. Jain (1992) are also included.

Chapter 5 is devoted to the study of integrals of the type:

$$\int_{-\infty}^{\infty} \frac{e^{at^2+bt}}{e^{ct}+d} dt$$

for particular values of a, b, c, d, evaluated by Ramanujan. Mordell (1933) classified these according to the values of the parameters and evaluated them in terms of Jacobi's theta and other related functions, using the method of complex contour integration. Professor Agarwal presents the general method of evaluation of different standard forms of this integral and relates them to those studied by Ramanujan, who used transform calculus to evaluate his integrals. Integrals associated with Riemann's zeta functions and elliptic modular relations are not discussed, as pointed out by the author himself. The chapter concludes with the mention of the example of a definite integral with fractional derivatives in the integrand stated in the third Quarterly Report. Ramanujan's formal deduction is based on his Master theorem and it agrees with the classical Liouville's definition of a fractional derivative of a function.

In Volume II, Prof. Agarwal presents a critical appraisal of Ramanujan's extensive and intriguing work on elliptic functions. Results pertaining to theta functions, partial theta functions, 'mock' theta functions (discovered by Ramanujan during the last year of his life on his return to India), as well as Lambert series and their relationship with elliptic functions, 'mock' theta functions and allied functions. While theta functions and partial theta functions are covered in chapter 1 of this volume and Lambert series and related functions are dealt with in chapter 5, the major part of this volume is concerned with the 'mock' theta function results of Ramanujan, presented in three extensive chapters (2, 3 and 4), contained in the 'Lost' Notebook, which was made available to the world in a facsimile edition, by Narosa, for the first time in the centenary year of Ramanujan's birth 1987 (though it was discovered in the estate of G.N. Watson by Prof. George E. Andrews of the Pennsylvania State University, in Spring 1976).

After giving the definitions of the four Jacobi theta functions and the 'false' theta functions (viz. theta functions with the 'wrong' signs for the terms) defined by L.J. Rogers, Prof. Agarwal introduces the Ramanujan notation for the theta function in terms of his symmetric function:

$$f(a,b) = \sum_{k=-\infty}^{\infty} (ab)^{k(k-1)/2}(a^k + b^k), \quad |ab| < 1.$$

In terms of this symmetric function, Ramanujan defines:

$$f(qe^{2iz}, qe^{-2iz}) = \theta_3(z,q), \text{ where } q = e^{i\pi\tau} \text{ and } |q| < 1.$$

Several general properties of the function $f(a,b)$ are then presented. Jacobi's triple product identity and other such identities due to D. Hickerson (1988) and G.E. Andrews and D. Hickerson (1991) are derived explicitly, due to their importance to simplify calculations in later chapters on 'mock' theta functions. A number of theta function expansions in the 'lost' notebook pertain to 'partial' theta functions. Some of these are stated and G.E. Andrews (1981) derived a general basic hypergeometric identity and showed the results of Ramanujan as special cases of it.

Ramanujan defined four third order mock theta functions and to this set three more were added by Watson. Watson used the transformations of basic hypergeometric series for obtaining new definitions for all the seven functions. Agarwal himself has contributed significantly to the theory of 'mock' theta functions by showing that most of the general identities of Andrews (referred above) belong to a very general class of basic hypergeometric transformations. His results are presented and those of Andrews deduced from them. Furthermore, Agarwal defines the third order mock theta functions in terms of a ${}_2\Phi_1$ basic hypergeometric series and deduces many of the mock theta function properties from the well-known properties of the ${}_2\Phi_1$. Ramanujan gave ten mock theta functions of order five, in two groups of five each, and three functions of order seven. He asserted that the members of each of the two groups of mock theta functions of order five are related amongst those belonging to the same group only, while the three mock theta functions of order seven are not related to each other. The works of Andrews, Agarwal and M. Gupta on the mock theta functions of order five are presented in detail. A. Gupta and Agarwal showed that mock theta functions of order five and seven are defined through basic hypergeometric series of type ${}_3\Phi_2$ and ${}_4\Phi_3$. They have also made attempts to develop the theory of the above types of basic hypergeometric series to obtain new transformations and definitions for certain mock theta functions of orders five and seven. It is pointed out that the absence of a general transformation theory for the ${}_3\Phi_2(a, b, c; e, f; z)$ series [except when the argument z is q (the base parameter itself) or ef/abc], is the main reason why there exists no general transformation theory for mock theta functions of order five.

Observations of Agarwal on the relationship between the 'mock' theta functions and the basic hypergeometric series lead him to define:

> *the order of a mock theta function as* $(2r+1)$ *if it is expressible in terms of a* ${}_{r+1}\Phi_r$ *series, on a single base* q^k, $k \leq r+1$. *There may be in the definition of the mock theta function an additive term with* ${}_{r+1}\Phi_r$ *consisting of* θ*-products, which do not affect the order.*

While this is an intersting observation by itself, it is simplistic, to say the least. For, mystery still surrounds the incomplete work of Ramanujan in this area contributing to the belief that Ramanujan was working on a general theory of mock theta functions, whose preliminary results are the ones in the 'lost' notebook of his and that he was snatched away by fate before he could reveal his grand scheme!

This two volume work of Prof. Agarwal is a deep study of some of the work of Ramanujan on ordinary and basic hypergeometric series, on definite integrals and theta, partial theta and mock theta functions. It is very original in parts and has a minimum overlap with the comprehensive five part work on the notebooks of Ramanujan by Bruce C. Berndt[9]. This work presents, in as coherent a way as is possible, the work of Agarwal and his school of students and coworkers. It is a valuable supplement for the research scholar and for mathematicians and presents the author's understanding of the 'how' and 'why' of what Ramanujan did.

---

[9] The author's reference to these Parts I to V as the Berndt Notebooks is unfortunate, especially in view of the significance of the Ramanujan notebooks and the 'Lost' notebook, which are the source materials for both Berndt and Agarwal.

Dyson on Ramanujan's notebooks

Freeman J. Dyson, the renowned Physicist ([XVI], p.25), concludes his article entitled: *A Walk through Ramanujan's Garden*, with the following advise:

> *In conclusion, I would like to urge all of you who are working in the many fields of mathematics which have been enriched by Ramanujan's ideas to go back to the source the collected papers and the notebooks. . . . The notebooks . . . are now appearing in a splendidly annotated version edited by Bruce Berndt [VIII]. The "lost" notebook is now accessible to us through the devoted labors of George Andrews ([53], [56]). When I started my walk through Ramanujan's garden 47 years ago, only the collected papers were available. A year after I chose Hardy and Wright's "Theory of Numbers" (Oxford, Clarendon Press, 1938) as a school prize, I won another prize. For the second prize I chose Ramanujan's collected papers. The collected papers have traveled with me from England to America and are still as fresh to-day as they were in 1940. Whenever I am angry or depressed, I pull down the collected papers from the shelf and take a quiet stroll in Ramanujan's garden. I recommend this therapy to all of you who suffer from headaches or jangled nerves. And Ramanujan's papers are not only a good therapy for headaches. They also are full of beautiful ideas which may help you to do more interesting mathematics.*

Certainly several of us will not find this therapy useful. Since Dyson, Erdös and Selberg were among the very best in their chosen fields, they were greatly benefited by an early introduction to the Collected Papers. The rest can derive the benefit of the extensive study of Ramanujan's work by Hardy [IV] and Berndt [VIII] to begin appreciating the prolific, original work of the mathematical genius in his published work and in his notebooks.

MODULAR EQUATIONS AND APPROXIMATIONS TO π.

By S. Ramanujan.

1. If we suppose that

$$(1)\quad (1+e^{-\pi\sqrt{n}})(1+e^{-3\pi\sqrt{n}})(1+e^{-5\pi\sqrt{n}})\ldots = 2^{\frac14}e^{-\pi\sqrt{n}/24}G_n$$

and

$$(2)\quad (1-e^{-\pi\sqrt{n}})(1-e^{-3\pi\sqrt{n}})(1-e^{-5\pi\sqrt{n}})\ldots = 2^{\frac14}e^{-\pi\sqrt{n}/24}g_n,$$

then G_n and g_n can always be expressed as roots of algebraical equations when n is any rational number. For we know that

$$(3)\quad (1+q)(1+q^3)(1+q^5)\ldots = 2^{\frac16}q^{\frac1{24}}(kk')^{-\frac1{12}}$$

and

$$(4)\quad (1-q)(1-q^3)(1-q^5)\ldots = 2^{\frac16}q^{\frac1{24}}k^{-\frac1{12}}k'^{\frac16}.$$

Now the relation between the moduli k and l, which makes

$$n\frac{K'}{K} = \frac{L'}{L},$$

where $n = r/s$, r and s being positive integers, is expressed by the modular equation of the rs^{th} degree. If we suppose that $k = l'$, $k' = l$, so that $K = L'$, $K' = L$, then

$$q = e^{-\pi L'/L} = e^{-\pi\sqrt{n}},$$

and the corresponding value of k may be found by the solution of an algebraical equation.

From (1), (2), (3), and (4) it may easily be deduced that

$$(5)\quad g_{4n} = 2^{\frac14}g_nG_n,$$

$$(6)\quad G_n = G_{1/n},\quad 1/g_n = g_{4/n},$$

$$(7)\quad (g_nG_n)^8(G_n^8 - g_n^8) = \tfrac14.$$

I shall consider only integral values of n. It follows from (7) that we need only consider one of G_n or g_n for any given value of n; and from (5) that we may suppose n not divisible by 4. It is most convenient to consider g_n when n is even, and G_n when n is odd.

2. Suppose then that n is odd. The values of G_n and g_{2n} are got from the same modular equation. For example, let us take the modular equation of the 5th degree, viz.,

$$(8)\quad \left(\frac{u}{v}\right)^3 + \left(\frac{v}{u}\right)^3 = 2\left(u^2v^2 - \frac{1}{u^2v^2}\right),$$

where $2^{\frac14}q^{\frac1{24}}u = (1+q)(1+q^3)(1+q^5)\ldots$

and $2^{\frac14}q^{\frac5{24}}v = (1+q^5)(1+q^{15})(1+q^{25})\ldots.$

By changing q to $-q$ the above equation may also be written as

$$(9)\quad \left(\frac{v}{u}\right)^3 - \left(\frac{u}{v}\right)^3 = 2\left(u^2v^2 + \frac{1}{u^2v^2}\right),$$

where $2^{\frac14}q^{\frac1{24}}u = (1-q)(1-q^3)(1-q^5)\ldots$

and $2^{\frac14}q^{\frac5{24}}v = (1-q^5)(1-q^{15})(1-q^{25})\ldots.$

If we put $q = e^{-\pi/\sqrt5}$ in (8), so that $u = G_{1/5}$ and $v = G_5$, and hence $u = v$, we see that

$$v^4 - v^{-4} = 1.$$

Hence $\quad v^4 = \dfrac{1+\sqrt5}{2},\quad G_5 = \left(\dfrac{1+\sqrt5}{2}\right)^{\frac14}.$

Similarly, by putting $q = e^{-\pi\sqrt{(2/5)}}$, so that $u = g_{2/5}$ and $v = g_{10}$, and hence $u = 1/v$, we see that

$$v^6 - v^{-6} = 4.$$

Hence $\quad v^2 = \dfrac{1+\sqrt5}{2},\quad g_{10} = \sqrt{\left(\dfrac{1+\sqrt5}{2}\right)}.$

Similarly it can be shown that

$$G_9 = \left(\frac{1+\sqrt3}{\sqrt2}\right)^{\frac13},\quad g_{18} = (\sqrt2+\sqrt3)^{\frac13},$$

$$G_{17} = \sqrt{\left(\frac{5+\sqrt{17}}{8}\right)} + \sqrt{\left(\frac{\sqrt{17}-3}{8}\right)},$$

$$g_{34} = \sqrt{\left(\frac{7+\sqrt{17}}{8}\right)} + \sqrt{\left(\frac{\sqrt{17}-1}{8}\right)},$$

and so on.

3. In order to obtain approximations for π we take logarithms of (1) and (2). Thus

$$(10)\quad \pi = \frac{24}{\sqrt{n}}\log(2^{\frac14}G_n),$$

$$\pi = \frac{24}{\sqrt{n}}\log(2^{\frac14}g_n),$$

approximately, the error being nearly $\dfrac{24}{\sqrt{n}}e^{-\pi\sqrt{n}}$ in both cases. These equations may also be written as

$$(11)\quad e^{\pi\sqrt{n}/24} = 2^{\frac14}G_n,\quad e^{\pi\sqrt{n}/24} = 2^{\frac14}g_n.$$

In those cases in which G_n^{12} and g_n^{12} are simple quadratic surds we may use the forms

$$(G_n^{12}+G_n^{-12})^{\frac1{12}},\quad (g_n^{12}+g_n^{-12})^{\frac1{12}},$$

instead of G_n and g_n; for we have

$$g_n^{12} = \tfrac18 e^{\frac12\pi\sqrt{n}} - \tfrac32 e^{-\frac12\pi\sqrt{n}},$$

approximately, and so

$$g_n^{12} + g_n^{-12} = \tfrac18 e^{\frac12\pi\sqrt{n}} + \tfrac{13}{2}e^{-\frac12\pi\sqrt{n}},$$

approximately, so that

$$(12)\quad \pi = \frac{2}{\sqrt{n}}\log\{8(g_n^{12}+g_n^{-12})\},$$

the error being about $\dfrac{104}{\sqrt{n}}e^{-\pi\sqrt{n}}$, which is of the same order as the error in the formulæ (10). The formula (12) often leads to simpler results. Thus the formula (10) gives

$$e^{\pi\sqrt{18}/24} = 2^{\frac14}g_{18}$$

or

$$e^{\frac14\pi\sqrt{18}} = 10\sqrt2 + 8\sqrt3.$$

But if we use the formula (12), or

$$e^{\pi\sqrt{n}/24} = 2^{\frac14}(g_n^{12}+g_n^{-12})^{\frac1{12}},$$

we get a simpler form, viz.,

$$e^{\frac14\pi\sqrt{18}} = 2\sqrt7.$$

4. The values of g_{2n} and G_n are obtained from the same equation. The approximation by means of g_{2n} is preferable to that by G_n for the following reasons.

(*a*) It is more accurate. Thus the error when we use G_{65} contains a factor $e^{-\pi\sqrt{65}}$, whereas that when we use g_{130} contains a factor $e^{-\pi\sqrt{130}}$.

(*b*) For many values of n, g_{2n} is simpler in form than G_n; thus

$$g_{130} = \sqrt{\left\{(2+\sqrt5)\left(\frac{3+\sqrt{13}}{2}\right)\right\}},$$

while

$$G_{65} = \left\{\left(\frac{1+\sqrt5}{2}\right)\left(\frac{3+\sqrt{13}}{2}\right)\right\}^{1/4} \times \sqrt{\left\{\sqrt{\left(\frac{9+\sqrt{65}}{8}\right)} + \sqrt{\left(\frac{1+\sqrt{65}}{8}\right)}\right\}}.$$

(*c*) For many values of n, g_{2n} involves quadratic surds only, even when G_n is a root of an equation of higher order. Thus G_{23}, G_{29}, G_{31} are roots of cubic equations, G_{47}, G_{79} are those of quintic equations, and G_{71} is that of a septic equation, while g_{46}, g_{58}, g_{62}, g_{94}, g_{142} and g_{158} are all expressible by quadratic surds.

5. Since G_n and g_n can be expressed as roots of algebraical equations with rational coefficients, the same is true of G_n^{24} or g_n^{24}. So let us suppose that

$$1 = ag_n^{-24} - bg_n^{-48} + \ldots,$$

or

$$g_n^{24} = a - bg_n^{-24} + \ldots.$$

But we know that

$$64e^{-\pi\sqrt{n}}g_n^{24} = 1 - 24e^{-\pi\sqrt{n}} + 276e^{-2\pi\sqrt{n}} - \ldots,$$

$$64g_n^{24} = e^{\pi\sqrt{n}} - 24 + 276e^{-\pi\sqrt{n}} - \ldots,$$

$$64a - 64bg_n^{-24} + \ldots = e^{\pi\sqrt{n}} - 24 + 276e^{-\pi\sqrt{n}} - \ldots,$$

$$64a - 4096be^{-\pi\sqrt{n}} + \ldots = e^{\pi\sqrt{n}} - 24 + 276e^{-\pi\sqrt{n}} - \ldots,$$

that is

$$(13)\quad e^{\pi\sqrt{n}} = (64a+24) - (4096b+276)e^{-\pi\sqrt{n}} + \ldots.$$

Similarly, if

$$1 = aG_n^{-24} - bG_n^{-48} + \ldots,$$

then

$$(14)\quad e^{\pi\sqrt{n}} = (64a-24) - (4096b+276)e^{-\pi\sqrt{n}} + \ldots.$$

From (13) and (14) we can find whether $e^{\pi\sqrt{n}}$ is very nearly an integer for given values of n, and ascertain also the number of 9's or 0's in the decimal part. But if G_n and g_n be simple quadratic surds we may work independently as follows. We have for example

$$g_{22} = \sqrt{(1+\sqrt2)}.$$

Hence $\quad 64g_{22}^{24} = e^{\pi\sqrt{22}} - 24 + 276e^{-\pi\sqrt{22}} - \ldots,$

$\quad\quad\quad 64g_{22}^{-24} = 4096e^{-\pi\sqrt{22}} + \ldots,$

so that

$$64(g_{22}^{24}+g_{22}^{-24}) = e^{\pi\sqrt{22}} - 24 + 4372e^{-\pi\sqrt{22}} + \ldots = 64\{(1+\sqrt2)^{12} + (1-\sqrt2)^{12}\}.$$

Hence $\quad e^{\pi\sqrt{22}} = 2508951.9982\ldots.$

Again $\quad G_{37} = (6+\sqrt{37})^{\frac14},$

$$64G_{37}^{24} = e^{\pi\sqrt{37}} + 24 + 276e^{-\pi\sqrt{37}} + \ldots,$$

$$64G_{37}^{-24} = 4096e^{-\pi\sqrt{37}} - \ldots,$$

so that

$$64\left(G_{37}^{24}+G_{37}^{-24}\right)=e^{\pi\sqrt{37}}+24+4372e^{-\pi\sqrt{37}}-\ldots$$
$$=64\{(6+\sqrt{37})^{6}+(6-\sqrt{37})^{6}\}.$$

Hence $\qquad e^{\pi\sqrt{37}}=199148647.999978\ldots.$

Similarly, from $\qquad g_{58}=\sqrt{\left(\frac{5+\sqrt{29}}{2}\right)},$

we obtain

$$64\left(g_{58}^{24}+g_{58}^{-24}\right)=e^{\pi\sqrt{58}}-24+4372e^{-\pi\sqrt{58}}+\ldots$$
$$=64\left\{\left(\frac{5+\sqrt{29}}{2}\right)^{12}+\left(\frac{5-\sqrt{29}}{2}\right)^{12}\right\}.$$

Hence $\qquad e^{\pi\sqrt{58}}=24591257751.99999982\ldots.$

6. I have calculated the values of G_n and g_n for a large number of values of n. Many of these results are equivalent to results given by Weber; for example,

$$G_{13}^{4}=\frac{3+\sqrt{13}}{2},\qquad G_{25}=\frac{1+\sqrt{5}}{2},$$
$$g_{30}^{4}=(2+\sqrt{5})(3+\sqrt{10}).\quad G_{37}^{4}=6+\sqrt{37},$$
$$G_{49}=\frac{7^{1/4}+\sqrt{(4+\sqrt{7})}}{2},\qquad g_{58}^{2}=\frac{5+\sqrt{29}}{2},$$
$$g_{70}^{2}=\frac{(3+\sqrt{5})(1+\sqrt{2})}{2},$$
$$G_{73}=\sqrt{\left(\frac{9+\sqrt{73}}{8}\right)}+\sqrt{\left(\frac{1+\sqrt{73}}{8}\right)},$$
$$G_{85}=\left(\frac{1+\sqrt{5}}{2}\right)\left(\frac{9+\sqrt{85}}{2}\right)^{1/4},$$
$$G_{97}=\sqrt{\left(\frac{13+\sqrt{97}}{8}\right)}+\sqrt{\left(\frac{5+\sqrt{97}}{8}\right)},$$
$$g_{190}^{2}=(2+\sqrt{5})(3+\sqrt{10}),$$
$$G_{385}^{2}=\tfrac{1}{8}(3+\sqrt{11})(\sqrt{5}+\sqrt{7})(\sqrt{7}+\sqrt{11})(3+\sqrt{5}),$$

and so on. I have also many results not given by Weber. I give a complete table of new results. In Weber's notation, $G_n=2^{-\frac{1}{4}}f\{\sqrt{(-n)}\}$ and $g_n=2^{-\frac{1}{4}}f_1\{\sqrt{(-n)}\}$.

TABLE I.

$$g_{62}+\frac{1}{g_{62}}=\tfrac{1}{2}\{\sqrt{(1+\sqrt{2})}+\sqrt{(9+5\sqrt{2})}\},$$

$$G_{65}^{2}=\sqrt{\left\{\left(\frac{1+\sqrt{5}}{2}\right)\left(\frac{3+\sqrt{13}}{2}\right)\right\}}\times\left\{\sqrt{\left(\frac{1+\sqrt{65}}{8}\right)}+\sqrt{\left(\frac{9+\sqrt{65}}{8}\right)}\right\},$$

$$g_{66}^{2}=\sqrt{(\sqrt{2}+\sqrt{3})}(7\sqrt{2}+3\sqrt{11})^{1/6}\times\left\{\sqrt{\left(\frac{7+\sqrt{33}}{8}\right)}+\sqrt{\left(\frac{\sqrt{33}-1}{8}\right)}\right\},$$

$$G_{69}^{2}=(3\sqrt{3}+\sqrt{23})^{1/4}\left(\frac{5+\sqrt{23}}{4}\right)^{1/6}\times\left\{\sqrt{\left(\frac{6+3\sqrt{3}}{4}\right)}+\sqrt{\left(\frac{2+3\sqrt{3}}{4}\right)}\right\},$$

$$G_{77}^{2}=\{\tfrac{1}{2}(\sqrt{7}+\sqrt{11})(8+3\sqrt{7})\}^{1/4}\times\left\{\sqrt{\left(\frac{6+\sqrt{11}}{4}\right)}+\sqrt{\left(\frac{2+\sqrt{11}}{4}\right)}\right\},$$

$$G_{777}^{2}=\sqrt{\left\{(2+\sqrt{3})(6+\sqrt{37})\left(\frac{\sqrt{3}+\sqrt{7}}{2}\right)\right\}}(246\sqrt{7}+107\sqrt{37})^{1/6}\times\left\{\sqrt{\left(\frac{6+3\sqrt{7}}{4}\right)}+\sqrt{\left(\frac{10+3\sqrt{7}}{4}\right)}\right\}\times\left\{\sqrt{\left(\frac{15+6\sqrt{7}}{2}\right)}+\sqrt{\left(\frac{17+6\sqrt{7}}{2}\right)}\right\},$$

$$G_{1225} = \left(\frac{1+\sqrt{5}}{2}\right)(6+\sqrt{35})^{1/4}\left\{\frac{7^{1/4}+\sqrt{(4+\sqrt{7})}}{2}\right\}^{3/2}$$
$$\times\left[\sqrt{\left\{\frac{43+15\sqrt{7}+(8+3\sqrt{7})\sqrt{(10\sqrt{7})}}{8}\right\}}+\sqrt{\left\{\frac{35+15\sqrt{7}+(8+3\sqrt{7})\sqrt{(10\sqrt{7})}}{8}\right\}}\right],$$

$$G^2_{1353} = \sqrt{\left\{(3+\sqrt{11})(5+3\sqrt{3})\left(\frac{11+\sqrt{123}}{2}\right)\right\}}$$
$$\times\left(\frac{6817+321\sqrt{451}}{4}\right)^{1/6}$$
$$\times\left\{\sqrt{\left(\frac{17+3\sqrt{33}}{8}\right)}+\sqrt{\left(\frac{25+3\sqrt{33}}{8}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{561+99\sqrt{33}}{8}\right)}+\sqrt{\left(\frac{569+99\sqrt{33}}{8}\right)}\right\},$$

$$G^2_{1645} = (2+\sqrt{5})\sqrt{\left\{(3+\sqrt{7})\left(\frac{7+\sqrt{47}}{2}\right)\right\}}\left(\frac{73\sqrt{5}+9\sqrt{329}}{2}\right)^{1/4}$$
$$\times\left\{\sqrt{\left(\frac{119+7\sqrt{329}}{8}\right)}+\sqrt{\left(\frac{127+7\sqrt{329}}{8}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{743+41\sqrt{329}}{8}\right)}+\sqrt{\left(\frac{751+41\sqrt{329}}{8}\right)}\right\}.$$

7. Hence we deduce the following approximate formulæ.

TABLE II.

$$e^{\frac{1}{8}\pi\sqrt{18}} = 2\sqrt{7},\quad e^{\pi\sqrt{22}/12} = 2+\sqrt{2},\quad e^{\frac{1}{4}\pi\sqrt{30}} = 20\sqrt{3}+16\sqrt{6},$$
$$e^{\frac{1}{4}\pi\sqrt{34}} = 12(4+\sqrt{17}),\quad e^{\frac{1}{2}\pi\sqrt{46}} = 144(147+104\sqrt{2}),$$
$$e^{\frac{1}{4}\pi\sqrt{42}} = 84+32\sqrt{6},\quad e^{\pi\sqrt{58}/12} = \frac{5+\sqrt{29}}{\sqrt{2}},$$
$$e^{\frac{1}{4}\pi\sqrt{70}} = 60\sqrt{35}+96\sqrt{14},\quad e^{\frac{1}{4}\pi\sqrt{78}} = 300\sqrt{3}+208\sqrt{6},$$
$$e^{\pi\sqrt{35}/24} = \frac{1+\sqrt{(3+2\sqrt{5})}}{\sqrt{2}},\quad e^{\frac{1}{4}\pi\sqrt{102}} = 800\sqrt{3}+196\sqrt{51},$$
$$e^{\frac{1}{4}\pi\sqrt{130}} = 12(323+40\sqrt{65}),\quad e^{\pi\sqrt{190}/12} = (2\sqrt{2}+\sqrt{10})(3+\sqrt{10}),$$
$$\pi = \frac{12}{\sqrt{130}}\log\left\{\frac{(2+\sqrt{5})(3+\sqrt{13})}{\sqrt{2}}\right\},$$

where $A(k)$ denotes an algebraic function of the special class described above. I shall use the letter A generally to denote a function of this type.

Now, if we put $k = l'$ and $k' = l$ in (16), we have

$$(17)\quad n\left\{1-24\left(\frac{1}{e^{2\pi\sqrt{n}}-1}+\frac{2}{e^{4\pi\sqrt{n}}-1}+\dots\right)\right\}$$
$$-\left\{1-24\left(\frac{1}{e^{2\pi/\sqrt{n}}-1}+\frac{2}{e^{4\pi/\sqrt{n}}-1}+\dots\right)\right\} = \left(\frac{K}{\pi}\right)^2 A(k).$$

The algebraic function $A(k)$ of course assumes a purely numerical form when we substitute the value of k deduced from the modular equation. But by substituting $k = l'$ and $k' = l$ in (15) we have

$$n^{\frac{1}{4}}e^{-\pi\sqrt{n}/12}(1-e^{-2\pi\sqrt{n}})(1-e^{-4\pi\sqrt{n}})(1-e^{-6\pi\sqrt{n}})\dots$$
$$= e^{-\pi/(12\sqrt{n})}(1-e^{-2\pi/\sqrt{n}})(1-e^{-4\pi/\sqrt{n}})(1-e^{-6\pi/\sqrt{n}})\dots.$$

Differentiating the above equation logarithmically we have

$$(18)\quad n\left\{1-24\left(\frac{1}{e^{2\pi\sqrt{n}}-1}+\frac{2}{e^{4\pi\sqrt{n}}-1}+\dots\right)\right\}$$
$$+\left\{1-24\left(\frac{1}{e^{2\pi/\sqrt{n}}-1}+\frac{2}{e^{4\pi/\sqrt{n}}-1}+\dots\right)\right\} = \frac{6\sqrt{n}}{\pi}.$$

Now, adding (17) and (18), we have

$$(19)\quad 1-\frac{3}{\pi\sqrt{n}}-24\left(\frac{1}{e^{2\pi\sqrt{n}}-1}+\frac{2}{e^{4\pi\sqrt{n}}-1}+\dots\right) = \left(\frac{K}{\pi}\right)^2 A(k).$$

But it is known that

$$1-24\left(\frac{q}{1+q}+\frac{3q^3}{1+q^3}+\frac{5q^5}{1+q^5}+\dots\right) = \left(\frac{2K}{\pi}\right)^2\left(1-2k^2\right),$$

so that

$$(20)\quad 1-24\left(\frac{1}{e^{\pi\sqrt{n}}+1}+\frac{3}{e^{3\pi\sqrt{n}}+1}+\dots\right) = \left(\frac{K}{\pi}\right)^2 A(k).$$

Hence, dividing (19) by (20), we have

$$(21)\quad \frac{1-\frac{3}{\pi\sqrt{n}}-24\left(\frac{1}{e^{2\pi\sqrt{n}}-1}+\frac{2}{e^{4\pi\sqrt{n}}-1}+\dots\right)}{1-24\left(\frac{1}{e^{\pi\sqrt{n}}+1}+\frac{3}{e^{3\pi\sqrt{n}}+1}+\dots\right)} = R,$$

Similarly we can find the sum of (19) when $n = 21, 33, 57, 93$, etc., by combining the values of $f(3)$ and $f(7)$, $f(3)$ and $f(11)$, and so on, obtained from Table III.

11. The errors in (22) and (24) being about

$$8\pi e^{-\pi\sqrt{n}}(\pi\sqrt{n}-3),\quad 24\pi(10\pi\sqrt{n}-31)e^{-2\pi\sqrt{n}},$$

we cannot expect a high degree of approximation for small values of n. Thus, if we put $n = 7, 9, 16$, and 25 in (24), we get

$$\frac{19}{16}\sqrt{7} = 3.14180\dots,$$
$$\frac{7}{3}\left(1+\frac{\sqrt{3}}{5}\right) = 3.14162\dots,$$
$$\frac{99}{80}\left(\frac{7}{7-3\sqrt{2}}\right) = 3.14159274\dots,$$
$$\frac{63}{25}\left(\frac{17+15\sqrt{5}}{7+15\sqrt{5}}\right) = 3.14159265380\dots,$$

while $\pi = 3.14159265358\dots.$

But if we put $n = 25$ in (22), we get only

$$\frac{9}{5}+\sqrt{\frac{9}{5}} = 3.14164\dots.$$

12. Another curious approximation to π is

$$\left\{9^2+\frac{19^2}{22}\right\}^{\frac{1}{4}} = 3.14159265262\dots.$$

This value was obtained empirically, and it has no connection with the preceding theory.

The actual value of π, which I have used for purposes of calculation, is

$$\frac{355}{113}\left(1-\frac{.0003}{3533}\right) = 3.1415926535897943\dots,$$

which is greater than π by about 10^{-15}. This is obtained by simply taking the reciprocal of $1-(113\pi/355)$.

In this connection it may be interesting to note the following simple geometrical constructions for π. The first merely gives the ordinary value $355/113$. The second gives the value $(9^2+19^2/22)^{1/4}$ mentioned above.

$$f(2) = \frac{4KL}{\pi^2}(k'+l),$$
$$f(3) = \frac{4KL}{\pi^2}(1+kl+k'l'),$$
$$f(4) = \frac{4KL}{\pi^2}(\sqrt{k'}+\sqrt{l})^2,$$
$$f(5) = \frac{4KL}{\pi^2}(3+kl+k'l')\sqrt{\left(\frac{1+kl+k'l'}{2}\right)},$$
$$f(7) = \frac{12KL}{\pi^2}(1+kl+k'l'),$$
$$f(11) = \frac{8KL}{\pi^2}\{2(1+kl+k'l')+\sqrt{(kl)}+\sqrt{(k'l')}-\sqrt{(kk'll')}\},$$
$$f(15) = \frac{4KL}{\pi^2}[\{1+(kl)^{\frac{1}{2}}+(k'l')^{\frac{1}{2}}\}^2-\{1+kl+k'l'\}],$$
$$f(17) = \frac{4KL}{\pi^2}\sqrt{\{44(1+k^2l^2+k'^2l'^2)+168(kl+k'l'-kk'll')}$$
$$\overline{-102(1-kl-k'l')(4kk'll')^{\frac{1}{3}}-192(4kk'll')^{\frac{2}{3}}\}},$$
$$f(19) = \frac{24KL}{\pi^2}\{(1+kl+k'l')+\sqrt{(kl)}+\sqrt{(k'l')}-\sqrt{(kk'll')}\},$$
$$f(23) = \frac{4KL}{\pi^2}[11(1+kl+k'l')-16(4kk'll')^{\frac{1}{6}}$$
$$\times\{1+\sqrt{(kl)}+\sqrt{(k'l')}\}-20(4kk'll')^{\frac{1}{3}}],$$
$$f(31) = \frac{12KL}{\pi^2}[3(1+kl+k'l')+4\{\sqrt{(kl)}+\sqrt{(k'l')}+\sqrt{(kk'll')}\}$$
$$-4(kk'll')^{\frac{1}{4}}\{1+(kl)^{\frac{1}{4}}+(k'l')^{\frac{1}{4}}\}],$$
$$f(35) = \frac{4KL}{\pi^2}[2\{\sqrt{(kl)}+\sqrt{(k'l')}-\sqrt{(kk'll')}\}$$
$$+(4kk'll')^{-\frac{1}{6}}\{1-\sqrt{(kl)}-\sqrt{(k'l')}\}^2].$$

Thus the sum of the series (19) can be found in finite terms, when $n = 2, 3, 4, 5$, etc., from the equations in Table III. We can use the same table to find the sum of (19) when $n = 9, 25, 49$, etc.; but then we have also to use the equation

$$\frac{3}{\pi} = 1-24\left(\frac{1}{e^{2\pi}-1}+\frac{2}{e^{4\pi}-1}+\frac{3}{e^{6\pi}-1}+\dots\right),$$

which is got by putting $k = k' = 1/\sqrt{2}$ and $n = 1$ in (18).

where R can always be expressed in radicals if n is any rational number. Hence we have

$$(22)\qquad \pi = \frac{3}{(1-R)\sqrt{n}}$$

nearly, the error being about $8\pi e^{-\pi\sqrt{n}}(\pi\sqrt{n}-3)$.

9. We may get a still closer approximation from the following results.

It is known that

$$1+240\sum_{r=1}^{r=\infty}\frac{r^3q^{2r}}{1-q^{2r}} = \left(\frac{2K}{\pi}\right)^4(1-k^2k'^2),$$

and also that

$$1-504\sum_{r=1}^{r=\infty}\frac{r^5q^{2r}}{1-q^{2r}} = \left(\frac{2K}{\pi}\right)^6(1-2k^2)(1+\tfrac{1}{2}k^2k'^2).$$

Hence, from (19), we see that

$$(23)\quad \left\{1-\frac{3}{\pi\sqrt{n}}-24\sum_{r=1}^{r=\infty}\frac{r}{e^{2\pi r\sqrt{n}}-1}\right\}\left\{1+240\sum_{r=1}^{r=\infty}\frac{r^3}{e^{2\pi r\sqrt{n}}-1}\right\}$$
$$= R'\left\{1-504\sum_{r=1}^{r=\infty}\frac{r^5}{e^{2\pi r\sqrt{n}}-1}\right\},$$

where R' can always be expressed in radicals for any rational value of n. Hence

$$(24)\qquad \pi = \frac{3}{(1-R')\sqrt{n}},$$

nearly, the error being about $24\pi(10\pi\sqrt{n}-31)e^{-2\pi\sqrt{n}}$.

It will be seen that the error in (24) is much less than that in (22), if n is at all large.

10. In order to find R and R' the series in (16) must be calculated in finite terms. I shall give the final results for a few values of n.

TABLE III.

$$q = e^{-\pi K'/K},\quad q^n = e^{-\pi L'/L},$$
$$f(q) = n\left(1-24\sum_1^\infty\frac{q^{2mn}}{1-q^{2mn}}\right)-\left(1-24\sum_1^\infty\frac{q^{2m}}{1-q^{2m}}\right),$$

$$\pi = \frac{24}{\sqrt{142}}\log\left\{\sqrt{\left(\frac{10+11\sqrt{2}}{4}\right)}+\sqrt{\left(\frac{10+7\sqrt{2}}{4}\right)}\right\},$$
$$\pi = \frac{12}{\sqrt{190}}\log\{(2\sqrt{2}+\sqrt{10})(3+\sqrt{10})\}.$$
$$\pi = \frac{12}{\sqrt{310}}\log[\tfrac{1}{4}(3+\sqrt{5})(2+\sqrt{2})\{(5+2\sqrt{10})+\sqrt{(61+20\sqrt{10})}\}].$$
$$\pi = \frac{4}{\sqrt{522}}\log\left[\left(\frac{5+\sqrt{29}}{\sqrt{2}}\right)^3(5\sqrt{29}+11\sqrt{6})\right.$$
$$\left.\times\left\{\sqrt{\left(\frac{9+3\sqrt{6}}{4}\right)}+\sqrt{\left(\frac{5+3\sqrt{6}}{4}\right)}\right\}^6\right].$$

The last five formulæ are correct to 15, 16, 18, 22, and 31 places of decimals respectively.

8. Thus we have seen how to approximate to π by means of logarithms of surds. I shall now show how to obtain approximations in terms of surds only. If

$$n\frac{K'}{K} = \frac{L'}{L},$$

we have

$$\frac{n\,dk}{kk'^2K^2} = \frac{dl}{ll'^2L^2}.$$

But, by means of the modular equation connecting k and l, we can express dk/dl as an algebraic function of k, a function moreover in which all coefficients which occur are algebraic numbers. Again,

$$q = e^{-\pi K'/K},\quad q^n = e^{-\pi L'/L},$$

and

$$(15)\quad \frac{q^{\frac{1}{12}}(1-q^2)(1-q^4)(1-q^6)\dots}{q^{\frac{1}{12}n}(1-q^{2n})(1-q^{4n})(1-q^{6n})\dots} = \left(\frac{kk'}{ll'}\right)^{\frac{1}{6}}\sqrt{\left(\frac{K}{L}\right)}.$$

Differentiating this equation logarithmically, and using the formula

$$\frac{dq}{dk} = \frac{\pi^2q}{2kk'^2K^2},$$

we see that

$$(16)\quad n\left\{1-24\left(\frac{q^{2n}}{1-q^{2n}}+\frac{2q^{4n}}{1-q^{4n}}+\dots\right)\right\}$$
$$-\left\{1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\dots\right)\right\} = \frac{KL}{\pi^2}A(k),$$

(1) Let AB (fig. 1) be a diameter of a circle whose centre is O.

Bisect AO at M and trisect OB at T.

Draw TP perpendicular to AB and meeting the circumference at P.

Draw a chord BQ equal to PT and join AQ.

Draw OS and TR parallel to BQ and meeting AQ at S and R respectively.

Draw a chord AD equal to AS and a tangent $AC=RS$.

Join BC, BD, and CD and draw EX, parallel to CD, meeting BC at X.

Then the square on BX is very nearly equal to the area of the circle, the error being less than a tenth of an inch when the diameter is 40 miles long.

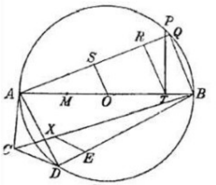

Fig. 1.

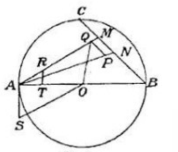

Fig. 2.

(2) Let AB (fig 2) be a diameter of a circle whose centre is O.

Bisect the arc ACB at C and trisect AO at T.

Join BC and cut off from it CM and MN equal to AT.

Join AM and AN and cut off from the latter AP equal to AM.

Through P draw PQ parallel to MN and meeting AM at Q.

Join OQ and through T draw TR, parallel to OQ, and meeting AQ at R.

Draw AS perpendicular to AO and equal to AR, and join OS.

Then the mean proportional between OS and OB will be very nearly equal to a sixth of the circumference, the error being less than a twelfth of a inch when the diameter is 8000 miles long.

13. I shall conclude this paper by giving a few series for $1/\pi$.

It is known that, when $k \leq 1/\sqrt{2}$,

$$(25)\qquad \left(\frac{2K}{\pi}\right)^2 = 1+\left(\frac{1}{2}\right)^2(2kk')^2+\left(\frac{1.3}{2.4}\right)^2(2kk')^4+\dots.$$

Hence we have

$$(26)\qquad q^{\frac{1}{3}}(1-q^2)^4(1-q^4)^4(1-q^6)^4\dots$$
$$=\left(\frac{1}{4}kk'\right)^{\frac{2}{3}}\left\{1+\left(\frac{1}{2}\right)^2(2kk')^2+\left(\frac{1.3}{2.4}\right)^2(2kk')^4+\dots\right\}.$$

Differentiating both sides in (26) logarithmically with respect to k, we can easily show that

$$(27)\qquad 1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\frac{3q^6}{1-q^6}+\dots\right)$$
$$=(1-2k^2)\left\{1+4\left(\frac{1}{2}\right)^2(2kk')^2+7\left(\frac{1.3}{2.4}\right)^2(2kk')^4+\dots\right\}.$$

But it follows from (19) that, when $q=e^{-\pi\sqrt{n}}$, n being a rational number, the left-hand side of (27) can be expressed in the form

$$A\left(\frac{2K}{\pi}\right)^2+\frac{B}{\pi},$$

where A and B are algebraic numbers expressible by surds. Combining (25) and (27) in such a way as to eliminate the term $(2K/\pi)^2$, we are left with a series for $1/\pi$. Thus, for example,

$$(28)\qquad \frac{4}{\pi}=1+\frac{7}{4}\left(\frac{1}{2}\right)^3+\frac{13}{4^2}\left(\frac{1.3}{2.4}\right)^3+\frac{19}{4^3}\left(\frac{1.3.5}{2.4.6}\right)^3+\dots,$$
$$(q=e^{-\pi\sqrt{3}},\ 2kk'=\tfrac{1}{2}),$$

$$(29)\qquad \frac{16}{\pi}=5+\frac{47}{64}\left(\frac{1}{2}\right)^3+\frac{89}{64^2}\left(\frac{1.3}{2.4}\right)^3+\frac{131}{64^3}\left(\frac{1.3.5}{2.4.6}\right)^3+\dots,$$
$$(q=e^{-\pi\sqrt{7}},\ 2kk'=\tfrac{1}{8}),$$

$$(30)\qquad \frac{32}{\pi}=(5\sqrt{5}-1)+\frac{47\sqrt{5}+29}{64}\left(\frac{1}{2}\right)^3\left(\frac{\sqrt{5}-1}{2}\right)^8+\dots,$$
$$\frac{89\sqrt{5}+59}{64^2}\left(\frac{1.3}{2.4}\right)^3\left(\frac{\sqrt{5}-1}{2}\right)^{16}+\dots,$$
$$\left[q=e^{-\pi\sqrt{15}},\ 2kk'=\frac{1}{8}\left(\frac{\sqrt{5}-1}{2}\right)^4\right];$$

here $(5\sqrt{5}-1)$, $(47\sqrt{5}+29)$, $(89\sqrt{5}+59)$, etc. are in arithmetical progression.

14. The ordinary modular equations express the relations which hold between k and l when $nK'/K=L'/L$, or $q^n=Q$, where

$$q=e^{-\pi K'/K},\quad Q=e^{-\pi L'/L},$$
$$K=1+\left(\frac{1}{2}\right)^2k^2+\left(\frac{1.3}{2.4}\right)^2k^4+\dots.$$

There are corresponding theories in which q is replaced by one or other of the functions

$$q_1=e^{-\pi K_1'\sqrt{2}/K_1},\quad q_2=e^{-2\pi K_2'/(K_2\sqrt{3})}\quad q_3=e^{-2\pi K_3'/K_3},$$

where

$$K_1=1+\frac{1.3}{4^2}k^2+\frac{1.3.5.7}{4^2.8^2}k^4+\frac{1.3.5.7.9.11}{4^2.8^2.12^2}k^6+\dots,$$
$$K_2=1+\frac{1.2}{3^2}k^2+\frac{1.2.4.5}{3^2.6^2}k^4+\frac{1.2.4.5.7.8}{3^2.6^2.9^2}k^6+\dots.$$
$$K_3=1+\frac{1.5}{6^2}k^2+\frac{1.5.7.11}{6^2.12^2}k^4+\frac{1.5.7.11.13.17}{6^2.12^2.18^2}k^6+\dots.$$

From these theories we can deduce further series for $1/\pi$, such as

$$(31)\qquad \frac{27}{4\pi}=2+17.\frac{1}{2}.\frac{1}{3}.\frac{2}{3}.\left(\frac{2}{27}\right)$$
$$+32.\frac{1.3}{2.4}.\frac{1.4}{3.6}.\frac{2.5}{3.6}.\left(\frac{2}{27}\right)^2+\dots,$$

$$(32)\qquad \frac{15\sqrt{3}}{2\pi}=4+37.\frac{1}{2}.\frac{1}{3}.\frac{2}{3}.\left(\frac{4}{125}\right)$$
$$+70.\frac{1.3}{2.4}.\frac{1.4}{3.6}.\frac{2.5}{3.6}.\left(\frac{4}{125}\right)^2+\dots,$$

$$(33)\qquad \frac{5\sqrt{5}}{2\pi\sqrt{3}}=1+12.\frac{1}{2}.\frac{1}{6}.\frac{5}{6}.\left(\frac{4}{125}\right)$$
$$+23.\frac{1.3}{2.4}.\frac{1.7}{6.12}.\frac{5.11}{6.12}.\left(\frac{4}{125}\right)^2+\dots,$$

$$(34)\qquad \frac{85\sqrt{85}}{18\pi\sqrt{3}}=8+141.\frac{1}{2}.\frac{1}{6}.\frac{5}{6}.\left(\frac{4}{85}\right)^3$$
$$+274.\frac{1.3}{2.4}.\frac{1.7}{6.12}.\frac{5.11}{6.12}.\left(\frac{4}{85}\right)^6+\dots,$$

$$(35)\qquad \frac{4}{\pi}=\frac{3}{2}-\frac{23}{2^3}.\frac{1}{2}.\frac{1.3}{4^2}+\frac{43}{2^6}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}-\dots,$$

$$(36)\qquad \frac{4}{\pi\sqrt{3}}=\frac{3}{4}-\frac{31}{3.4^3}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{59}{3^2.4^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}-\dots,$$

$$(37)\qquad \frac{4}{\pi}=\frac{23}{18}-\frac{283}{18^3}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{543}{18^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}-\dots,$$

$$(38)\qquad \frac{4}{\pi\sqrt{5}}=\frac{41}{72}-\frac{685}{5.72^3}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{1329}{5^2.72^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}-\dots,$$

$$(39)\qquad \frac{4}{\pi}=\frac{1123}{882}-\frac{22583}{882^3}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{44043}{882^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}-\dots,$$

$$(40)\qquad \frac{2\sqrt{3}}{\pi}=1+\frac{9}{9}.\frac{1}{2}.\frac{1.3}{4^2}+\frac{17}{9^2}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}+\dots,$$

$$(41)\qquad \frac{1}{2\pi\sqrt{2}}=\frac{1}{9}+\frac{11}{9^3}.\frac{1}{2}.\frac{1.3}{4^2}+\frac{21}{9^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}+\dots,$$

$$(42)\qquad \frac{1}{3\pi\sqrt{3}}=\frac{3}{49}+\frac{43}{49^3}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{83}{49^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}+\dots,$$

$$(43)\qquad \frac{2}{\pi\sqrt{11}}=\frac{19}{99}+\frac{299}{99^3}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{579}{99^5}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}+\dots,$$

$$(44)\qquad \frac{1}{2\pi\sqrt{2}}=\frac{1103}{99^2}+\frac{27493}{99^6}.\frac{1}{2}.\frac{1.3}{4^2}$$
$$+\frac{53883}{99^{10}}.\frac{1.3}{2.4}.\frac{1.3.5.7}{4^2.8^2}+\dots.$$

In all these series the first factors in each term form an arithmetical progression; *e.g.*, 2, 17, 32, 47, ..., in (31), and 4, 37, 70, 103, ..., in (32). The first two series belong to the theory of q_2, the next two to that of q_3, and the rest to that of q_1.

The last series (44) is extremely convergent. Thus, taking only the first term, we see that

$$\frac{1103}{99^2}=.11253953678\dots,$$
$$\frac{1}{2\pi\sqrt{2}}=.11253953951\dots.$$

15. In concluding this paper I have to remark that the series

$$1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\frac{3q^6}{1-q^6}+\dots\right),$$

which has been discussed in §§ 8–13, is very closely connected with the perimeter of an ellipse whose eccentricity is k. For, if a and b be the semi-major and the semi-minor axes, it is known that

$$(45)\qquad p=2\pi a\left\{1-\frac{1}{2^2}k^2-\frac{1^2.3}{2^2.4^2}k^4-\frac{1^2.3^2.5}{2^2.4^2.6^2}k^6-\dots\right\},$$

where p is the perimeter and k the eccentricity. It can easily be seen from (45) that

$$(46)\qquad p=4ak'^2\left\{K+k\frac{dK}{dk}\right\}.$$

But, taking the equation

$$q^{\frac{1}{12}}(1-q^2)(1-q^4)(1-q^6)\dots=(2kk')^{\frac{1}{6}}\sqrt{(K/\pi)},$$

and differentiating both sides logarithmically with respect to k, and combining the result with (46) in such a way as to eliminate dK/dk, we can show that

$$(47)\qquad p=\frac{4a}{3K}\left[K^2(1+k'^2)+(\tfrac{1}{2}\pi)^2\right.$$
$$\left.\times\left\{1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\dots\right)\right\}\right].$$

But we have shown already that the right-hand side of (47) can be expressed in terms of K if $q=e^{-\pi\sqrt{n}}$, where n is any rational number. It can also be shown that K can be expressed in terms of Γ-functions if q be of the forms $e^{-\pi n}$, $e^{-\pi n\sqrt{2}}$ and $e^{-\pi n\sqrt{3}}$, where n is rational. Thus, for example, we have

$$(48)\qquad \begin{cases} k=\sin\dfrac{\pi}{4},\quad q=e^{-\pi}, \\ \qquad p=a\sqrt{\left(\dfrac{\pi}{2}\right)}\left\{\dfrac{\Gamma(\frac{1}{4})}{\Gamma(\frac{3}{4})}+\dfrac{\Gamma(\frac{3}{4})}{\Gamma(\frac{5}{4})}\right\}, \\ k=\tan\dfrac{\pi}{8},\quad q=e^{-\pi\sqrt{2}}, \\ \qquad p=a\sqrt{\left(\dfrac{\pi}{4}\right)}\left\{\dfrac{\Gamma(\frac{1}{8})}{\Gamma(\frac{5}{8})}+\dfrac{\Gamma(\frac{5}{8})}{\Gamma(\frac{9}{8})}\right\}, \\ k=\sin\dfrac{\pi}{12},\quad q=e^{-\pi\sqrt{3}}, \\ \qquad p=a\sqrt{\left(\dfrac{\pi}{\sqrt{3}}\right)}\left\{\left(1+\dfrac{1}{\sqrt{3}}\right)\dfrac{\Gamma(\frac{1}{3})}{\Gamma(\frac{5}{6})}+2\dfrac{\Gamma(\frac{5}{6})}{\Gamma(\frac{1}{3})}\right\}, \\ \dfrac{b}{a}=\tan^2\dfrac{\pi}{8},\quad q=e^{-2\pi}, \\ \qquad p=(a+b)\sqrt{\left(\dfrac{\pi}{2}\right)}\left\{\dfrac{1}{2}\dfrac{\Gamma(\frac{1}{4})}{\Gamma(\frac{3}{4})}+\dfrac{\Gamma(\frac{3}{4})}{\Gamma(\frac{5}{4})}\right\}, \end{cases}$$

and so on.

16. The following approximations for p were obtained empirically :—

$$(49)\qquad p=\pi[3(a+b)-\sqrt{\{(a+3b)(3a+b)\}}+\epsilon],$$

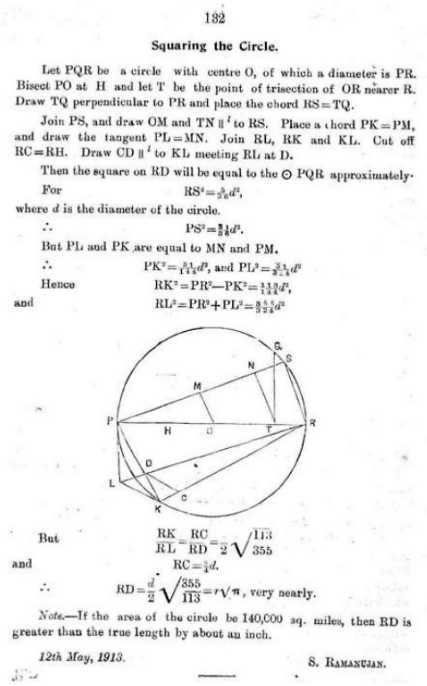
where ϵ is about $ak^{12}/1048576$;

$$(50)\qquad p=\pi\left\{(a+b)+\frac{3(a-b)^2}{10(a+b)+\sqrt{(a^2+14ab+b^2)}}+\epsilon\right\},$$

where ϵ is about $3ak^{20}/68719476736$.

Squaring the Circle

https://www.imsc.res.in/~rao/ramanujan/collectedpapers/squaring/squaring.htm



Squaring the Circle.

Let PQR be a circle with centre O, of which a diameter is PR. Bisect PO at H and let T be the point of trisection of OR nearer R. Draw TQ perpendicular to PR and place the chord RS = TQ.

Join PS, and draw OM and TN $\|^l$ to RS. Place a chord PK = PM, and draw the tangent PL = MN. Join RL, RK and KL. Cut off RC = RH. Draw CD $\|^l$ to KL meeting RL at D.

Then the square on RD will be equal to the ⊙ PQR approximately.

For $$RS^2 = \tfrac{5}{36}d^2,$$

where d is the diameter of the circle.

$$\therefore \quad PS^2 = \tfrac{31}{36}d^2.$$

But PL and PK are equal to MN and PM.

$$\therefore \quad PK^2 = \tfrac{31}{144}d^2, \text{ and } PL^2 = \tfrac{31}{324}d^2$$

Hence $$RK^2 = PR^2 - PK^2 = \tfrac{113}{144}d^2,$$

and $$RL^2 = PR^2 + PL^2 = \tfrac{355}{324}d^2$$

But $$\frac{RK}{RL} = \frac{RC}{RD} = \frac{3}{2}\sqrt{\frac{113}{355}}$$

and $$RC = \tfrac{3}{4}d.$$

$$\therefore \quad RD = \frac{d}{2}\sqrt{\frac{355}{113}} = r\sqrt{\pi}, \text{ very nearly.}$$

Note.—If the area of the circle be 140,000 sq. miles, then RD is greater than the true length by about an inch.

MODULAR EQUATIONS AND APPROXIMATIONS TO π

(*Quarterly Journal of Mathematics*, XLV, 1914, 350—372)

1. If we suppose that

$$(1+e^{-\pi\sqrt{n}})(1+e^{-3\pi\sqrt{n}})(1+e^{-5\pi\sqrt{n}})\ldots=2^{\frac14}e^{-\pi\sqrt{n}/24}G_n \quad\ldots\ldots\ldots(1)$$

and

$$(1-e^{-\pi\sqrt{n}})(1-e^{-3\pi\sqrt{n}})(1-e^{-5\pi\sqrt{n}})\ldots=2^{\frac14}e^{-\pi\sqrt{n}/24}g_n, \quad\ldots\ldots\ldots(2)$$

then G_n and g_n can always be expressed as roots of algebraical equations when n is any rational number. For we know that

$$(1+q)(1+q^3)(1+q^5)\ldots=2^{\frac16}q^{\frac1{24}}(kk')^{-\frac1{12}} \quad\ldots\ldots\ldots\ldots\ldots(3)$$

and

$$(1-q)(1-q^3)(1-q^5)\ldots=2^{\frac16}q^{\frac1{24}}k^{-\frac1{12}}k'^{\frac16}. \quad\ldots\ldots\ldots\ldots\ldots(4)$$

Now the relation between the moduli k and l, which makes

$$n\frac{K'}{K}=\frac{L'}{L},$$

where $n=r/s$, r and s being positive integers, is expressed by the modular equation of the rsth degree. If we suppose that $k=l'$, $k'=l$, so that $K=L'$, $K'=L$, then

$$q=e^{-\pi L'/L}=e^{-\pi\sqrt{n}},$$

and the corresponding value of k may be found by the solution of an algebraical equation.

From (1), (2), (3), and (4) it may easily be deduced that

$$g_{4n}=2^{\frac14}g_nG_n, \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

$$G_n=G_{1/n},\quad 1/g_n=g_{4/n}, \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6)$$

$$(g_nG_n)^8(G_n^8-g_n^8)=\tfrac14. \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

I shall consider only integral values of n. It follows from (7) that we need consider only one of G_n or g_n for any given value of n; and from (5) that we may suppose n not divisible by 4. It is most convenient to consider g_n when n is even, and G_n when n is odd.

2. Suppose then that n is odd. The values of G_n and g_{4n} are got from the same modular equation. For example, let us take the modular equation of the 5th degree, viz.

$$\left(\frac{u}{v}\right)^3+\left(\frac{v}{u}\right)^3=2\left(u^2v^2-\frac{1}{u^2v^2}\right), \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(8)$$

where

$$2^{\frac14}q^{\frac1{24}}u=(1+q)(1+q^3)(1+q^5)\ldots$$

and

$$2^{\frac14}q^{\frac5{24}}v=(1+q^5)(1+q^{15})(1+q^{25})\ldots.$$

By changing q to $-q$ the above equation may also be written as

$$\left(\frac{v}{u}\right)^3-\left(\frac{u}{v}\right)^3=2\left(u^2v^2+\frac{1}{u^2v^2}\right), \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(9)$$

where

$$2^{\frac14}q^{\frac1{24}}u=(1-q)(1-q^3)(1-q^5)\ldots$$

and

$$2^{\frac14}q^{\frac5{24}}v=(1-q^5)(1-q^{15})(1-q^{25})\ldots.$$

If we put $q=e^{-\pi/\sqrt5}$ in (8), so that $u=G_{\frac15}$ and $v=G_5$, and hence $u=v$, we see that

$$v^4-v^{-4}=1.$$

Hence

$$v^4=\frac{1+\sqrt5}{2},\quad G_5=\left(\frac{1+\sqrt5}{2}\right)^{\frac14}.$$

Similarly, by putting $q=e^{-\pi\sqrt{\frac25}}$, so that $u=g_{\frac25}$ and $v=g_{10}$, and hence $u=1/v$, we see that

$$v^6-v^{-6}=4.$$

Hence

$$v^2=\frac{1+\sqrt5}{2},\quad g_{10}=\sqrt{\left(\frac{1+\sqrt5}{2}\right)}.$$

Similarly it can be shewn that

$$G_9=\left(\frac{1+\sqrt3}{\sqrt2}\right)^{\frac13},\quad g_{18}=(\sqrt2+\sqrt3)^{\frac13},$$

$$G_{17}=\sqrt{\left(\frac{5+\sqrt{17}}{8}\right)}+\sqrt{\left(\frac{\sqrt{17}-3}{8}\right)},$$

$$g_{34}=\sqrt{\left(\frac{7+\sqrt{17}}{8}\right)}+\sqrt{\left(\frac{\sqrt{17}-1}{8}\right)},$$

and so on.

3. In order to obtain approximations for π we take logarithms of (1) and (2). Thus

$$\left.\begin{aligned}\pi&=\frac{24}{\sqrt n}\log(2^{\frac14}G_n)\\ \pi&=\frac{24}{\sqrt n}\log(2^{\frac14}g_n)\end{aligned}\right\}, \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(10)$$

approximately, the error being nearly $\frac{24}{\sqrt n}e^{-\pi\sqrt n}$ in both cases. These equations may also be written as

$$e^{\pi\sqrt{n}/24}=2^{\frac14}G_n,\quad e^{\pi\sqrt{n}/24}=2^{\frac14}g_n. \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(11)$$

In those cases in which G_n^{12} and g_n^{12} are simple quadratic surds we may use the forms

$$(G_n^{12}+G_n^{-12})^{\frac1{12}},\quad (g_n^{12}+g_n^{-12})^{\frac1{12}},$$

instead of G_n and g_n, for we have

$$g_n^{12}=\tfrac18e^{\frac12\pi\sqrt n}-\tfrac32e^{-\frac12\pi\sqrt n},$$

approximately, and so

$$g_n^{12}+g_n^{-12}=\tfrac18e^{\frac12\pi\sqrt n}+\tfrac{13}{2}e^{-\frac12\pi\sqrt n},$$

approximately, so that

$$\pi = \frac{2}{\sqrt{n}} \log \{8(g_n^{12}+g_n^{-12})\}, \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(12)$$

the error being about $\frac{104}{\sqrt{n}}e^{-\pi\sqrt{n}}$, which is of the same order as the error in the formulæ (10). The formula (12) often leads to simpler results. Thus the second of formulae (10) gives

$$e^{\pi\sqrt{18}/24} = 2^{\frac14} g_{18}$$

or

$$e^{\frac14\pi\sqrt{18}} = 10\sqrt2 + 8\sqrt3.$$

But if we use the formula (12), or

$$e^{\pi\sqrt{n}/24} = 2^{\frac14}(g_n^{12}+g_n^{-12})^{\frac{1}{12}},$$

we get a simpler form, viz.

$$e^{\frac18\pi\sqrt{18}} = 2\sqrt7.$$

4. The values of g_{2n} and G_n are obtained from the same equation. The approximation by means of g_{2n} is preferable to that by G_n for the following reasons.

(*a*) It is more accurate. Thus the error when we use G_{65} contains a factor $e^{-\pi\sqrt{65}}$, whereas that when we use g_{130} contains a factor $e^{-\pi\sqrt{130}}$.

(*b*) For many values of n, g_{2n} is simpler in form than G_n; thus

$$g_{130} = \sqrt{\left\{(2+\sqrt5)\left(\frac{3+\sqrt{13}}{2}\right)\right\}},$$

while

$$G_{65} = \left\{\left(\frac{1+\sqrt5}{2}\right)\left(\frac{3+\sqrt{13}}{2}\right)\right\}^{\frac14} \sqrt{\left\{\sqrt{\left(\frac{9+\sqrt{65}}{8}\right)} + \sqrt{\left(\frac{1+\sqrt{65}}{8}\right)}\right\}}.$$

(*c*) For many values of n, g_{2n} involves quadratic surds only, even when G_n is a root of an equation of higher order. Thus G_{23}, G_{29}, G_{31} are roots of cubic equations, G_{47}, G_{79} are those of quintic equations, and G_{71} is that of a septic equation, while g_{46}, g_{58}, g_{62}, g_{94}, g_{142}, and g_{158} are all expressible by quadratic surds.

5. Since G_n and g_n can be expressed as roots of algebraical equations with rational coefficients, the same is true of G_n^{24} or g_n^{24}. So let us suppose that

$$1 = ag_n^{-24} - bg_n^{-48} + \ldots,$$

or

$$g_n^{24} = a - bg_n^{-24} + \ldots.$$

But we know that

$$64e^{-\pi\sqrt{n}}g_n^{24} = 1 - 24e^{-\pi\sqrt{n}} + 276e^{-2\pi\sqrt{n}} - \ldots,$$

$$64g_n^{24} = e^{\pi\sqrt{n}} - 24 + 276e^{-\pi\sqrt{n}} - \ldots,$$

$$64a - 64bg_n^{-24} + \ldots = e^{\pi\sqrt{n}} - 24 + 276e^{-\pi\sqrt{n}} - \ldots,$$

$$64a - 4096be^{-\pi\sqrt{n}} + \ldots = e^{\pi\sqrt{n}} - 24 + 276e^{-\pi\sqrt{n}} - \ldots,$$

that is

$$e^{\pi\sqrt{n}} = (64a+24) - (4096b+276)e^{-\pi\sqrt{n}} + \ldots. \quad \ldots\ldots\ldots(13)$$

Similarly, if

$$1 = aG_n^{-24} - bG_n^{-48} + \ldots,$$

then

$$e^{\pi\sqrt{n}} = (64a-24) - (4096b+276)e^{-\pi\sqrt{n}} + \ldots. \quad \ldots\ldots\ldots(14)$$

From (13) and (14) we can find whether $e^{\pi\sqrt{n}}$ is very nearly an integer for given values of n, and ascertain also the number of 9's or 0's in the decimal part. But if G_n and g_n be simple quadratic surds we may work independently as follows. We have, for example,

$$g_{22} = \sqrt{(1+\sqrt2)}.$$

Hence

$$64g_{22}^{24} = e^{\pi\sqrt{22}} - 24 + 276e^{-\pi\sqrt{22}} - \ldots,$$

$$64g_{22}^{-24} = 4096e^{-\pi\sqrt{22}} + \ldots,$$

so that

$$64(g_{22}^{24}+g_{22}^{-24}) = e^{\pi\sqrt{22}} - 24 + 4372e^{-\pi\sqrt{22}} + \ldots = 64[(1+\sqrt2)^{12} + (1-\sqrt2)^{12}].$$

Hence

$$e^{\pi\sqrt{22}} = 2508951{\cdot}9982\ldots.$$

Again

$$G_{37} = (6+\sqrt{37})^{\frac14},$$

$$64G_{37}^{24} = e^{\pi\sqrt{37}} + 24 + 276e^{-\pi\sqrt{37}} + \ldots,$$

$$64G_{37}^{-24} = 4096e^{-\pi\sqrt{37}} - \ldots,$$

so that

$$64(G_{37}^{24}+G_{37}^{-24}) = e^{\pi\sqrt{37}} + 24 + 4372e^{-\pi\sqrt{37}} - \ldots = 64[(6+\sqrt{37})^6 + (6-\sqrt{37})^6].$$

Hence

$$e^{\pi\sqrt{37}} = 199148647{\cdot}999978\ldots.$$

Similarly, from

$$g_{58} = \sqrt{\left(\frac{5+\sqrt{29}}{2}\right)},$$

we obtain

$$64(g_{58}^{24}+g_{58}^{-24}) = e^{\pi\sqrt{58}} - 24 + 4372e^{-\pi\sqrt{58}} + \ldots$$
$$= 64\left\{\left(\frac{5+\sqrt{29}}{2}\right)^{12} + \left(\frac{5-\sqrt{29}}{2}\right)^{12}\right\}.$$

Hence

$$e^{\pi\sqrt{58}} = 24591257751{\cdot}99999982\ldots.$$

6. I have calculated the values of G_n and g_n for a large number of values of n. Many of these results are equivalent to results given by Weber; for example,

$$G_{13}^4 = \frac{3+\sqrt{13}}{2}, \qquad G_{25} = \frac{1+\sqrt5}{2},$$

$$g_{30}^6 = (2+\sqrt5)(3+\sqrt{10}), \qquad G_{37}^4 = 6+\sqrt{37},$$

$$G_{49} = \frac{7^{\frac14}+\sqrt{(4+\sqrt7)}}{2}, \qquad g_{58}^2 = \frac{5+\sqrt{29}}{2},$$

$$g_{70}^2 = \frac{(3+\sqrt5)(1+\sqrt2)}{2},$$

$$G_{73} = \sqrt{\left(\frac{9+\sqrt{73}}{8}\right)} + \sqrt{\left(\frac{1+\sqrt{73}}{8}\right)},$$

$$G_{85} = \left(\frac{1+\sqrt5}{2}\right)\left(\frac{9+\sqrt{85}}{2}\right)^{\frac14},$$

$$G_{97} = \sqrt{\left(\frac{13+\sqrt{97}}{8}\right)} + \sqrt{\left(\frac{5+\sqrt{97}}{8}\right)},$$

$$g_{190}^2 = (2+\sqrt5)(3+\sqrt{10}),$$

$$G_{385}^2 = \tfrac18(3+\sqrt{11})(\sqrt5+\sqrt7)(\sqrt7+\sqrt{11})(3+\sqrt5),$$

and so on. I have also many results not given by Weber. I give a complete table of new results. In Weber's notation, $G_n = 2^{-\frac14}f\{\sqrt{(-n)}\}$ and $g_n = 2^{-\frac14}f_1\{\sqrt{(-n)}\}$.

TABLE I.

$$g_{62} + \frac{1}{g_{62}} = \tfrac12\{\sqrt{(1+\sqrt2)} + \sqrt{(9+5\sqrt2)}\},$$

$$G_{65}^2 = \sqrt{\left\{\left(\frac{1+\sqrt5}{2}\right)\left(\frac{3+\sqrt{13}}{2}\right)\right\}}\left\{\sqrt{\left(\frac{1+\sqrt{65}}{8}\right)} + \sqrt{\left(\frac{9+\sqrt{65}}{8}\right)}\right\},$$

$$g_{66}^2 = \sqrt{(\sqrt2+\sqrt3)}(7\sqrt2+3\sqrt{11})^{\frac16}\left\{\sqrt{\left(\frac{7+\sqrt{33}}{8}\right)} + \sqrt{\left(\frac{\sqrt{33}-1}{8}\right)}\right\},$$

$$G_{69}^2 = (3\sqrt3+\sqrt{23})^{\frac14}\left(\frac{5+\sqrt{23}}{4}\right)^{\frac16}\left\{\sqrt{\left(\frac{6+3\sqrt3}{4}\right)} + \sqrt{\left(\frac{2+3\sqrt3}{4}\right)}\right\},$$

$$G_{77}^2 = \{\tfrac12(\sqrt7+\sqrt{11})(8+3\sqrt7)\}^{\frac14}\left\{\sqrt{\left(\frac{6+\sqrt{11}}{4}\right)} + \sqrt{\left(\frac{2+\sqrt{11}}{4}\right)}\right\},$$

$$G_{81}^3 = \frac{(2\sqrt3+2)^{\frac13}+1}{(2\sqrt3-2)^{\frac13}-1},$$

$$g_{90} = \{(2+\sqrt5)(\sqrt5+\sqrt6)\}^{\frac16}\left\{\sqrt{\left(\frac{3+\sqrt6}{4}\right)} + \sqrt{\left(\frac{\sqrt6-1}{4}\right)}\right\},$$

$$g_{94} + \frac{1}{g_{94}} = \tfrac12\{\sqrt{(7+\sqrt2)} + \sqrt{(7+5\sqrt2)}\},$$

$$g_{98} + \frac{1}{g_{98}} = \tfrac12\{\sqrt2 + \sqrt{(14+4\sqrt{14})}\},$$

$$g_{114}^2 = \sqrt{(\sqrt2+\sqrt3)}(3\sqrt2+\sqrt{19})^{\frac16}\left\{\sqrt{\left(\frac{23+3\sqrt{57}}{8}\right)} + \sqrt{\left(\frac{15+3\sqrt{57}}{8}\right)}\right\},$$

$$G_{117} = \tfrac12\left(\frac{3+\sqrt{13}}{2}\right)^{\frac14}(2\sqrt3+\sqrt{13})^{\frac16}\{3^{\frac14} + \sqrt{(4+\sqrt3)}\},$$

$$\left.\begin{aligned} G_{121} + \frac{1}{G_{121}} &= \left(\frac{11}{2}\right)^{\frac16}\left\{\left(3+\frac{1}{3\sqrt3}\right)^{\frac13} + \left(3-\frac{1}{3\sqrt3}\right)^{\frac13}\right\} \\ \frac{1}{G_{121}} &= \frac{1}{3\sqrt2}[(11-3\sqrt{11})^{\frac13}\{(3\sqrt{11}+3\sqrt3-4)^{\frac13} \\ &\qquad + (3\sqrt{11}-3\sqrt3-4)^{\frac13}\} - 2] \end{aligned}\right\},$$

$$g_{126} = \sqrt{\left(\frac{\sqrt3+\sqrt7}{2}\right)}(\sqrt6+\sqrt7)^{\frac16}\left\{\sqrt{\left(\frac{3+\sqrt2}{4}\right)} + \sqrt{\left(\frac{\sqrt2-1}{4}\right)}\right\}^2,$$

$$g_{138}^2 = \sqrt{\left(\frac{3\sqrt3+\sqrt{23}}{2}\right)}(78\sqrt2+23\sqrt{23})^{\frac16}$$
$$\times\left\{\sqrt{\left(\frac{5+2\sqrt6}{4}\right)} + \sqrt{\left(\frac{1+2\sqrt6}{4}\right)}\right\},$$

$$G_{141}^2 = (4\sqrt3+\sqrt{47})^{\frac14}\left(\frac{7+\sqrt{47}}{\sqrt2}\right)^{\frac16}\left\{\sqrt{\left(\frac{18+9\sqrt3}{4}\right)} + \sqrt{\left(\frac{14+9\sqrt3}{4}\right)}\right\},$$

$$G_{145}^2 = \sqrt{\left\{\frac{(2+\sqrt5)(5+\sqrt{29})}{2}\right\}}\left\{\sqrt{\left(\frac{17+\sqrt{145}}{8}\right)} + \sqrt{\left(\frac{9+\sqrt{145}}{8}\right)}\right\},$$

$$\frac{1}{G_{147}} = 2^{-\frac{1}{12}}\left[\frac12 + \frac{1}{\sqrt3}\left\{\sqrt{\left(\frac74\right)} - (28)^{\frac16}\right\}\right],$$

$$G_{153} = \left\{\sqrt{\left(\frac{5+\sqrt{17}}{8}\right)} + \sqrt{\left(\frac{\sqrt{17}-3}{8}\right)}\right\}^2$$
$$\times\left\{\sqrt{\left(\frac{37+9\sqrt{17}}{4}\right)} + \sqrt{\left(\frac{33+9\sqrt{17}}{4}\right)}\right\}^{\frac13},$$

$$g_{154}^2 = \sqrt{\left\{(2\sqrt2+\sqrt7)\left(\frac{\sqrt7+\sqrt{11}}{2}\right)\right\}}$$
$$\times\left\{\sqrt{\left(\frac{13+2\sqrt{22}}{4}\right)} + \sqrt{\left(\frac{9+2\sqrt{22}}{4}\right)}\right\},$$

$$g_{158} + \frac{1}{g_{158}} = \tfrac12\{\sqrt{(9+\sqrt2)} + \sqrt{(17+13\sqrt2)}\},$$

$$\left.\begin{aligned} G_{169} + \frac{1}{G_{169}} &= \left(\frac{13}{4}\right)^{\frac16}\left\{\left(1+\frac{1}{3\sqrt3}\right)^{\frac13} + \left(1-\frac{1}{3\sqrt3}\right)^{\frac13}\right\}^2 \\ \frac{1}{G_{169}} &= \frac13\left[(\sqrt{13}-2) + \left(\frac{13-3\sqrt{13}}{2}\right)^{\frac13}\right. \\ &\qquad \left.\times\left\{\left(3\sqrt3-\frac{11-\sqrt{13}}{2}\right)^{\frac13} - \left(3\sqrt3+\frac{11-\sqrt{13}}{2}\right)^{\frac13}\right\}\right] \end{aligned}\right\},$$

$$g_{198} = \sqrt{(1+\sqrt2)}(4\sqrt2+\sqrt{33})^{\frac16}\left\{\sqrt{\left(\frac{9+\sqrt{33}}{8}\right)} + \sqrt{\left(\frac{1+\sqrt{33}}{8}\right)}\right\},$$

$$G_{205} = \left(\frac{1+\sqrt5}{2}\right)\left(\frac{3\sqrt5+\sqrt{41}}{2}\right)^{\frac14}\left\{\sqrt{\left(\frac{7+\sqrt{41}}{8}\right)} + \sqrt{\left(\frac{\sqrt{41}-1}{8}\right)}\right\},$$

$$G_{213}^2 = (5\sqrt3+\sqrt{71})^{\frac14}\left(\frac{59+7\sqrt{71}}{4}\right)^{\frac16}$$
$$\times\left\{\sqrt{\left(\frac{21+12\sqrt3}{2}\right)} + \sqrt{\left(\frac{19+12\sqrt3}{2}\right)}\right\},$$

$$G_{217}^2 = \left\{\sqrt{\left(\frac{9+4\sqrt7}{2}\right)} + \sqrt{\left(\frac{11+4\sqrt7}{2}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{12+5\sqrt7}{4}\right)} + \sqrt{\left(\frac{16+5\sqrt7}{4}\right)}\right\},$$

$$G_{225} = \left(\frac{1+\sqrt5}{4}\right)(2+\sqrt3)^{\frac13}\{\sqrt{(4+\sqrt{15})} + 15^{\frac14}\},$$

$$g_{238}=\left\{\sqrt{\left(\frac{1+2\sqrt2}{4}\right)}+\sqrt{\left(\frac{5+2\sqrt2}{4}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{1+3\sqrt2}{4}\right)}+\sqrt{\left(\frac{5+3\sqrt2}{4}\right)}\right\},$$

$$G_{265}^2=\sqrt{\left\{(2+\sqrt5)\left(\frac{7+\sqrt{53}}{2}\right)\right\}}\left\{\sqrt{\left(\frac{89+5\sqrt{265}}{8}\right)}+\sqrt{\left(\frac{81+5\sqrt{265}}{8}\right)}\right\},$$

$$G_{289}=\left[\sqrt{\left\{\frac{17+\sqrt{17}+17^{\frac14}(5+\sqrt{17})}{16}\right\}}+\sqrt{\left\{\frac{1+\sqrt{17}+17^{\frac14}(5+\sqrt{17})}{16}\right\}}\right]^2,$$

$$G_{301}^2=\left\{(8+3\sqrt7)\left(\frac{23\sqrt{43}+57\sqrt7}{2}\right)\right\}^{\frac14}$$
$$\times\left\{\sqrt{\left(\frac{46+7\sqrt{43}}{4}\right)}+\sqrt{\left(\frac{42+7\sqrt{43}}{4}\right)}\right\},$$

$$g_{310}=\left(\frac{1+\sqrt5}{2}\right)\sqrt{(1+\sqrt2)}\left\{\sqrt{\left(\frac{7+2\sqrt{10}}{4}\right)}+\sqrt{\left(\frac{3+2\sqrt{10}}{4}\right)}\right\},$$

$$\left.\begin{aligned}G_{325}&=\left(\frac{3+\sqrt{13}}{2}\right)^{\frac14}t,\text{ where}\\ &t^3+t^2\left(\frac{1-\sqrt{13}}{2}\right)^2+t\left(\frac{1+\sqrt{13}}{2}\right)^2+1\\ &\qquad=\sqrt5\left\{t^3-t^2\left(\frac{1+\sqrt{13}}{2}\right)+t\left(\frac{1-\sqrt{13}}{2}\right)-1\right\}\end{aligned}\right\},$$

$$G_{333}=\tfrac12(6+\sqrt{37})^{\frac14}(7\sqrt3+2\sqrt{37})^{\frac16}\{\sqrt{(7+2\sqrt3)}+\sqrt{(3+2\sqrt3)}\},$$

$$\left.\begin{aligned}G_{363}&=2^{\frac1{12}}t,\text{ where}\\ &2t^3-t^2\{(4+\sqrt{33})+\sqrt{(11+2\sqrt{33})}\}\\ &\qquad-t\{1+\sqrt{(11+2\sqrt{33})}\}-1=0\end{aligned}\right\},$$

$$G_{441}^2=\left(\frac{\sqrt3+\sqrt7}{2}\right)(2+\sqrt3)^{\frac13}\left\{\frac{2+\sqrt7+\sqrt{(7+4\sqrt7)}}{2}\right\}\left\{\frac{\sqrt{(3+\sqrt7)}+(6\sqrt7)^{\frac14}}{\sqrt{(3+\sqrt7)}-(6\sqrt7)^{\frac14}}\right\},$$

$$G_{445}=\sqrt{(2+\sqrt5)}\left(\frac{21+\sqrt{445}}{2}\right)^{\frac14}\sqrt{\Big\{\Big(\frac{13+\sqrt{89}}{8}\Big)}+\sqrt{\left(\frac{5+\sqrt{89}}{8}\right)}\Big\},$$

$$G_{465}^2=\sqrt{\left\{(2+\sqrt3)\left(\frac{1+\sqrt5}{2}\right)\left(\frac{3\sqrt3+\sqrt{31}}{2}\right)\right\}}(5\sqrt5+2\sqrt{31})^{\frac16}$$
$$\times\left\{\sqrt{\left(\frac{2+\sqrt{31}}{4}\right)}+\sqrt{\left(\frac{6+\sqrt{31}}{4}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{11+2\sqrt{31}}{2}\right)}+\sqrt{\left(\frac{13+2\sqrt{31}}{2}\right)}\right\},$$

$$G_{505}^2=(2+\sqrt5)\sqrt{\left\{\left(\frac{1+\sqrt5}{2}\right)(10+\sqrt{101})\right\}}$$
$$\times\left\{\left(\frac{5\sqrt5+\sqrt{101}}{4}\right)+\sqrt{\left(\frac{105+\sqrt{505}}{8}\right)}\right\},$$

$$g_{522}=\sqrt{\left(\frac{5+\sqrt{29}}{2}\right)}(5\sqrt{29}+11\sqrt6)^{\frac16}\left\{\sqrt{\left(\frac{9+3\sqrt6}{4}\right)}+\sqrt{\left(\frac{5+3\sqrt6}{4}\right)}\right\},$$

$$G_{553}^2=\left\{\sqrt{\left(\frac{96+11\sqrt{79}}{4}\right)}+\sqrt{\left(\frac{100+11\sqrt{79}}{4}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{141+16\sqrt{79}}{2}\right)}+\sqrt{\left(\frac{143+16\sqrt{79}}{2}\right)}\right\},$$

$$g_{630}=(\sqrt{14}+\sqrt{15})^{\frac16}\sqrt{\left\{(1+\sqrt2)\left(\frac{3+\sqrt5}{2}\right)\left(\frac{\sqrt3+\sqrt7}{2}\right)\right\}}$$
$$\times\left\{\sqrt{\left(\frac{\sqrt{15}+\sqrt7+2}{4}\right)}+\sqrt{\left(\frac{\sqrt{15}+\sqrt7-2}{4}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{\sqrt{15}+\sqrt7+4}{8}\right)}+\sqrt{\left(\frac{\sqrt{15}+\sqrt7-4}{8}\right)}\right\},$$

$$G_{765}^2=\left(\frac{3+\sqrt5}{2}\right)(16+\sqrt{255})^{\frac16}\sqrt{\left\{(4+\sqrt{15})\left(\frac{9+\sqrt{85}}{2}\right)\right\}}$$
$$\times\left\{\sqrt{\left(\frac{6+\sqrt{51}}{4}\right)}+\sqrt{\left(\frac{10+\sqrt{51}}{4}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{18+3\sqrt{51}}{4}\right)}+\sqrt{\left(\frac{22+3\sqrt{51}}{4}\right)}\right\},$$

$$G_{777}^2=\sqrt{\left\{(2+\sqrt3)(6+\sqrt{37})\left(\frac{\sqrt3+\sqrt7}{2}\right)\right\}}(246\sqrt7+107\sqrt{37})^{\frac16}$$
$$\times\left\{\sqrt{\left(\frac{6+3\sqrt7}{4}\right)}+\sqrt{\left(\frac{10+3\sqrt7}{4}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{15+6\sqrt7}{2}\right)}+\sqrt{\left(\frac{17+6\sqrt7}{2}\right)}\right\},$$

$$G_{1225}=\left(\frac{1+\sqrt5}{2}\right)(6+\sqrt{35})^{\frac14}\left\{\frac{7^{\frac14}+\sqrt{(4+\sqrt7)}}{2}\right\}^{\frac32}$$
$$\times\left[\sqrt{\left\{\frac{43+15\sqrt7+(8+3\sqrt7)\sqrt{(10\sqrt7)}}{8}\right\}}\right.$$
$$\left.+\sqrt{\left\{\frac{35+15\sqrt7+(8+3\sqrt7)\sqrt{(10\sqrt7)}}{8}\right\}}\right],$$

$$G_{1353}^2=\sqrt{\left\{(3+\sqrt{11})(5+3\sqrt3)\left(\frac{11+\sqrt{123}}{2}\right)\right\}}$$
$$\times\left(\frac{6817+321\sqrt{451}}{4}\right)^{\frac16}$$
$$\times\left\{\sqrt{\left(\frac{17+3\sqrt{33}}{8}\right)}+\sqrt{\left(\frac{25+3\sqrt{33}}{8}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{561+99\sqrt{33}}{8}\right)}+\sqrt{\left(\frac{569+99\sqrt{33}}{8}\right)}\right\},$$

$$G_{1645}^2=(2+\sqrt5)\sqrt{\left\{(3+\sqrt7)\left(\frac{7+\sqrt{47}}{2}\right)\right\}}\left(\frac{73\sqrt5+9\sqrt{329}}{2}\right)^{\frac14}$$
$$\times\left\{\sqrt{\left(\frac{119+7\sqrt{329}}{8}\right)}+\sqrt{\left(\frac{127+7\sqrt{329}}{8}\right)}\right\}$$
$$\times\left\{\sqrt{\left(\frac{743+41\sqrt{329}}{8}\right)}+\sqrt{\left(\frac{751+41\sqrt{329}}{8}\right)}\right\}.$$

7. Hence we deduce the following approximate formulæ.

TABLE II.

$$e^{\frac18\pi\sqrt{18}}=2\sqrt7,\quad e^{\pi\sqrt{22}/12}=2+\sqrt2,\quad e^{\frac14\pi\sqrt{30}}=20\sqrt3+16\sqrt6,$$
$$e^{\frac14\pi\sqrt{34}}=12(4+\sqrt{17}),\quad e^{\frac12\pi\sqrt{46}}=144(147+104\sqrt2),$$
$$e^{\frac14\pi\sqrt{42}}=84+32\sqrt6,\quad e^{\pi\sqrt{58}/12}=\frac{5+\sqrt{29}}{\sqrt2},$$
$$e^{\frac14\pi\sqrt{70}}=60\sqrt{35}+96\sqrt{14},\quad e^{\frac14\pi\sqrt{78}}=300\sqrt3+208\sqrt6,$$
$$e^{\pi\sqrt{55}/24}=\frac{1+\sqrt{(3+2\sqrt5)}}{\sqrt2},\quad e^{\frac14\pi\sqrt{102}}=800\sqrt3+196\sqrt{51},$$
$$e^{\frac14\pi\sqrt{130}}=12(323+40\sqrt{65}),\quad e^{\pi\sqrt{190}/12}=(2\sqrt2+\sqrt{10})(3+\sqrt{10}),$$
$$\pi=\frac{12}{\sqrt{130}}\log\left\{\frac{(2+\sqrt5)(3+\sqrt{13})}{\sqrt2}\right\},$$
$$\pi=\frac{24}{\sqrt{142}}\log\left\{\sqrt{\left(\frac{10+11\sqrt2}{4}\right)}+\sqrt{\left(\frac{10+7\sqrt2}{4}\right)}\right\},$$
$$\pi=\frac{12}{\sqrt{190}}\log\{(2\sqrt2+\sqrt{10})(3+\sqrt{10})\},$$
$$\pi=\frac{12}{\sqrt{310}}\log[\tfrac14(3+\sqrt5)(2+\sqrt2)\{(5+2\sqrt{10})+\sqrt{(61+20\sqrt{10})}\}],$$
$$\pi=\frac{4}{\sqrt{522}}\log\left[\left(\frac{5+\sqrt{29}}{\sqrt2}\right)^3(5\sqrt{29}+11\sqrt6)\right.$$
$$\left.\times\left\{\sqrt{\left(\frac{9+3\sqrt6}{4}\right)}+\sqrt{\left(\frac{5+3\sqrt6}{4}\right)}\right\}^6\right].$$

The last five formulæ are correct to 15, 16, 18, 22, and 31 places of decimals respectively.

8. Thus we have seen how to approximate to π by means of logarithms of surds. I shall now shew how to obtain approximations in terms of surds only. If

$$n\frac{K'}{K}=\frac{L'}{L},$$

we have
$$\frac{ndk}{kk'^2K^2}=\frac{dl}{ll'^2L^2}.$$

But, by means of the modular equation connecting k and l, we can express dk/dl as an algebraic function of k, a function moreover in which all coefficients which occur are algebraic numbers. Again,

$$q=e^{-\pi K'/K},\quad q^n=e^{-\pi L'/L},$$
$$\frac{q^{\frac1{12}}(1-q^2)(1-q^4)(1-q^6)\ldots}{q^{\frac{n}{12}}(1-q^{2n})(1-q^{4n})(1-q^{6n})}=\left(\frac{kk'}{ll'}\right)^{\frac16}\sqrt{\left(\frac{K}{L}\right)}.\quad\ldots\ldots(15)$$

Differentiating this equation logarithmically, and using the formula

$$\frac{dq}{dk}=\frac{\pi^2q}{2kk'^2K^2},$$

we see that

$$n\left\{1-24\left(\frac{q^{2n}}{1-q^{2n}}+\frac{2q^{4n}}{1-q^{4n}}+\ldots\right)\right\}$$
$$-\left\{1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\ldots\right)\right\}=\frac{KL}{\pi^2}A(k),\quad\ldots(16)$$

where $A(k)$ denotes an algebraic function of the special class described above. I shall use the letter A generally to denote a function of this type.

Now, if we put $k=l'$ and $k'=l$ in (16), we have

$$n\left\{1-24\left(\frac{1}{e^{2\pi\sqrt n}-1}+\frac{2}{e^{4\pi\sqrt n}-1}+\ldots\right)\right\}$$
$$-\left\{1-24\left(\frac{1}{e^{2\pi/\sqrt n}-1}+\frac{2}{e^{4\pi/\sqrt n}-1}+\ldots\right)\right\}=\left(\frac{K}{\pi}\right)^2A(k).\quad\ldots(17)$$

The algebraic function $A(k)$ of course assumes a purely numerical form when we substitute the value of k deduced from the modular equation. But by substituting $k=l'$ and $k'=l$ in (15) we have

$$n^{\frac14}e^{-\pi\sqrt n/12}(1-e^{-2\pi\sqrt n})(1-e^{-4\pi\sqrt n})(1-e^{-6\pi\sqrt n})\ldots$$
$$=e^{-\pi/(12\sqrt n)}(1-e^{-2\pi/\sqrt n})(1-e^{-4\pi/\sqrt n})(1-e^{-6\pi/\sqrt n})\ldots.$$

Differentiating the above equation logarithmically we have

$$n\left\{1-24\left(\frac{1}{e^{2\pi\sqrt n}-1}+\frac{2}{e^{4\pi\sqrt n}-1}+\ldots\right)\right\}$$
$$+\left\{1-24\left(\frac{1}{e^{2\pi/\sqrt n}-1}+\frac{2}{e^{4\pi/\sqrt n}-1}+\ldots\right)\right\}=\frac{6\sqrt n}{\pi}.\quad\ldots\ldots\ldots(18)$$

Now, adding (17) and (18), we have

$$1-\frac{3}{\pi\sqrt n}-24\left(\frac{1}{e^{2\pi\sqrt n}-1}+\frac{2}{e^{4\pi\sqrt n}-1}+\ldots\right)=\left(\frac{K}{\pi}\right)^2A(k).\quad\ldots\ldots(19)$$

But it is known that

$$1-24\left(\frac{q}{1+q}+\frac{3q^3}{1+q^3}+\frac{5q^5}{1+q^5}+\ldots\right)=\left(\frac{2K}{\pi}\right)^2(1-2k^2),$$

so that
$$1-24\left(\frac{1}{e^{\pi\sqrt n}+1}+\frac{3}{e^{3\pi\sqrt n}+1}+\ldots\right)=\left(\frac{K}{\pi}\right)^2A(k).\quad\ldots\ldots\ldots(20)$$

Hence, dividing (19) by (20), we have

$$\frac{1-\dfrac{3}{\pi\sqrt n}-24\left(\dfrac{1}{e^{2\pi\sqrt n}-1}+\dfrac{2}{e^{4\pi\sqrt n}-1}+\ldots\right)}{1-24\left(\dfrac{1}{e^{\pi\sqrt n}+1}+\dfrac{3}{e^{3\pi\sqrt n}+1}+\ldots\right)}=R,\quad\ldots\ldots\ldots(21)$$

where R can always be expressed in radicals if n is any rational number. Hence we have

$$\pi = \frac{3}{(1-R)\sqrt{n}}, \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(22)$$

nearly, the error being about $8\pi e^{-\pi\sqrt{n}}(\pi\sqrt{n}-3)$.

9. We may get a still closer approximation from the following results. It is known that

$$1 + 240\sum_{r=1}^{r=\infty}\frac{r^3q^{2r}}{1-q^{2r}} = \left(\frac{2K}{\pi}\right)^4(1-k^2k'^2),$$

and also that

$$1 - 504\sum_{r=1}^{r=\infty}\frac{r^5q^{2r}}{1-q^{2r}} = \left(\frac{2K}{\pi}\right)^6(1-2k^2)(1+\tfrac{1}{2}k^2k'^2).$$

Hence, from (19), we see that

$$\left\{1-\frac{3}{\pi\sqrt{n}}-24\sum_{r=1}^{r=\infty}\frac{r}{e^{2\pi r\sqrt{n}}-1}\right\}\left\{1+240\sum_{r=1}^{r=\infty}\frac{r^3}{e^{2\pi r\sqrt{n}}-1}\right\}$$
$$= R'\left\{1-504\sum_{r=1}^{r=\infty}\frac{r^5}{e^{2\pi r\sqrt{n}}-1}\right\}, \ \ldots\ldots(23)$$

where R' can always be expressed in radicals for any rational value of n. Hence

$$\pi = \frac{3}{(1-R')\sqrt{n}}, \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(24)$$

nearly, the error being about $24\pi(10\pi\sqrt{n}-31)e^{-2\pi\sqrt{n}}$

It will be seen that the error in (24) is much less than that in (22), if n is at all large.

10. In order to find R and R' the series in (16) must be calculated in finite terms. I shall give the final results for a few values of n.

TABLE III.

$$q = e^{-\pi K'/K}, \quad q^n = e^{-\pi L'/L},$$

$$f(q) = n\left(1-24\sum_1^\infty\frac{q^{2mn}}{1-q^{2mn}}\right) - \left(1-24\sum_1^\infty\frac{q^{2m}}{1-q^{2m}}\right).$$

$$f(2) = \frac{4KL}{\pi^2}(k'+l),$$

$$f(3) = \frac{4KL}{\pi^2}(1+kl+k'l'),$$

$$f(4) = \frac{4KL}{\pi^2}(\sqrt{k'}+\sqrt{l})^2,$$

$$f(5) = \frac{4KL}{\pi^2}(3+kl+k'l')\sqrt{\left(\frac{1+kl+k'l'}{2}\right)},$$

$$f(11) = \frac{8KL}{\pi^2}\{2(1+kl+k'l')+\sqrt{(kl)}+\sqrt{(k'l')}-\sqrt{(kk'll')}\},$$

$$f(15) = \frac{4KL}{\pi^2}[\{1+(kl)^{\frac{1}{2}}+(k'l')^{\frac{1}{2}}\}^2-\{1+kl+k'l'\}],$$

$$f(17) = \frac{4KL}{\pi^2}\sqrt{\{44(1+k^2l^2+k'^2l'^2)+168(kl+k'l'-kk'll')}$$
$$-102(1-kl-k'l')(4kk'll')^{\frac{1}{2}}-192(4kk'll')^{\frac{3}{4}}\},$$

$$f(19) = \frac{24KL}{\pi^2}\{(1+kl+k'l')+\sqrt{(kl)}+\sqrt{(k'l')}-\sqrt{(kk'll')}\},$$

$$f(23) = \frac{4KL}{\pi^2}[11(1+kl+k'l')-16(4kk'll')^{\frac{1}{6}}\{1+\sqrt{(kl)}+\sqrt{(k'l')}\}$$
$$-20(4kk'll')^{\frac{1}{3}}],$$

$$f(31) = \frac{12KL}{\pi^2}[3(1+kl+k'l')+4\{\sqrt{(kl)}+\sqrt{(k'l')}+\sqrt{(kk'll')}\}$$
$$-4(kk'll')^{\frac{1}{4}}\{1+(kl)^{\frac{1}{4}}+(k'l')^{\frac{1}{4}}\}],$$

$$f(35) = \frac{4KL}{\pi^2}[2\{\sqrt{(kl)}+\sqrt{(k'l')}-\sqrt{(kk'll')}\}$$
$$+(4kk'll')^{-\frac{1}{6}}\{1-\sqrt{(kl)}-\sqrt{(k'l')}\}^2].$$

Thus the sum of the series (19) can be found in finite terms, when $n = 2, 3, 4, 5, \ldots$, from the equations in Table III. We can use the same table to find the sum of (19) when $n = 9, 25, 49, \ldots$; but then we have also to use the equation

$$\frac{3}{\pi} = 1-24\left(\frac{1}{e^{2\pi}-1}+\frac{2}{e^{4\pi}-1}+\frac{3}{e^{6\pi}-1}+\cdots\right),$$

which is got by putting $k = k' = 1/\sqrt{2}$ and $n = 1$ in (18).

Similarly we can find the sum of (19) when $n = 21, 33, 57, 93, \ldots$, by combining the values of $f(3)$ and $f(7)$, $f(3)$ and $f(11)$, and so on, obtained from Table III.

11. The errors in (22) and (24) being about

$$8\pi e^{-\pi\sqrt{n}}(\pi\sqrt{n}-3), \quad 24\pi(10\pi\sqrt{n}-31)e^{-2\pi\sqrt{n}},$$

we cannot expect a high degree of approximation for small values of n. Thus, if we put $n = 7, 9, 16$, and 25 in (24), we get

$$\frac{19}{16}\sqrt{7} = 3{\cdot}14180\ldots,$$

$$\frac{7}{3}\left(1+\frac{\sqrt{3}}{5}\right) = 3{\cdot}14162\ldots,$$

$$\frac{99}{80}\left(\frac{7}{7-3\sqrt{2}}\right) = 3{\cdot}14159274\ldots,$$

$$\frac{63}{25}\left(\frac{17+15\sqrt{5}}{7+15\sqrt{5}}\right) = 3{\cdot}14159265380\ldots,$$

while $\pi = 3{\cdot}14159265358\ldots.$

But if we put $n = 25$ in (22), we get only

$$\frac{9}{5}+\sqrt{\left(\frac{9}{5}\right)} = 3{\cdot}14164\ldots.$$

12. Another curious approximation to π is

$$\left(9^2+\frac{19^2}{22}\right)^{\frac{1}{4}} = 3{\cdot}14159265262\ldots.$$

This value was obtained empirically, and it has no connection with the preceding theory.

The actual value of π, which I have used for purposes of calculation, is

$$\frac{355}{113}\left(1-\frac{{\cdot}0003}{3533}\right) = 3{\cdot}1415926535897943\ldots,$$

which is greater than π by about 10^{-16}. This is obtained by simply taking the reciprocal of $1-(113\pi/355)$.

In this connection it may be interesting to note the following simple geometrical constructions for π. The first merely gives the ordinary value 355/113. The second gives the value $(9^2+19^2/22)^{\frac{1}{4}}$ mentioned above.

(1) Let AB (Fig. 1) be a diameter of a circle whose centre is O.

Bisect AO at M and trisect OB at T.

Draw TP perpendicular to AB and meeting the circumference at P.

Draw a chord BQ equal to PT and join AQ.

Draw OS and TR parallel to BQ and meeting AQ at S and R respectively.

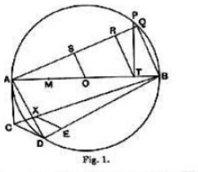

Fig. 1.

Draw a chord AD equal to AS and a tangent $AC = RS$.

Join BC, BD, and CD; cut off $BE = BM$, and draw EX, parallel to CD, meeting BC at X.

Then the square on BX is very nearly equal to the area of the circle, the error being less than a tenth of an inch when the diameter is 40 miles long.

(2) Let AB (Fig. 2) be a diameter of a circle whose centre is O.

Bisect the arc ACB at C and trisect AO at T.

Join BC and cut off from it CM and MN equal to AT.

Join AM and AN and cut off from the latter AP equal to AM.

Through P draw PQ parallel to MN and meeting AM at Q.

Join OQ and through T draw TR, parallel to OQ, and meeting AQ at R.

Draw AS perpendicular to AO and equal to AR, and join OS.

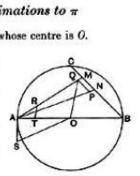

Fig. 2.

Then the mean proportional between OS and OB will be very nearly equal to a sixth of the circumference, the error being less than a twelfth of an inch when the diameter is 8000 miles long.

13. I shall conclude this paper by giving a few series for $1/\pi$.

It is known that, when $k \leqslant 1/\sqrt{2}$,

$$\left(\frac{2K}{\pi}\right)^2 = 1+\left(\frac{1}{2}\right)^3(2kk')^2+\left(\frac{1.3}{2.4}\right)^3(2kk')^4+\ldots. \ \ldots\ldots\ldots(25)$$

Hence we have

$$q^{\frac{1}{3}}(1-q^2)^4(1-q^4)^4(1-q^6)^4\ldots$$
$$= \left(\frac{1}{4}kk'\right)^{\frac{2}{3}}\left\{1+\left(\frac{1}{2}\right)^3(2kk')^2+\left(\frac{1.3}{2.4}\right)^3(2kk')^4+\ldots\right\}. \ \ldots\ldots(26)$$

Differentiating both sides in (26) logarithmically with respect to k, we can easily shew that

$$1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\frac{3q^6}{1-q^6}+\ldots\right)$$
$$= (1-2k^2)\left\{1+4\left(\frac{1}{2}\right)^3(2kk')^2+7\left(\frac{1.3}{2.4}\right)^3(2kk')^4+\ldots\right\}. \ \ldots(27)$$

But it follows from (19) that, when $q = e^{-\pi\sqrt{n}}$, n being a rational number, the left-hand side of (27) can be expressed in the form

$$A\left(\frac{2K}{\pi}\right)^2+\frac{B}{\pi},$$

where A and B are algebraic numbers expressible by surds. Combining (25) and (27) in such a way as to eliminate the term $(2K/\pi)^2$, we are left with a series for $1/\pi$. Thus, for example,

$$\frac{4}{\pi} = 1+\frac{7}{4}\left(\frac{1}{2}\right)^3+\frac{13}{4^2}\left(\frac{1.3}{2.4}\right)^3+\frac{19}{4^3}\left(\frac{1.3.5}{2.4.6}\right)^3+\ldots,$$
$$(q = e^{-\pi\sqrt{3}},\ 2kk' = \tfrac{1}{2}). \ \ldots\ldots\ldots\ldots\ldots(28)$$

$$\frac{16}{\pi} = 5+\frac{47}{64}\left(\frac{1}{2}\right)^3+\frac{89}{64^2}\left(\frac{1.3}{2.4}\right)^3+\frac{131}{64^3}\left(\frac{1.3.5}{2.4.6}\right)^3+\ldots,$$
$$(q = e^{-\pi\sqrt{7}},\ 2kk' = \tfrac{1}{8}). \ \ldots\ldots\ldots\ldots\ldots(29)$$

$$\frac{32}{\pi}=(5\sqrt5-1)+\frac{47\sqrt5+29}{64}\left(\frac12\right)^3\left(\frac{\sqrt5-1}{2}\right)^8$$
$$+\frac{89\sqrt5+59}{64^2}\left(\frac{1.3}{2.4}\right)^3\left(\frac{\sqrt5-1}{2}\right)^{16}+\dots,$$
$$\left[q=e^{-\pi\sqrt{30}},\ 2kk'=\frac18\left(\frac{\sqrt5-1}{2}\right)\right];\ \dots\dots\dots(30)$$

here $5\sqrt5-1$, $47\sqrt5+29$, $89\sqrt5+59$, ... are in arithmetical progression.

14. The ordinary modular equations express the relations which hold between k and l when $nK'/K=L'/L$, or $q^n=Q$, where

$$q=e^{-\pi K'/K},\quad Q=e^{-\pi L'/L},$$
$$K=1+\left(\frac12\right)^2k^2+\left(\frac{1.3}{2.4}\right)^2k^4+\dots.$$

There are corresponding theories in which q is replaced by one or other of the functions

$$q_1=e^{-\pi K_1'\sqrt2/K_1},\quad q_2=e^{-2\pi K_2'/(K_2\sqrt3)},\quad q_3=e^{-2\pi K_3'/K_3},$$

where

$$K_1=1+\frac{1.3}{4^2}k^2+\frac{1.3.5.7}{4^2.8^2}k^4+\frac{1.3.5.7.9.11}{4^2.8^2.12^2}k^6+\dots,$$
$$K_2=1+\frac{1.2}{3^2}k^2+\frac{1.2.4.5}{3^2.6^2}k^4+\frac{1.2.4.5.7.8}{3^2.6^2.9^2}k^6+\dots,$$
$$K_3=1+\frac{1.5}{6^2}k^2+\frac{1.5.7.11}{6^2.12^2}k^4+\frac{1.5.7.11.13.17}{6^2.12^2.18^2}k^6+\dots.$$

From these theories we can deduce further series for $1/\pi$, such as

$$\frac{27}{4\pi}=2+17\,\frac12\,\frac13\,\frac23\left(\frac{2}{27}\right)$$
$$+32\,\frac{1.3}{2.4}\,\frac{1.4}{3.6}\,\frac{2.5}{3.6}\left(\frac{2}{27}\right)^2+\dots,\ \dots\dots(31)$$

$$\frac{15\sqrt3}{2\pi}=4+37\,\frac12\,\frac13\,\frac23\left(\frac{4}{125}\right)$$
$$+70\,\frac{1.3}{2.4}\,\frac{1.4}{3.6}\,\frac{2.5}{3.6}\left(\frac{4}{125}\right)^2+\dots,\ \dots\dots(32)$$

$$\frac{5\sqrt5}{2\pi\sqrt3}=1+12\,\frac12\,\frac16\,\frac56\left(\frac{4}{125}\right)$$
$$+23\,\frac{1.3}{2.4}\,\frac{1.7}{6.12}\,\frac{5.11}{6.12}\left(\frac{4}{125}\right)^2+\dots,\ \dots(33)$$

$$\frac{85\sqrt{85}}{18\pi\sqrt3}=8+141\,\frac12\,\frac16\,\frac56\left(\frac{4}{85}\right)^3$$
$$+274\,\frac{1.3}{2.4}\,\frac{1.7}{6.12}\,\frac{5.11}{6.12}\left(\frac{4}{85}\right)^6+\dots,\ \dots(34)$$

$$\frac4\pi=\frac32-\frac{23}{2^3}\,\frac12\,\frac{1.3}{4^2}+\frac{43}{2^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}-\dots,\ \dots\dots\dots\dots\dots(35)$$

$$\frac{4}{\pi\sqrt3}=\frac34-\frac{31}{3.4^3}\,\frac12\,\frac{1.3}{4^2}+\frac{59}{3^2.4^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}-\dots\ \dots\dots\dots(36)$$

$$\frac4\pi=\frac{23}{18}-\frac{283}{18^3}\,\frac12\,\frac{1.3}{4^2}+\frac{543}{18^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}-\dots,\ \dots\dots\dots(37)$$

$$\frac{4}{\pi\sqrt5}=\frac{41}{72}-\frac{685}{5.72^3}\,\frac12\,\frac{1.3}{4^2}+\frac{1329}{5^2.72^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}-\dots,\ \dots\dots(38)$$

$$\frac4\pi=\frac{1123}{882}-\frac{22583}{882^3}\,\frac12\,\frac{1.3}{4^2}+\frac{44043}{882^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}-\dots,\ \dots(39)$$

$$\frac{2\sqrt3}{\pi}=1+\frac99\,\frac12\,\frac{1.3}{4^2}+\frac{17}{9^2}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}+\dots,\ \dots\dots\dots\dots\dots(40)$$

$$\frac{1}{2\pi\sqrt2}=\frac19+\frac{11}{9^3}\,\frac12\,\frac{1.3}{4^2}+\frac{21}{9^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}+\dots,\ \dots\dots\dots\dots(41)$$

$$\frac{1}{3\pi\sqrt3}=\frac{3}{49}+\frac{43}{49^3}\,\frac12\,\frac{1.3}{4^2}+\frac{83}{49^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}+\dots\ \dots\dots\dots(42)$$

$$\frac{2}{\pi\sqrt{11}}=\frac{19}{99}+\frac{299}{99^3}\,\frac12\,\frac{1.3}{4^2}+\frac{579}{99^5}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}+\dots,\ \dots\dots\dots(43)$$

$$\frac{1}{2\pi\sqrt2}=\frac{1103}{99^2}+\frac{27493}{99^6}\,\frac12\,\frac{1.3}{4^2}+\frac{53883}{99^{10}}\,\frac{1.3}{2.4}\,\frac{1.3.5.7}{4^2.8^2}+\dots\ \dots(44)$$

In all these series the first factors in each term form an arithmetical progression; e.g. 2, 17, 32, 47, ..., in (31), and 4, 37, 70, 103, ..., in (32). The first two series belong to the theory of q_2, the next two to that of q_3, and the rest to that of q_1.

The last series (44) is extremely rapidly convergent. Thus, taking only the first term, we see that

$$\frac{1103}{99^2}=\cdot11253953678\dots,$$
$$\frac{1}{2\pi\sqrt2}=\cdot11253953951\dots.$$

15. In concluding this paper I have to remark that the series

$$1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\frac{3q^6}{1-q^6}+\dots\right),$$

which has been discussed in §§ 8—13, is very closely connected with the perimeter of an ellipse whose eccentricity is k. For, if a and b be the semi-major and the semi-minor axes, it is known that

$$p=2\pi a\left\{1-\frac{1}{2^2}k^2-\frac{1^2.3}{2^2.4^2}k^4-\frac{1^2.3^2.5}{2^2.4^2.6^2}k^6-\dots\right\},\ \dots\dots\dots(45)$$

where p is the perimeter and k the eccentricity. It can easily be seen from (45) that

$$p=4ak'^2\left\{K+k\frac{dK}{dk}\right\}.\ \dots\dots\dots\dots\dots\dots\dots\dots(46)$$

But, taking the equation

$$q^{\frac1{12}}(1-q^2)(1-q^4)(1-q^6)\dots=(2kk')^{\frac16}\sqrt{(K/\pi)},$$

and differentiating both sides logarithmically with respect to k, and combining the result with (46) in such a way as to eliminate dK/dk, we can shew that

$$p=\frac{4a}{3K}\left[K^2(1+k'^2)+(\tfrac12\pi)^2\left\{1-24\left(\frac{q^2}{1-q^2}+\frac{2q^4}{1-q^4}+\dots\right)\right\}\right].\ (47)$$

But we have shewn already that the right-hand side of (47) can be expressed in terms of K if $q=e^{-\pi\sqrt n}$, where n is any rational number. It can also be shewn that K can be expressed in terms of Γ-functions if q be of the forms $e^{-\pi n}$, $e^{-\pi n\sqrt2}$ and $e^{-\pi n\sqrt3}$, where n is rational. Thus, for example, we have

$$\left.\begin{aligned}
&k=\sin\frac\pi4,\quad q=e^{-\pi},\\
&\qquad p=a\sqrt{\left(\frac\pi2\right)}\left\{\frac{\Gamma(\frac14)}{\Gamma(\frac34)}+\frac{\Gamma(\frac34)}{\Gamma(\frac54)}\right\},\\
&k=\tan\frac\pi8,\quad q=e^{-\pi\sqrt2},\\
&\qquad p=a\sqrt{\left(\frac\pi4\right)}\left\{\frac{\Gamma(\frac18)}{\Gamma(\frac58)}+\frac{\Gamma(\frac58)}{\Gamma(\frac98)}\right\},\\
&k=\sin\frac{\pi}{12},\quad q=e^{-\pi\sqrt3},\\
&\qquad p=a\sqrt{\left(\frac{\pi}{\sqrt3}\right)}\left\{\left(1+\frac{1}{\sqrt3}\right)\frac{\Gamma(\frac13)}{\Gamma(\frac56)}+2\frac{\Gamma(\frac56)}{\Gamma(\frac13)}\right\},\\
&\frac ba=\tan^2\frac\pi8,\quad q=e^{-2\pi},\\
&\qquad p=(a+b)\sqrt{\left(\frac\pi2\right)}\left\{\frac12\frac{\Gamma(\frac14)}{\Gamma(\frac34)}+\frac{\Gamma(\frac34)}{\Gamma(\frac14)}\right\},
\end{aligned}\right\}\ \dots\dots(48)$$

and so on.

16. The following approximations for p were obtained empirically:

$$p=\pi\left[3(a+b)-\sqrt{\{(a+3b)(3a+b)\}}+\epsilon\right],\ \dots\dots\dots\dots\dots(49)$$

where ϵ is about $ak^{12}/1048576$;

$$p=\pi\left\{(a+b)+\frac{3(a-b)^2}{10(a+b)+\sqrt{(a^2+14ab+b^2)}}+\epsilon\right\},\ \dots\dots\dots(50)$$

where ϵ is about $3ak^{20}/68719476736$.

5

SQUARING THE CIRCLE

(*Journal of the Indian Mathematical Society*, v, 1913, 132)

Let PQR be a circle with centre O, of which a diameter is PR. Bisect PO at H and let T be the point of trisection of OR nearer R. Draw TQ perpendicular to PR and place the chord $RS = TQ$.

Join PS, and draw OM and TN parallel to RS. Place a chord $PK = PM$, and draw the tangent $PL = MN$. Join RL, RK and KL. Cut off $RC = RH$. Draw CD parallel to KL, meeting RL at D.

Then the square on RD will be equal to the circle PQR approximately.

For $$RS^2 = \tfrac{5}{36} d^2,$$
where d is the diameter of the circle.

Therefore $$PS^2 = \tfrac{31}{36} d^2.$$

But PL and PK are equal to MN and PM respectively.

Therefore $$PK^2 = \tfrac{31}{144} d^2, \text{ and } PL^2 = \tfrac{31}{324} d^2.$$

Hence $$RK^2 = PR^2 - PK^2 = \tfrac{113}{144} d^2,$$

and $$RL^2 = PR^2 + PL^2 = \tfrac{355}{324} d^2.$$

But $$\frac{RK}{RL} = \frac{RC}{RD} = \frac{3}{2}\sqrt{\frac{113}{355}},$$

and $$RC = \tfrac{3}{4} d.$$

Therefore $$RD = \frac{d}{2}\sqrt{\frac{355}{113}} = r\sqrt{\pi}, \text{ very nearly.}$$

Note.—If the area of the circle be 140,000 square miles, then RD is greater than the true length by about an inch.

1.6 Orthogonal Trajectories. *Optional*

An important type of problem in physics or geometry is to find a family of curves that intersect a given family of curves at right angles. The new curves are called **orthogonal trajectories** of the given curves (and conversely). Examples are curves of equal temperature (*isotherms*) and curves of heat flow, curves of equal altitude (*contour lines*) on a map and curves of steepest descent on that map, curves of equal potential (*equipotential curves*, curves of equal voltage—the concentric circles in Fig. 22), and curves of electric force (the straight radial segments in Fig. 22).

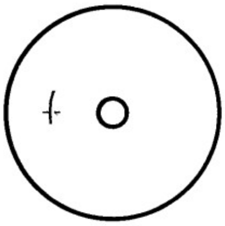

Fig. 22. Equipotential lines and curves of electric force (dashed) between two concentric (black) circles (cylinders in space)

Here the **angle of intersection** between two curves is defined to be the angle between the tangents of the curves at the intersection point. *Orthogonal* is another word for *perpendicular*.

In many cases orthogonal trajectories can be found by using ODEs, as follows. Let

$$G(x, y, c) = 0 \tag{1}$$

be a given family of curves in the xy-plane, where each curve is specified by some value of c. This is called a **one-parameter family of curves**, and c is called the *parameter* of the family. For instance, a one-parameter family of quadratic parabolas is given by (Fig. 23)

$$y = cx^2 \qquad \text{or, written as in (1),} \qquad G(x, y, c) = y - cx^2 = 0.$$

Step 1. Find an ODE for which the given family is a general solution. Of course, this ODE must no longer contain the parameter c. In our example we solve algebraically for c and then differentiate and simplify; thus,

$$\frac{y}{x^2} = c, \qquad \frac{y'x^2 - 2xy}{x^4} = 0,$$

hence

$$y' = \frac{2y}{x}.$$

The last of these equations is the ODE of the given family of curves. It is of the form

$$y' = f(x, y). \tag{2}$$

Step 2. Write down the ODE of the orthogonal trajectories, that is, the ODE whose general solution gives the orthogonal trajectories of the given curves. This ODE is

$$\tilde{y}' = -\frac{1}{f(x, \tilde{y})} \tag{3}$$

with the same f as in (2). Why? Well, a given curve passing through a point (x_0, y_0) has slope $f(x_0, y_0)$ at that point, by (2). The trajectory through (x_0, y_0) has slope $-1/f(x_0, y_0)$ by (3). The product of these slopes is -1, as we see. From calculus it is known that this is the condition for orthogonality (perpendicularity) of two straight lines (the tangents at (x_0, y_0)), hence of the curve and its orthogonal trajectory at (x_0, y_0).

Step 3. Solve (3).

For our parabolas $y = cx^2$ we have $y' = 2y/x$. Hence their orthogonal trajectories are obtained from $\tilde{y}' = -x/2\tilde{y}$ or $2\tilde{y}\tilde{y}' + x = 0$. By integration, $\tilde{y}^2 + \frac{1}{2}x^2 = c^*$. These are the ellipses in Fig. 23 with semi-axes $\sqrt{2c^*}$ and $\sqrt{c^*}$. Here, $c^* > 0$ because $c^* = 0$ gives just the origin, and $c^* < 0$ gives no real solution at all.

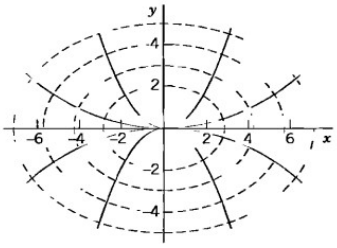

Fig. 23. Parabolas and orthogonal trajectories (ellipses) in the text

---

[illegible]

1–12 ORTHOGONAL TRAJECTORIES

Sketch or graph some of the given curves. Guess what their orthogonal trajectories may look like. Find these trajectories.

(Show the details of your work.)

1. $y = 4x + c$ **2.** $y = c/x$

3. $y = cx$ **4.** $y^2 = 2x^2 + c$

5. $x^2y = c$ **6.** $y = ce^{-3x}$

7. $y = ce^{x^2/2}$ **8.** $x^2 - y^2 = c$

9. $4x^2 + y^2 = c$ **10.** $x = c\sqrt{y}$

11. $x = ce^{y/4}$ **12.** $x^2 + (y - c)^2 = c^2$

13–15 OTHER FORMS OF THE ODEs (2) AND (3)

13. **(y as independent variable)** Show that (3) may be written $dx/d\tilde{y} = -f(x, \tilde{y})$. Use this form to find the orthogonal trajectories of $y = 2x + ce^{-x}$.

14. **(Family $g(x, y) = c$)** Show that if a family is given as $g(x, y) = c$, then the orthogonal trajectories can be obtained from the following ODE, and use the latter to solve Prob. 6 written in the form $g(x, y) = c$.

$$\frac{d\tilde{y}}{dx} = \frac{\partial g/\partial \tilde{y}}{\partial g/\partial x}$$

15. **(Cauchy–Riemann equations)** Show that for a family $u(x, y) = c = const$ the orthogonal trajectories $v(x, y) = c^* = const$ can be obtained from the following *Cauchy–Riemann equations* (which are basic in complex analysis in Chap. 13) and use them to find the orthogonal trajectories of $e^x \sin y = const$. (Here, subscripts denote partial derivatives.)

$$u_x = v_y, \qquad u_y = -v_x$$

16–20 **APPLICATIONS**

16. **(Fluid flow)** Suppose that the *streamlines* of the flow (paths of the particles of the fluid) in Fig. 24 are $\Psi(x, y) = xy = const$. Find their orthogonal trajectories (called **equipotential lines,** for reasons given in Sec. 18.4).

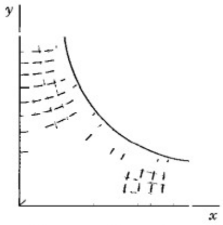

Fig. 24. Flow in a channel in Problem 16

17. **(Electric field)** Let the electric equipotential lines (curves of constant potential) between two concentric cylinders (Fig. 22) be given by $u(x, y) = x^2 + y^2 = c$. Use the method in the text to find their orthogonal trajectories (the curves of electric force).

18. **(Electric field)** The lines of electric force of two opposite charges of the same strength at $(-1, 0)$ and $(1, 0)$ are the circles through $(-1, 0)$ and $(1, 0)$. Show that these circles are given by $x^2 + (y - c)^2 = 1 + c^2$. Show that the **equipotential lines** (orthogonal trajectories of those circles) are the circles given by $(x + c^*)^2 + \tilde{y}^2 = c^{*2} - 1$ (dashed in Fig. 25).

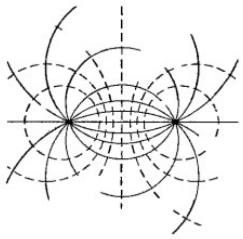

Fig. 25. Electric field in Problem 18

19. **(Temperature field)** Let the **isotherms** (curves of constant temperature) in a body in the upper half-plane $y > 0$ be given by $4x^2 + 9y^2 = c$. Find the orthogonal trajectories (the curves along which heat will flow in regions filled with heat-conducting material and free of heat sources or heat sinks).

20. **TEAM PROJECT. Conic Sections.** **(A)** State the main steps of the present method of obtaining orthogonal trajectories.

(B) Find conditions under which the orthogonal trajectories of families of ellipses $x^2/a^2 + y^2/b^2 = c$ are again conic sections. Illustrate your result graphically by sketches or by using your CAS. What happens if $a \to 0$? If $b \to 0$?

(C) Investigate families of hyperbolas $x^2/a^2 - y^2/b^2 = c$ in a similar fashion.

(D) Can you find more complicated curves for which you get ODEs that you can solve? Give it a try.

1.7 Existence and Uniqueness of Solutions

The initial value problem

$$|y'| + |y| = 0, \qquad y(0) = 1$$

has no solution because $y = 0$ (that is, $y(x) = 0$ for all x) is the only solution of the ODE. The initial value problem

$$y' = 2x, \qquad y(0) = 1$$

2.2.2 Waves from Geometry

Let's dig into some illuminating mathematics to grasp what these gravitational waves (GWs) really are. General Relativity is enshrined within the *Einstein Field Equations*,

$$G_{\mu\nu} := R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} = 8\pi T_{\mu\nu}, \tag{2.1}$$

where $G_{\mu\nu}$ is the Einstein tensor, $R_{\mu\nu} := R^{\lambda}_{\mu\lambda\nu}$ is the Ricci tensor derived from the Riemann curvature tensor, $R = g^{\mu\nu}R_{\mu\nu}$ is the Ricci scalar, $g_{\mu\nu}$ is the metric, $T_{\mu\nu}$ is the stress-energy tensor, and we assume natural units such that $G = c = 1$.

We consider the linearized treatment of GWs that Einstein originally studied (11; 12). In the following, Greek indices refer to 4-D spacetime coordinates, while Roman indices refer to 3-D spatial coordinates. The derivation presented here closely follows the treatment in Maggiore (29). We start with spatially-flat 4-D Minkowski spacetime, with $\eta_{\mu\nu} = \mathrm{diag}(-1, 1, 1, 1)$, which upon adding a perturbation results in

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}, \tag{2.2}$$

where $h_{\mu\nu}$ is a tensor metric perturbation quantity that we treat only in the weak field case, $|h_{\mu\nu}| \ll 1$. This metric perturbation is assumed to be so small that the usual index raising and lowering operations can be performed with the Minkowski metric. Expanding the Einstein tensor to linear order in $h_{\mu\nu}$ in this perturbed spacetime gives,

$$G_{\mu\nu} = \frac{1}{2}\left(\partial_\mu\partial^\alpha h_{\alpha\nu} + \partial_\nu\partial^\alpha h_{\alpha\mu} - \partial_\mu\partial_\nu h - \Box h_{\mu\nu} + \eta_{\mu\nu}\Box h - \eta_{\mu\nu}\partial^\alpha\partial^\beta h_{\alpha\beta}\right), \tag{2.3}$$

where $\partial_\mu \equiv \partial/\partial x^\mu$; $\partial^\mu \equiv \eta^{\mu\nu}\partial_\nu$; $h = \eta^{\mu\nu}h_{\mu\nu}$ is the trace of $h_{\mu\nu}$; and $\Box = \eta^{\mu\nu}\partial_\mu\partial_\nu$ is the flat space d'Alembertian operator. This is a bit cumbersome, so we change variables in an effort to tidy this up. We define the trace-reversed perturbation, $\bar{h}_{\mu\nu} = h_{\mu\nu} - n_{\mu\nu}h/2$, which also implies that $\bar{h} = \eta^{\mu\nu}\bar{h}_{\mu\nu} = h - 2h = -h$, such that $h_{\mu\nu} = \bar{h}_{\mu\nu} - n_{\mu\nu}\bar{h}/2$. The Einstein tensor then becomes

$$G_{\mu\nu} = \frac{1}{2}\left(\partial_\mu\partial^\alpha \bar{h}_{\alpha\nu} + \partial_\nu\partial^\alpha \bar{h}_{\alpha\mu} - \Box\bar{h}_{\mu\nu} - \eta_{\mu\nu}\partial^\alpha\partial^\beta \bar{h}_{\alpha\beta}\right). \tag{2.4}$$

Similar to electromagnetism, we can ditch spurious degrees of freedom from our equations by choosing an appropriate gauge. If we consider the coordinate transformation $x^\alpha \mapsto x^\alpha + \xi^\alpha$, the transformation of the metric perturbation to first order is $h_{\mu\nu} \mapsto h_{\mu\nu} - (\partial_\mu\xi_\nu + \partial_\nu\xi_\mu)$. Asserting $\partial_\mu\xi_\nu$ to be of the same order as $|h_{\mu\nu}|$, the transformed metric perturbation retains the condition $|h_{\alpha\beta}| \ll 1$. This symmetry allows us to choose the *Lorenz gauge* (sometimes referred to as the *De Donder gauge*, or *Hilbert gauge*, or *harmonic gauge*) where $\partial^\nu\bar{h}_{\mu\nu} = 0$, such that the Einstein tensor reduces to the much more compact

$$G_{\mu\nu} = -\frac{1}{2}\Box\bar{h}_{\mu\nu}. \tag{2.5}$$

Note that in choosing the Lorenz gauge we have imposed 4 conditions that reduce the number of degrees of freedom in the symmetric 4×4 $h_{\mu\nu}$ matrix from 10 down to 6. Finally, the field equations reduce to

$$\Box \bar{h}_{\mu\nu} = -16\pi T_{\mu\nu}, \tag{2.6}$$

which can be generally solved using the radiative Green's function:

$$\bar{h}_{\mu\nu}(\vec{x}, t) = 4 \int d^4x' \frac{T_{\mu\nu}(\vec{x}', t)}{|\vec{x} - \vec{x}'|}. \tag{2.7}$$

Examining Eq. 2.6 far from the source gives $\Box \bar{h}_{\mu\nu} = 0$, whose solution is clearly wave-like with propagation speed c. We might think that all components of the metric perturbation are radiative. This is a gauge artefact (13), where, in general, we can split the metric perturbation into (i) gauge degrees of freedom, (ii) physical, radiative degrees of freedom, and (iii) physical, non-radiative degrees of freedom. The Lorenz gauge is preserved under a coordinate transformation $x^\mu \mapsto x^\mu + \xi^\mu$, provided that $\Box \xi_\mu = 0$, which also implies that $\Box \xi_{\mu\nu} \equiv \Box(\partial_\mu \xi_\nu + \partial_\nu \xi_\mu - \eta_{\mu\nu} \partial_\rho \xi_\rho) = 0$. This means that the 6 independent components of $\bar{h}_{\mu\nu}$ can have $\xi_{\mu\nu}$ subtracted, which depend on 4 independent functions ξ_μ, thereby distilling the GW information down to 2 independent components of the metric perturbation. The conditions imposed on $\bar{h}_{\mu\nu}$ are such that $\bar{h} = 0$ (therefore $h_{\mu\nu} = \bar{h}_{\mu\nu}$), and $h^{0i} = 0$, which lead to the following properties of the metric perturbation that define the *transverse-traceless* (TT) gauge:

$$h^{0\mu} = 0, \quad h^i_i = 0, \quad \partial^j h_{ij} = 0. \tag{2.8}$$

Choosing a coordinate system such that we have a plane GW propagating in the z-direction in a vacuum, we can write the solution to $\Box \bar{h}_{\mu\nu} = 0$ as

$$h^{\mathrm{TT}}_{\mu\nu}(t, z) = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & h_+ & h_\times & 0 \\ 0 & h_\times & -h_+ & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \cos\left[\omega(t - z)\right], \tag{2.9}$$

where h_+ and $h_\times$ are the amplitudes of the two distinct polarizations of GWs permitted within general relativity, denoted as "plus" (+) and "cross" (×) modes for how they tidally deform a circular ring of test masses in the plane perpendicular to the direction of propagation.

The tidal deformation of spacetime caused by a GW as it propagates is at the heart of all ground-based (LIGO-Virgo-KAGRA), Galactic-scale (pulsar-timing arrays), and planned space-borne (LISA) detection efforts. Consider the *coordinate* separation of two spatially-separated test masses as a GW sweeps by. The test masses fall along geodesics of the perturbed spacetime, such that in the weak-field regime, and to first order in amplitude of the wave, the coordinate separation of the test masses remains unchanged. However, the

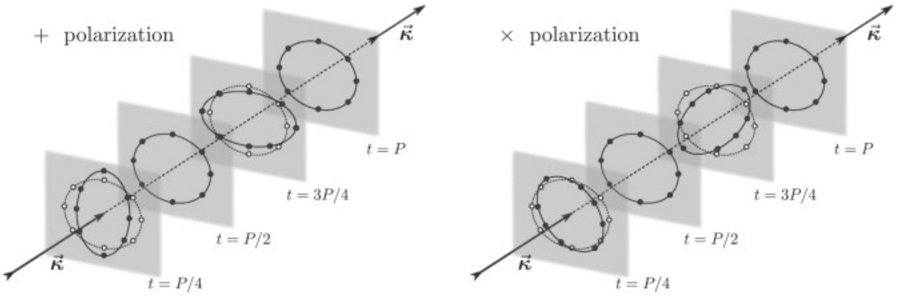

Figure 2.2: The periodic deformation of spacetime caused by a GW is illustrated for the two distinct polarizations permitted within GR. The influence of the GW is entirely in the plane perpendicular to the direction of propagation. Figure reproduced with permission from Ref. (30).

proper separation between the test masses *is* affected, and depends on the wave properties. The fractional change in the proper distance between two test masses separated by $\Delta x = L$ on the x-axis of a coordinate system due to the passage of a GW is given by $\delta L/L \simeq h_{xx}/2$, leading to a definition of the GW amplitude as the *strain*. For a periodic signal such that $h_{xx}(t, z = 0) = h_+ \cos \omega t$, we see that this proper distance separation oscillates according to $\delta \ddot{L} = -2\pi^2 f^2 L h_+ \cos \omega t$. We can see from Eq. 2.9 that the $+$-polarisation will lengthen distances along the x-axis while simultaneously contracting distances along the y-axis. The influence of the $h_\times$ mode is similar, but rotated by $\pi/4$ degrees counter-clockwise in the xy-plane. This tidal deformation in the plane perpendicular to the direction of propagation is illustrated for a full wave-cycle in Fig. 2.2.

2.2.2.1 The Quadrupole Formula

In the weak-field ($v \ll 1$) limit, far from a source, the leading order contribution to the solution of Eq. 2.6 is a function of the accelerating quadrupole moment of the source's mass distribution. Stress-energy conservation implies that the monopole makes no contribution due to conservation of the system's total energy, while the dipole moment makes no contribution due to conservation of momentum of the system's center-of-mass. Therefore the *quadrupole radiation formula* for the spatial components of the metric perturbation is (12),

$$h_{ij} = \frac{2}{r}\Lambda_{ij,kl}\frac{d^2 Q_{kl}}{dt^2}, \tag{2.10}$$

where r is the distance to the source, and Q_{kl} is the *reduced* quadrupole moment of $\rho(t, \vec{x})$ (the source's mass density), which is defined as,

$$Q_{ij} = \int d^3x\, \rho(t, \vec{x}) \left(x_i x_j - \frac{1}{3} r^2 \delta_{ij} \right), \tag{2.11}$$

and $\Lambda_{ik,jl}$ is the *Lambda tensor* that projects the metric perturbation in the Lorenz gauge into the TT gauge (see Ref. (29)).

The most relevant source system for us is a binary composed of compact objects (COs), whether white dwarfs, neutron stars, or black holes. Let us consider that each CO (of mass M) orbits one another at a distance $R(t)$ from their common center of mass (assumed to be far enough apart that we can ignore any tidal disruption effects) with slowly varying angular velocity $\omega(t)$. The COs are assumed to be moving at non-relativistic speeds to simplify the calculation of the quadrupole moment tensor. Kepler's third law gives us $\omega^2 = M/4R^3$, such that the total energy of the system is $E = -M^2/4R$. The orbital geometry is defined such that it lies in the $x-y$ plane with the origin coinciding with the system's center of mass. Each CO's coordinates at $t = 0$ are thus

$$x_1 = -x_2 = R\cos\omega t, \quad y_1 = -y_2 = R\sin\omega t, \quad z_1 = z_2 = 0. \tag{2.12}$$

Evaluating the second time-derivative of the reduced quadrupole mass-moment, and plugging into Eq. 2.10, the radiative components of the GWs from this system are

$$h_{\mu\nu} = -\frac{8MR^2\omega^2}{r}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \cos 2\omega t & \sin 2\omega t & 0 \\ 0 & \sin 2\omega t & -\cos 2\omega t & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \tag{2.13}$$

where the GW frequency is *twice* the binary orbital frequency due to the quadrupolar nature of the emission. Note that the distance to the source is directly encoded in the amplitude of this leading-order radiative term.

Just like electromagnetic waves, or even waves on a string, the energy density in GWs is $\propto \omega^2 h^2$, where h is the amplitude of the wave. The amplitude is already proportional to a second time derivative of the reduced quadrupole moment, where the the factor of ω implies an additional time derivative. Therefore, based on simple scaling arguments, the energy density in GWs should be proportional to a quadratic combination of the third time-derivative of the quadrupole mass moment. In a background spacetime that is approximately flat far from the source, the Issacson stress-energy tensor of a GW is

$$T_{\mu\nu} = \frac{1}{32\pi}\langle \partial_\mu \hat{h}_{\alpha\beta} \partial_\nu \hat{h}^{\alpha\beta} \rangle, \tag{2.14}$$

where $\langle\cdot\rangle$ denotes an average over several wave cycles. Evaluating the energy-flux elements of Eq. 2.14 in the quadrupole approximation, and integrating over the sphere, the GW luminosity of the source system

$$L_{\mathrm{GW}} \equiv \frac{dE_{\mathrm{GW}}}{dt} = \frac{1}{5}\left\langle \frac{d^3 Q_{ij}}{dt^3}\frac{d^3 Q^{ij}}{dt^3} \right\rangle, \tag{2.15}$$

which, for a CO binary gives

$$L_{\mathrm{GW}} = \frac{128}{5} M^2 R^4 \omega^6 = \frac{128}{5} 4^{1/3} \left(\frac{\pi M}{P}\right)^{10/3} \tag{2.16}$$

By equating the loss in the binary's orbital energy with GW emission, we can get a qualitative understanding of the frequency and strain evolution as the binary inspirals toward an eventual merger. The rate of change of the binary's orbital period is $dP/dt \propto P^{-5/3}$, such that the GW frequency evolution is $df_{\mathrm{GW}}/dt \propto f_{\mathrm{GW}}^{11/3}$. The strain amplitude is $h \propto R^2 f_{\mathrm{GW}}^2 \propto f_{\mathrm{GW}}^{2/3}$. Hence the orbital evolution, as driven by GW emission, causes the strain amplitude to increase in tune with the frequency, with both said to be "chirping" as the binary progresses toward merger.

2.3 STOCHASTIC GRAVITATIONAL WAVE BACKGROUNDS

Imagine yourself at a crowded party. All the guests are mingling and chatting to create a background hum of the usual social small-talk. You perk up your ears to attempt to hear whether your friend is stuck in an awkward conversation across the room, but alas, all you can hear is that damned background hum. Nevertheless, if we brought the lens of statistical inference to this party banter, there would be interesting information – the distribution of laughter could tell us whether this is a party worth sticking around at, and by localizing regions of high laughter one may be able to zero-in on the life and soul of this get-together. Occasionally, someone who may have had a bit too much to drink may forget to regulate their volume, creating a distinct sentence that can be heard above the fray.

Now imagine translating this scenario to GW signals. A cosmological population of systems emitting GWs of a similar frequency and comparable amplitude may not be able to be individually resolved by a detector. In such a scenario, the signals sum incoherently to produce a stochastic background of GWs (SGWB). "Stochastic" here formally means that we treat this background as a random process that is only studiable in terms of its statistical properties. As a function of time, the SGWB may look like random fluctuations without any discernible information, but if we dig deeper and look at its spectral information then it begins to reveal its secrets. It may have more power at lower frequencies than at higher frequencies, indicating that it varies on longer timescales. It may have a sharp uptick at a few frequencies, potentially revealing a few of those loud "voices" at the party. Let us now see how we describe a SGWB, and how it manifests as signals in our detectors. Much of the material in the following subsections has been adapted from the excellent treatment in Romano & Cornish (31).

La quadrature du cercle

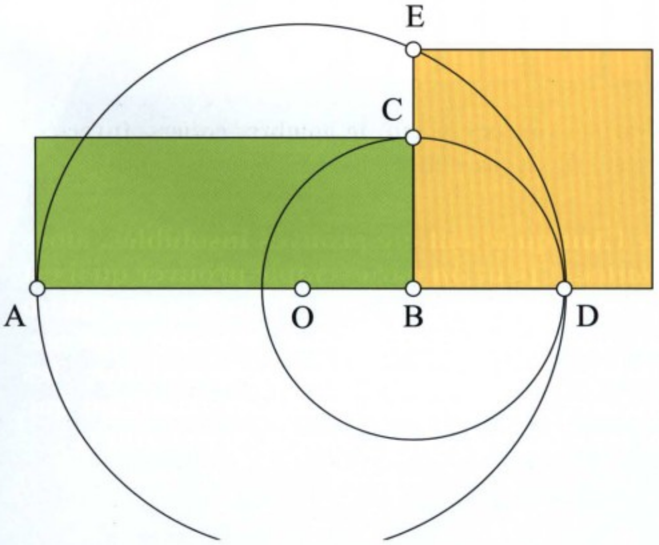
« Quadrature du cercle » a pris le sens de « problème impossible ». Pourtant, elle est réalisable ! De manière approchée, elle correspond au calcul du nombre π. De façon exacte, à l'invention de divers instruments ou techniques. Alors qu'est-ce qui est impossible dans la quadrature ?

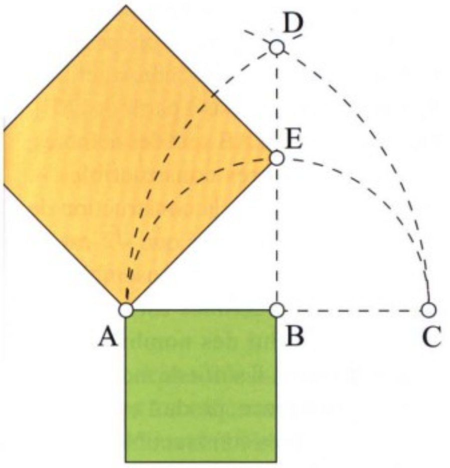
Pour calculer l'aire d'un domaine, les mathématiciens de l'Antiquité cherchaient à construire un carré de même aire que le domaine donné. Cette opération est simple si on part d'un rectangle, par exemple. Dans ce cas, la construction se fait à la règle et au compas (voir *le Cercle*, Bibliothèque Tangente 36, 2009).



De façon générale, pour les Anciens Grecs, résoudre un problème revenait souvent à construire sa solution à la règle et au compas. De façon précise, la procédure est la suivante. On se donne une figure composée d'un certain nombre de points (au moins deux). Ensuite, on demande de construire, à la règle (non graduée) et au compas, la solution d'un problème associée à cette figure. Par exemple, on peut construire la diagonale d'un carré en n'en connaissant qu'un côté, [AB], en utilisant trois fois le compas et deux fois la règle. Cette construc-

Quadrature du rectangle à la règle et au compas : le carré jaune a même aire que le rectangle vert. Pour construire le carré à partir du rectangle, on trace d'abord le cercle de centre B passant par C. Il coupe le prolongement de [AB] en D, puis le milieu O de [AD] et le cercle de centre O passant par D. Il coupe le prolongement de [BC] en E. On construit alors un carré de côté [BE].

tion permet de réaliser la duplication du carré, c'est-à-dire de construire un carré d'aire double d'un carré donné.



Duplication du carré : le carré jaune a une aire double de celle du carré vert. Pour construire le jaune à partir du vert, on trace le cercle de centre B passant par A, il recoupe (AB) en C. On trace alors les cercles de centres A et C passant par C et A. Ils se coupent en un point D. On trace la droite (BD). Elle coupe le premier cercle en un point E. [AE] est un côté du carré d'aire double, qui se trouve ainsi complètement déterminé.

Sur le papier, une telle construction donne une valeur approchée médiocre. La précision totale est impossible, sauf en idéal. Pour les mathématiciens grecs comme pour leurs successeurs, derrière ces objets (règle et compas) se cachent des concepts. Ceux-ci sont définissables de manière abstraite à partir de la notion de distance, plus court chemin d'une part et points équidistants de l'autre. Dans le monde des idées dont parle Platon (au IV^e siècle avant notre ère), la construction à la règle et au compas est exacte. Cette justification est souvent avancée pour expliquer l'utilisation exclusive de ces instruments. Son défaut

De la construction à la règle et au compas

Partons de deux points distincts O et I. Réaliser une construction géométrique à la règle et au compas à partir de ces deux points revient à définir une suite de points $(A_n)_{n \geq 0}$ avec $A_0 = O$, $A_1 = I$, et, pour tout $n > 1$, A_n déterminé par intersection de droites ou de cercles construits à partir des points précédents. Munissons le plan d'un repère orthonormé dont O est l'origine et I le point de coordonnées $(1, 0)$. Les droites et les cercles du plan possèdent des équations cartésiennes du type $ax + by = c$ et $(x - a)^2 + (y - b)^2 = c^2$, où les paramètres a, b et c sont déterminés par opérations algébriques sur les coordonnées des points définissant ces droites et ces cercles. Les coordonnées d'un point A_n de la suite s'obtiennent donc par résolution de systèmes de la forme :

$$\begin{cases} ax + by = c \\ a'x + b'y = c' \end{cases}, \quad \begin{cases} ax + by = c \\ (x - a')^2 + (y - b')^2 = c'^2 \end{cases},$$

$$\text{ou} \begin{cases} (x - a)^2 + (y - b)^2 = c \\ (x - a')^2 + (y - b')^2 = c'^2 \end{cases}.$$

En résolvant ces systèmes, on observe que les coordonnées du point A_n sont solutions d'équations algébriques de degré 1 ou 2, équations dont les coefficients sont obtenus à partir des coordonnées des points A_0, $A_1 \ldots A_{n-1}$. Cela permet de justifier le résultat de Wantzel : les coordonnées des points constructibles sont obtenues par succession d'additions, de soustractions, de multiplications, de divisions et de passages à la racines carrés à partir de nombres entiers. Inversement, il est possible de construire un point dont les coordonnées soient de la forme ci-dessus.

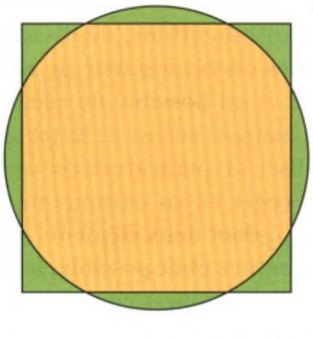
Réaliser la quadrature du cercle revient à construire à la règle et au compas une suite finie de points $(A_n)_{n \geq 0}$ dont deux éléments A_k et A_m vérifient. Si cette quadrature était possible, les coordonnées des points étant des nombres constructibles, π serait lui aussi un nombre constructible. En prouvant en 1882 que π est transcendant, Lindemann établit par la même occasion que π n'est pas constructible : la quadrature du cercle est impossible.

D. D.

L'impossibilité de la quadrature tient dans les moyens autorisés…

est de s'appliquer également à d'autres, comme l'équerre, que les mathématiciens grecs refusaient pour leurs constructions. De fait, la raison profonde de l'utilisation exclusive de la règle et du compas est d'ordre mystique, pas mathématique. Le cercle et la droite sont considérés comme les seules formes parfaites. Chez les pythagoriciens, le cercle est associé au « un », donc à la divinité, la droite à la rectitude morale, aux hommes droits. Les mathématiciens grecs s'engluèrent très vite dans la pensée que toute grandeur doit être construite à la règle et au compas, idée abandonnée de nos jours même si d'aucuns veulent l'adapter à l'ère informatique. L'idée est aussi pertinente que de remplacer les automobiles par des diligences tirées par des robots.

Cette question d'un autre temps permet simplement de motiver celle de l'existence de nombres non constructibles à la règle et au compas, π en particulier, qui est le rapport de l'aire d'un cercle au carré construit sur l'un de ses rayons. Autrement dit, la quadrature du cercle à la règle et au compas en un nombre fini d'étapes est impossible.

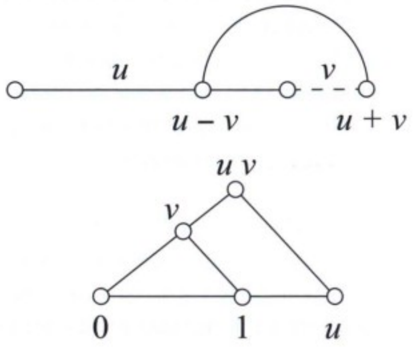


La quadrature du cercle consiste à construire, à la règle et au compas et en un nombre fini d'étapes, un carré de même surface.

Si on change les règles, la quadrature du cercle est possible, soit de façon approchée, soit en utilisant d'autres moyens que la règle et le compas.

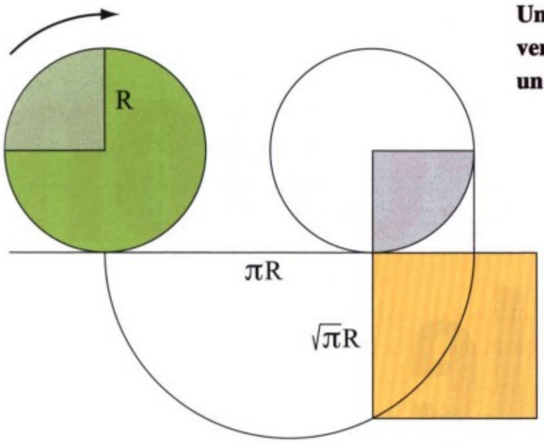
Corps des nombres constructibles

La construction à la règle et au compas se transpose parmi les nombres. On se donne un segment [AB] et on considère tous les segments [CD] constructibles à la règle et au compas à partir de [AB]. Les rapports CD / AB sont des nombres, appelés « nombres constructibles ». Ainsi, on déduit de la construction de la diagonale d'un carré que $\sqrt{2}$ est un nombre constructible. L'ensemble des nombres constructibles est un corps, inclus dans celui des nombres réels. Pour le prouver, il suffit de montrer que somme, différence, produit et quotient de deux nombres constructibles le sont de même. Les deux premiers cas se résolvent facilement avec un coup de règle et deux de compas. Pour les deux autres, il est nécessaire d'utiliser le théorème de Thalès. De plus, ce théorème permet de montrer que les nombres rationnels sont tous constructibles.



Constructions à la règle et au compas : si *u* et *v* sont constructibles, alors *u* + *v* et *u* – *v* le sont grâce à une utilisation du compas. Le produit *u v* l'est d'après le théorème de Thalès. L'inverse de *u* se construit en faisant coïncider *u v* avec 1 dans la figure du bas.

Par ailleurs, en utilisant les équations de droites et de cercles, on démontre que les nombres constructibles sont



Une quadrature du cercle. On fait tourner le cercle vert d'un demi-tour, ce qui introduit le nombre π, puis un carré de même aire que le cercle initial.

Carl von Lindemann a montré l'impossibilité de la quadrature du cercle en prouvant la transcendance du nombre π.

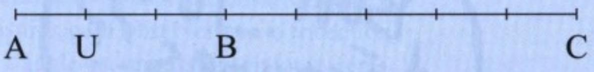
tous algébriques, c'est-à-dire solutions d'équations à coefficients entiers. Pierre-Laurent Wantzel (1814–1848) précisa ce corps des nombres constructibles et prouva ainsi l'impossibilité de certaines constructions, comme la duplication du cube, qui consiste à construire un cube de volume double d'un cube donné. Dans ce cas, il suffit de montrer que la racine cubique de 2 ne peut être construite, du fait des équations qu'elle vérifie.

Les premiers nombres non algébriques, c'est-à-dire *transcendants*, ont été découverts en 1844 par Joseph Liouville (1809–1882), mais il a fallu attendre Charles Hermite (1822–1901) en 1873 pour que la transcendance de la constante d'Euler *e* soit démontrée. En 1882, Ferdinand von Lindemann (1852–1939) montra que π est transcendant, donc non constructible. Sa preuve, très technique, dépasse largement les ambitions de cet article. Elle prouve l'impossibilité de la quadrature du cercle, ce qui n'a pas tari l'imagination des quadrateurs, qui continuent aujourd'hui encore à envoyer à *Tangente* leurs « solutions » à un problème que l'on sait insoluble depuis longtemps.

H. L.

Un peu d'histoire

Pour les mathématiciens de la Grèce antique, il n'existait pas d'autres nombres que ceux que nous nommons de nos jours les entiers naturels (et encore… 1 n'était pas considéré comme nombre, mais comme principe de tout nombre). Les premiers mathématiciens, comme Pythagore, pensaient que *« tout est nombre »*, c'est-à-dire que deux grandeurs (longueurs, aires…) avaient toujours une commune mesure, en d'autres termes étaient commensurables.



Commensurabilité : AB et AC sont commensurables s'il existe un point U tel que AB et AC soient multiples de AU.

Malheureusement pour sa doctrine, Pythagore prouva lui-même qu'il existe des grandeurs incommensurables, le côté et la diagonale d'un carré par exemple. Les longueurs commensurables correspondent à ce que nous nommons *nombres rationnels*, les autres aux *nombres irrationnels*. La diagonale du carré est cependant constructible à la règle et au compas, c'est pourquoi les mathématiciens grecs remplacèrent leur idéal de commensurabilité en celui de construction à la règle et au compas. Ils nous ont ainsi légué le problème de la quadrature du cercle, dont on n'a suspecté l'impossibilité que vers le XVI^{e} siècle.

La trisection de l'angle

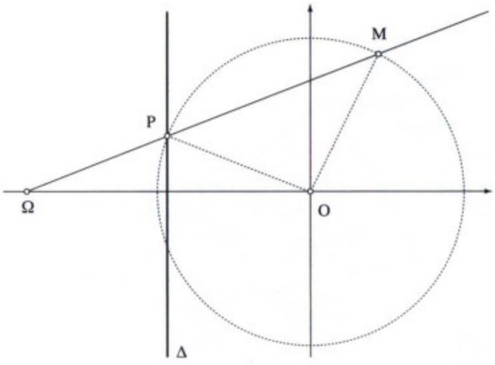
À l'aide d'une règle et d'un compas, il est assez facile de séparer un angle en deux parts égales en construisant une bissectrice. Est-il de même possible de le séparer en trois ? C'est le problème de la trisection de l'angle, qui date de l'antiquité grecque.

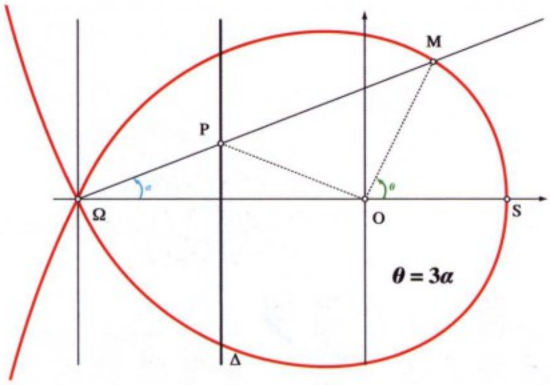
Bon ...tu découpes ??
Heu...
CATOUNE

De nombreux mathématiciens se sont investis dans le problème de la trisection de l'angle, proposant d'abord des solutions partielles, jusqu'à parvenir à établir que la trisection de l'angle est en fait impossible en toute généralité.

La trisectrice de Maclaurin

Parmi les solutions proposées pour amorcer une trisection à la règle et au compas, plusieurs sont basées sur l'introduction de courbes planes dont les points seraient constructibles à la règle et au compas. C'est le cas de la trisectrice de Maclaurin, introduite au XVIII^e siècle. Pour la définir, considérons deux points distincts O et Ω du plan et introduisons la médiatrice Δ du segment [OΩ]. Pour un point P variant sur Δ, on considère le point M déterminé par la deuxième l'intersection de la droite (PΩ) et du cercle de centre O passant par P.

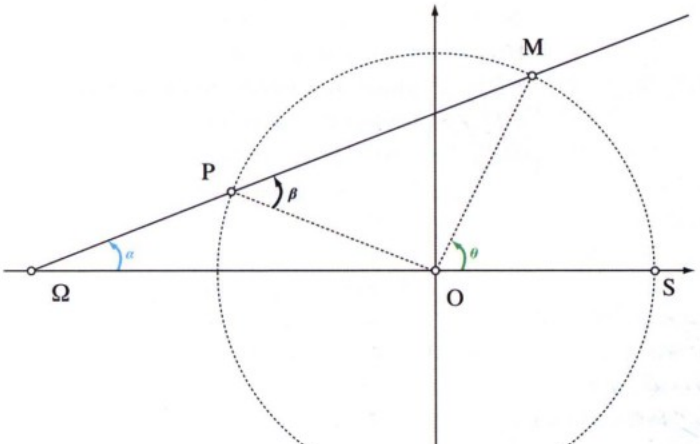




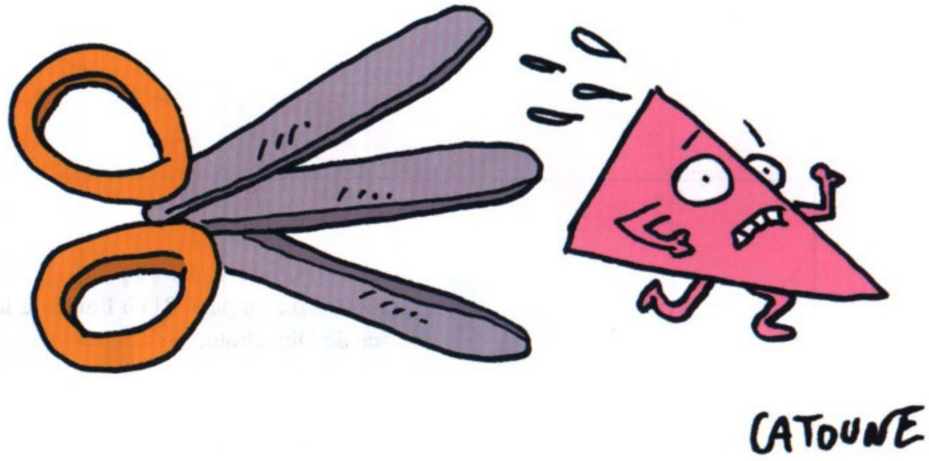
Ce point M parcourt la courbe trisectrice qui nous intéresse. Si l'angle à couper en trois est $\widehat{SOM}$, sa trisection apparaît comme étant $\widehat{S\Omega M}$.

En fait, cette courbe est inspirée d'une idée déjà introduite par Archimède. Considérons un cercle de rayon R dont le centre est le sommet de l'angle à découper. Définissons l'axe des abscisses par un côté de cet angle ; le cercle introduit coupe alors l'autre côté en un point M. À l'aide de notre règle graduée, traçons la droite issue de M coupant l'axe des abscisses en un point Ω et le cercle en un point P de sorte que ΩP = R. Par cette dernière condition, nous exploitons une graduation de la règle ; ce n'est donc pas une construction à la règle et au compas au sens strict. En observant que les triangles OPΩ et POM sont isocèles, on établit aisément que l'angle $\widehat{SOM}$ est égal au triple de $\widehat{S\Omega M}$.

La trisection de l'angle à la règle et au compas est cependant impossible. Certes, il est certains angles qu'il est facile de couper en trois ; c'est par exemple le cas de l'angle plat, de mesure π. En effet, puisque $\cos(\pi/3) = 1/2$, il n'est pas difficile de construire un angle de mesure $\pi/3$ (et c'est même très pratique pour découper un gâteau en six parts sensiblement égales…). Ensuite, pour observer que la trisection de l'angle est impossible en toute généralité, observons qu'un angle de mesure $\pi/3$ ne peut, lui, être séparé en trois. Pour cela, considérons le nombre

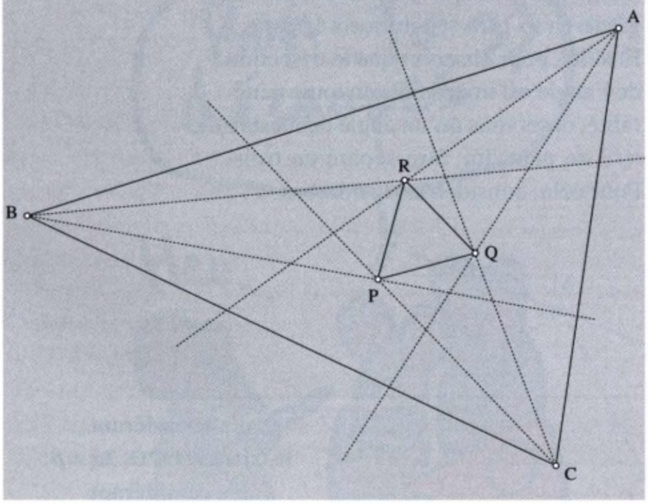


En considérant le triangle OPΩ, $2\alpha = \beta$.
En considérant le triangle POM, $2\beta = \alpha + \theta$.



Le triangle de Morley

Les bissectrices intérieures d'un triangle concourent en un point : c'est le centre du cercle inscrit dans ce triangle. Les trisectrices intérieures d'un triangle se coupent elles aussi de façon remarquable : leurs points d'intersection déterminent un triangle... équilatéral ! C'est le triangle de Morley, découvert par Frank Morley à la toute fin du XIX^e siècle.



$x = \cos(\pi/9)$. En exploitant l'identité $\cos(3a) = 4\cos^3 a - 3\cos a$, on établit que x est solution de l'équation $8x^3 - 6x - 1 = 0$. C'est une équation algébrique construite à partir d'une expression polynomiale à coefficients entiers (plus précisément, c'est une équation algébrique de degré 3).

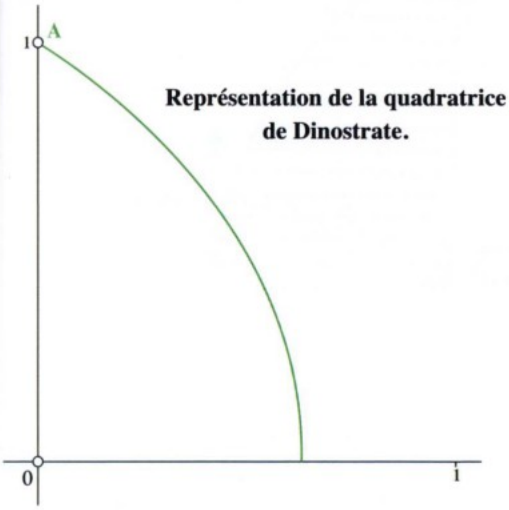
Au XIX^e siècle, Wantzel a caractérisé les points constructibles à la règle et au compas en un nombre fini d'étapes à partir d'une unité donnée. Ces points sont ceux dont les coordonnées sont racines d'équations algébriques de degré une puissance de 2, mais qui ne sont racines d'aucune de degré strictement inférieur. Par exemple, le point de coordonnées $(1 + \sqrt{5})/2$ et $2^{1/4}$ est constructible, car ses coordonnées sont respectivement racines des équations $x^2 - x - 1 = 0$ et $x^4 - 2 = 0$.

Si l'on pouvait construire un angle de mesure $\pi/9$ à la règle et au compas, il en serait de même du point de coordonnées $(\cos(\pi/9), \sin(\pi/9))$. Or, son abscisse x est solution d'une équation de degré 3, et on peut justifier qu'elle n'est solution d'aucune équation de degré strictement inférieur : la construction à la règle et au compas d'un angle de mesure $\pi/9$ est donc tout bonnement impossible. Il en est alors de même de la trisection de l'angle en général.

D. D.

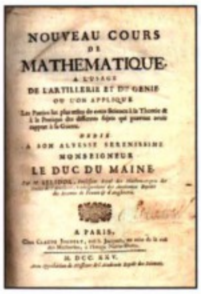
par Jean-Alain Roddier

La quadratrice de Dinostrate



Représentation de la quadratrice de Dinostrate.

À l'origine, la quadratrice de Dinostrate est une courbe servant à la trisection approchée des angles. Elle aurait été définie par le grec Hippias d'Élis au V^e siècle avant notre ère, avant d'être reprise un peu plus tard par le mathématicien grec Dinostrate pour effectuer la quadrature approchée du cercle.



NOUVEAU COURS
DE
MATHEMATIQUE
A L'USAGE
DE L'ARTILLERIE ET DU GENIE
OU L'ON APPLIQUE
DEDIÉ
A SON ALTESSE SERENISSIME
MONSEIGNEUR
LE DUC DU MAINE
A PARIS,
M. DCC. XXV.

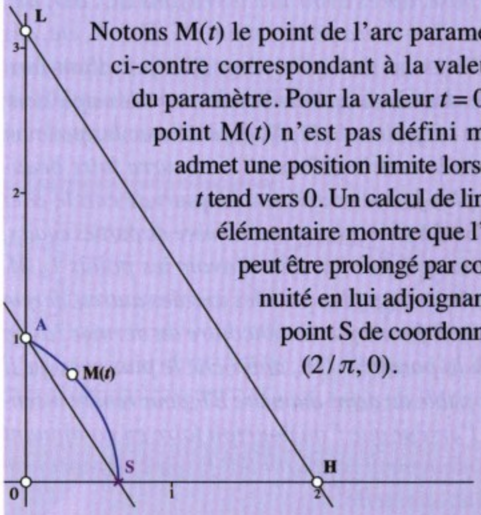
En 1725, dans son Nouveau Cours de mathématique à l'usage de l'artillerie et du génie, le mathématicien Bernard Forest de Bélidor (1698–1761) expose une méthode de construction point par point de la quadratrice de Dinostrate, puis il explique comment se servir de cette courbe construite « mécaniquement » pour réaliser la trisection de l'angle (voir l'article sur ce sujet). Une représentation paramétrique du support de la quadratrice de Dinostrate est

$$\begin{cases} x = \dfrac{t}{\tan\left(\dfrac{\pi}{2}t\right)}, & \text{avec } 0 < t \leq 1. \\ y = t \end{cases}$$

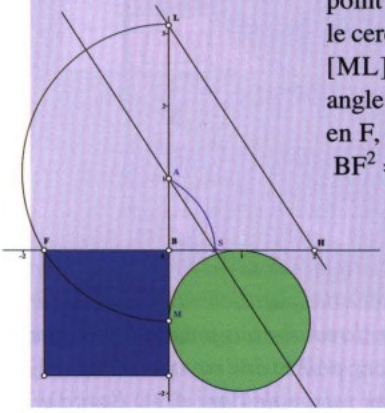
Dinostrate et la quadrature du cercle

La quadrature du cercle consiste à construire un carré d'aire π à partir d'un cercle de rayon 1, ce qui revient à construire un segment de longueur $\sqrt{\pi}$. On peut résoudre ce problème de manière exacte (voir en page 21) à l'aide de la quadratrice de Dinostrate.

Notons M(t) le point de l'arc paramétré ci-contre correspondant à la valeur t du paramètre. Pour la valeur $t = 0$, le point M(t) n'est pas défini mais admet une position limite lorsque t tend vers 0. Un calcul de limite élémentaire montre que l'arc peut être prolongé par continuité en lui adjoignant le point S de coordonnées $(2/\pi, 0)$.



Considérons le point H (2, 0), puis le point L d'intersection de l'axe des ordonnées avec la parallèle à la droite (AS) passant par H (voir la figure ci-dessus). L a pour coordonnées (0, π). On peut alors construire le segment [BF], qui a pour longueur $\sqrt{\pi}$. Pour cela, on considère le point M(–1, 0), puis le cercle de diamètre [ML]. Dans le triangle MFL rectangle en F, nous avons $BF^2 = BM\ BL = \pi$.

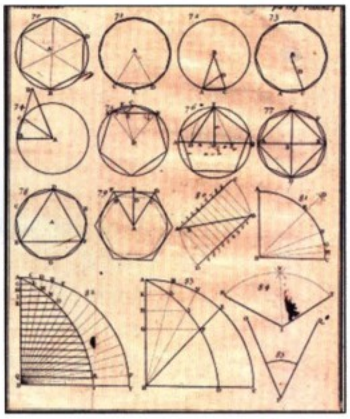


par Jean-Alain Roddier

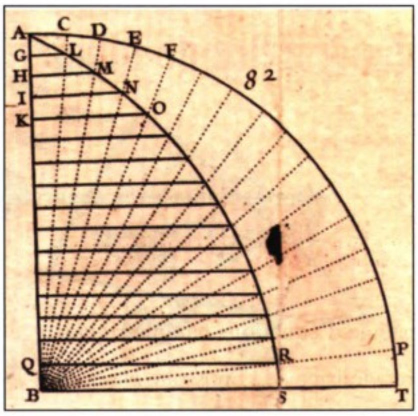
Le texte de Bélidor

Bernard Forest de Bélidor a décrit la construction point par point de la quadratrice de Dinostrate dans le texte suivant.

« Pour décrire cette courbe, il faut diviser le rayon AB en un grand nombre de parties égales ; de manière que le quart de cercle AT puisse être divisé en un même nombre de parties égales ; ainsi nous supposerons que l'on a divisé le quart de cercle en seize parties égales ; aussi bien que le rayon AB. Cela posé, après avoir tiré les rayons BC, BD, BE, BF, etc. l'on tirera par les points G, H, I, K, etc. des parallèles au demi-diamètre BT, qui allant rencontrer les rayons qui divisent le quart de cercle donneront les points L, M, N, O, etc. avec lesquels on tracera la courbe AS, que l'on pourra faire beaucoup plus juste, en divisant le quart de cercle & et le rayon BA en un plus grand nombre de parties égales, que l'on n'a fait ici, afin d'avoir les points L, M, N, O, beaucoup plus près les uns des autres, & que le point R formé par la rencontre du dernier rayon BP, & la parallèle QR, approche le plus près qu'il est possible du demi-diamètre BT, pour rendre insensible l'erreur que l'on pourroit faire en continuant mécaniquement la courbe AR jusqu'à la rencontre du demi-diamètre. »



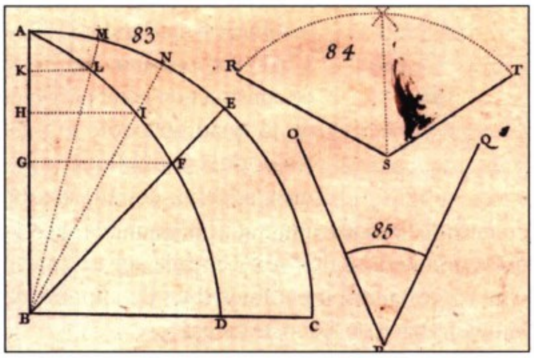
« Il faut remarquer que, par la génération de cette courbe, si l'on mène des parallèles HM & KO, qui ailleurs rencontrer la courbe aux points M & O, que si l'on tire par ces points des rayons BD & BF, qu'il y aura même raison de l'arc AD à l'arc DF, que de la ligne AH à la ligne HK. »



Autrement dit : $\frac{\text{longueur }(\overset{\frown}{AD})}{\text{longueur }(\overset{\frown}{DF})} = \frac{AH}{HK}$.

De là à la trisection de l'angle, il n'y a qu'un pas :

« Supposant que l'on ait tracé sur un morceau de corne ou de carton bien uni, la courbe AD de la façon qu'on vient de l'enseigner, on propose de diviser l'Angle OPQ en trois parties égales. Pour résoudre ce Problème, supposant que la courbe accompagnée de son quart de cercle AC, je fais l'angle ABE égal à l'angle donné, & au point F, où le rayon BE coupe la courbe AD, j'abaisse la perpendiculaire FG sur le diamètre AB, qui me donne la partie AG, que je divise en autant de parties égales que l'angle donné soit divisé. »



Pour ce qui relève de la trisection de l'angle obtus $\widehat{RST}$, Bélidor propose de diviser cet angle en deux angles égaux puis d'opérer la trisection de l'angle aigu ainsi obtenu.

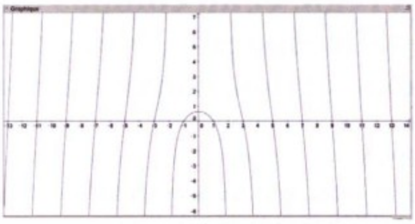
Impossibles, ces figures ? (4)

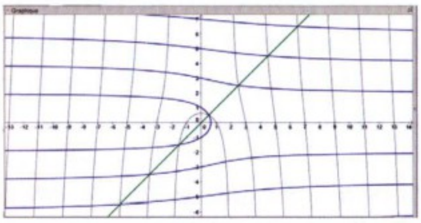
Équation paramétrique de la quadratrice de Dinostrate

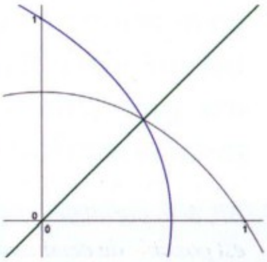
Les coordonnées du point P (voir les notations en page ci-contre) sont $(\cos(\pi t/2), \sin(\pi t/2))$. La droite (BP) a donc pour équation réduite $y = x\tan(\pi t/2)$. Le point R a pour ordonnée t (la même que celle du point Q) et il appartient à la droite (BP) ;on en déduit les coordonnées de R, qui sont : $\left(\dfrac{t}{\tan\left(\dfrac{\pi}{2}t\right)}, t\right)$.

Un système d'équations paramétriques de la quadratrice de Dinostrate est donc $\begin{cases} x = \dfrac{t}{\tan\left(\dfrac{\pi}{2}t\right)}, \\ y = t \end{cases}$ avec $t \in \mathbb{Q} \cap \,]0,1]$.

On peut ainsi obtenir une équation du support de la quadratrice de Dinostrate : $x = y/\tan(\pi y/2)$.
Pour construire cette courbe, il suffit de tracer la courbe d'équation $y = x/\tan(\pi x/2)$ puis de prendre sa symétrique par rapport à droite d'équation $y = x$. On se restreint ensuite à [0, 1].

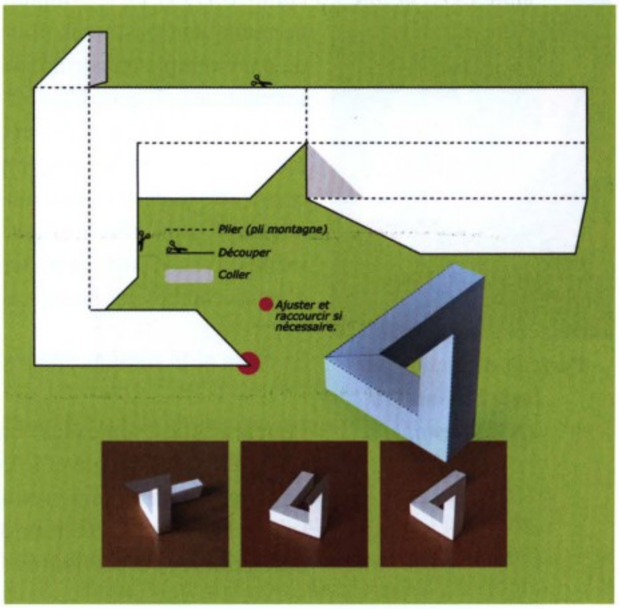






Réaliser le tripoutre

Pour réaliser un tripoutre, on peut commencer par reproduire, découper et assembler le modèle en suivant les simples indications de la figure ci-contre. Si tout se passe bien, vous obtiendrez une sorte de maquette avec quatre barres (en papier) à angle droit. Maintenant, il s'agit de se positionner avec un appareil photo face à la maquette et de choisir un point de vue, en jouant sur la distance qui sépare l'objectif de la maquette, afin de fusionner visuellement la barre supérieure proche du photographe avec la barre du fond (voir les différents essais ci-contre). Il est parfois nécessaire de rogner l'angle de la barre supérieure (marqué avec un point rouge) pour le faire coïncider parfaitement avec la barre à l'arrière-plan. Avec un peu de patience, et beaucoup d'essais, vous obtiendrez d'excellents résultats !



L'illustration ci-dessus montre comment notre cerveau perçoit un seul et unique triangle ABC alors que les droites qui le représentent dans l'espace réel ont une orientation fort différente. Il s'ensuit qu'il est possible de fabriquer de nombreuses variantes de la maquette pour atteindre le même résultat visuel.

(2) Use of analytic function or Airy's stress function in the form of complex variable; and

(3) Application of boundary conditions to determination of the unknowns.

The last step involves solving a system of linear equations, which can be neglected if conformal mapping, a powerful technique able to transform a complicated physical problem into a readily analyzable one, is employed. On the contrary, conformal mapping can be readily performed if Lagrange interpolation in the complex plane is used together. We will thus in section 2.4 develop a methodology which combines conformal mapping technique and complex DQ method for easily solving some two-dimensional potential problems.

2.1 Differential quadrature in the complex plane

Lagrange interpolation on the real line is one of the simplest interpolation methods and has been widely investigated over the past two centuries (Buchanan and Turner, 1997). It is possible to generalize Lagrange interpolation to the complex plane. Some changes are, however, necessary to account for more complicated cases special in the complex plane. In what follows, extension of Lagrange interpolation to the complex plane and differentiation of a function of a complex variable (or more exactly analytical function) by use of complex Lagrange polynomial are presented. Because books on complex variable theory are plenty, the reader is assumed to be familiar with basic knowledge of complex variables and analytic functions. Several books are listed in the reference section and the reader is referred to Chapter 8.

It is assumed that in the domain S in the two-dimensional complex plane encircled by its boundary Γ, an analytic function $\varphi(z)$ is defined. On the boundary Γ, N nodes are specified as shown in Fig. 2.1. These nodes are assumed to be a sequence in the form of

$$z_1, z_2, \ldots, z_N \tag{2.1}$$

on which the function values of the analytic function $\varphi(z)$ are known

$$\varphi_1, \varphi_2, \cdots, \varphi_N \tag{2.2}$$

Our purpose is to construct a polynomial of $z = x + iy$, where $i = \sqrt{-1}$ is the imaginary unit, in the form of

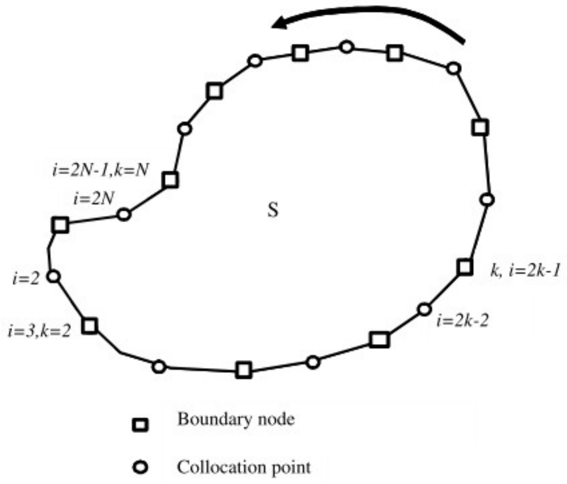

FIGURE 2.1: Boundary nodes and collocation points.

$$\varphi(z) = \sum_{k=1}^{N} \lambda_k(z)\varphi_k \tag{2.3}$$

satisfying

$$\lambda_k(z) = \begin{cases} 1 & z = z_k \\ 0 & z = z_j \neq z_k \end{cases} \quad k = 1, \cdots, N, \quad j = 1, \cdots, N. \tag{2.4}$$

This is the Kronecker delta function. It is its property that guarantees the interpolating polynomial $\varphi(z)$ equal to the function value φ_k at each node z_k. Direct extension of Lagrange polynomial on the real line to the complex plane leads to the following equations (Buchanan and Turner, 1997):

$$\lambda_k(z) = \frac{L_k(z)}{L_k(z_k)}, \quad L_k(z) = \prod_{\substack{j=1 \\ j \neq k}}^{N} (z - z_j), \tag{2.5}$$

where the symbol $\prod$ represents multiplication of the terms following the symbol.

It is straightforward to find the first- and second-order derivatives by differentiating Eq. (2.5) with respect to z

$$\varphi'(z) = \frac{d\varphi(z)}{dz} = \sum_{k=1}^{N} a_k(z)\varphi_k \text{ and } \varphi''(\mathrm{z}) = \frac{\mathrm{d}^2\varphi}{\mathrm{dz}^2} = \sum_{\mathrm{k}=1}^{\mathrm{N}} \mathrm{b_k(z)}\varphi_{\mathrm{k}} \tag{2.6}$$

where $a_k(z)$ are the coefficients for the first-order derivative. After some manipulations, we obtain the coefficients for $z \neq z_k$ as

$$a_k(z) = \frac{d\lambda_k(z)}{dz} = \frac{1}{z - z_k} \sum_{\substack{\ell=1 \\ \ell \neq k}}^{N} \frac{L_\ell(z_\ell)}{L_k(z_k)}, \quad k = 1, \cdots, N. \tag{2.7a}$$

And for $z = z_k$

$$a_k(z) = \sum_{\substack{\ell=1 \\ \ell \neq k}}^{N} a_\ell(z) \frac{L_\ell(z_\ell)}{L_k(z_k)}, \quad k = 1, \cdots, N. \tag{2.7b}$$

The coefficients for the second-order derivative can be obtained in the similar manner as

$$b_k(z) = \frac{da_k(z)}{dz} = \frac{d^2\lambda_k(z)}{dz^2} = \frac{z - z_k}{1} \sum_{\substack{\ell=1 \\ \ell \neq k}}^{N} a_\ell(z) \frac{L_\ell(z_\ell)}{L_k(z_k)} - \frac{z - z_k}{a_k(z)} \tag{2.8a}$$

$k = 1, \cdots, N, \text{if } \mathrm{z} \neq \mathrm{z_k}$, and

$$b_k(z) = \frac{1}{2} \sum_{\substack{\ell=1 \\ \ell \neq k}}^{N} b_\ell(z) \frac{L_\ell(z_\ell)}{L_k(z_k)}, \quad k = 1, \cdots, N, \quad \text{if} \quad \mathrm{z} = \mathrm{z_k}. \tag{2.8b}$$

Equations (2.7) and (2.8) are the most important formulas in this chapter. It is clearly shown that both first- and second-order derivatives are reduced to the weighted sum of the function values at the nodes. This greatly simplifies the numerical differentiation process without deteriorating numerical accuracy.

It is obvious that if N nodes are used, the interpolating polynomial degree is $(N-1)$. Using this idea, it can be shown that the approximation errors for the first-order derivative (R^1) and the second-order one (R^2) are

$$R^1(z_k) = \frac{\varphi^{(N)}(\xi) W^{(1)}(z_k)}{N!}, \quad k = 1, \ldots, N \tag{2.9a}$$

$$R^2(z_k) = \frac{\varphi^{(N)}(\xi) W^{(2)}(z_k)}{N!}, \quad k = 1, \ldots, N \tag{2.9b}$$

where $W(z) = \prod_{j=1}^{N} (z - z_j)$. These residual estimates show that it is possible to achieve high accuracy if the number of grid points N is large. Moreover accuracy is proportional to N or even to its powers.

The aforementioned formulas are identical to those on the real line if complex variable z is replaced by real variable x. But a complex polynomial is really different from a real polynomial in the sense that the former also allows for the appearance of the terms of negative powers. This is because a Laurent's series, in which terms of negative powers appear, in the complex plane replaces the Taylor's series on the real line. Terms of negative powers in a Laurent's series bring in convenience to treat infinite domain as these terms vanish or are constants at infinity. In "domain" type methods such as Finite Element Method (FEM), an infinite domain is approximated by a very large domain. This is not cost-effective. On the other hand, infinite domain problems can be easily handled by boundary methods such as Boundary Element Method (BEM). In the following, we will construct a Lagrange polynomial which contains terms of negative powers, and thus allows for effective treatment of infinite domain.

It is proposed to construct the Lagrange interpolation for infinite domain in the following way:

$$\lambda_k(z) = \frac{\Lambda_k(z)}{\Lambda_k(z_k)}, \quad \Lambda_k(z) = \prod_{\substack{j=1 \\ j\neq k}}^{N} \left(\frac{1}{z} - \frac{1}{z_j}\right). \tag{2.10}$$

It is clearly indicated that $\lambda_k(z)$ possesses the Kronecker delta function property defined by Eq. (2.4). After some algebraic operations, Eq. (2.10) turns out to be a rational interpolation. Hence, Lagrange interpolation in the complex plane is composed of two parts: polynomial and rational interpolations. Note that polynomial and rational approximations are two individual techniques on the real line, but each of them is a part of Lagrange interpolation in the complex plane.

This above procedure is justified by the fact that there are two types of analytical functions: holomorphic and meromorphic (Chapter 8). The former is differentiable in an open subset, and thus can be approximated by Lagrange polynomial in which all the terms have positive powers. The latter is differentiable except at finitely many points and thus can be approximated by a complex ration number.

To find the first- and second-order derivatives of $\Lambda_k(z)$, multiply both sides of Eq. (2.10) by $(1/z - 1/z_k)$ and then differentiate both sides with respect to z. The results after simple manipulations are

$$\varphi'(z) = \frac{d\varphi(z)}{dz} = \sum_{k=1}^{N} a_k(z)\varphi_k \tag{2.11}$$

for the first derivative, and

$$\varphi''(z) = \frac{d^2\varphi}{dz^2} = \sum_{k=1}^{N} b_k(z)\varphi_k \tag{2.12}$$

for the second derivative. The coefficients for the first-order derivative are

$$a_k(z) = \frac{d\lambda_k(z)}{dz} = -\frac{1}{z - z^2/z_k} \sum_{\substack{\ell=1 \\ \ell\neq k}}^{N} \frac{\Lambda_\ell(z_\ell)}{\Lambda_k(z_k)}, \quad k = 1, \cdots, N, \text{if} \quad \mathrm{z} \neq \mathrm{z_k} \tag{2.13}$$

and

$$a_k(z) = \sum_{\substack{\ell=1 \\ \ell\neq k}}^{N} a_l(z) \frac{\Lambda_\ell(z_\ell)}{\Lambda_k(z_k)}, \quad k = 1, \cdots, N, \text{if} \quad \mathrm{z} = \mathrm{z_k}. \tag{2.14}$$

The coefficients for the second-order derivative are

$$b_k(z) = \frac{da_k(z)}{dz} = \frac{d^2\lambda(z)}{dz^2} = -\frac{1}{z - z^2/z_k}\Big[\sum_{\substack{\ell=1 \\ \ell\neq k}}^{n} a_\ell(z) \frac{\Lambda_\ell(z_\ell)}{\Lambda_k(z_k)} - (1 - \frac{2z}{z_k}) a_k(z)\Big] \tag{2.15}$$

if $\quad z \neq z_k, k = 1, \cdots, N$ and

$$b_k(z) = \frac{z_k}{2 + z_k} \sum_{\substack{\ell=1 \\ \ell\neq k}}^{N} b_\ell(z) \frac{\Lambda_\ell(z_\ell)}{\Lambda_k(z_k)}, \text{if} \quad \mathrm{z} = \mathrm{z_k}, \mathrm{k} = 1, \cdots, \mathrm{N}. \tag{2.16}$$

Equations (2.6) to (2.8) are suitable for finite domain and Eqs. (2.11) to (2.16) are suitable for infinite domain.

Example 2.1 *Lagrange interpolation in the complex plane*

Lagrange interpolation in the complex plane is an extension of Lagrange interpolation on the real line. It plays a crucial role in complex DQ method, and the accuracy related with interpolation and numerical differentiation is of major concern. This example is designed to check its accuracy.

Suppose an analytic function $\varphi(z)$ is given in a domain encircled by its boundary Γ. Because the analytic function is given, its values on the boundary Γ are also known. Based on the function values on N nodes on the boundary Γ and Lagrange interpolation in Eqs. (2.5) to (2.8), the function value and its first- and second-order derivatives at any point within the domain can be obtained. Comparison of numerical and analytical results will reveal the accuracy of Lagrange interpolation in the complex plane.

Take $\varphi(z) = z^3$ in a unit circle bounded by Γ: $|z| = 1$ for example. N nodes on Γ are specified. The relative errors are defined

$$e_1 = \frac{|\varphi(z) - \varphi_0(z)|}{|\varphi_0(z)|}, \quad e_2 = \frac{|\varphi'(z) - \varphi_0'(z)|}{|\varphi_0'(z)|}, \quad e_3 = \frac{|\varphi''(z) - \varphi_0''(z)|}{|\varphi_0''(z)|} \quad (2.17)$$

where the subscript "$_0$" denotes the known function values, and thus $\varphi_0 = z^3$, $\varphi_0' = 3z^2$ and $\varphi_0'' = 6z$. The letters in Eq. (2.17) without subscripts denote the numerical results.

The relative errors defined by Eq. (2.17) for the point $z = \sqrt{2}(1+i)/4$ are shown in Fig. 2.2. When $N = 5$ the relative errors are up to 3%. As N increases to 10, the relative errors are dramatically reduced to the order of $10^{-5} \sim 10^{-4}$ %. As N increases to larger numbers, the relative errors increase rather than decrease. The reason is that as N increases, the order of Lagrange polynomial $L(z)$ in Eq. (2.5) is correspondingly raised and more higher-order terms appear in Lagrange polynomial. From numerical analysis, it is well known that higher-order monomials (of the type z^n) might introduce local oscillations to the numerical results, as a consequence, deteriorating numerical accuracy. However, the numerical accuracies as shown in Fig. 2.2 remain below 10^{-2}% for the second-order derivatives, 10^{-3}% for the first-order one and 10^{-4}% for the function values over the whole range. Such accuracy is encouraging.

If more similar analyses are performed at other points, which is omitted here for brevity, we are able to obtain the same conclusions (Zong, 2003a). Thus, as on the real line, Lagrange interpolation in the complex plane may also yield highly accurate results by use of a small number of nodes.

2.2 Complex DQ method for potential problems

In this and the next sections, the applicability and validity of the complex DQ method are demonstrated through the two-dimensional potential problems governed by Laplace's equation and plane linear elastic problems governed by bi-harmonic equation.

Consider a domain S encircled by its boundary Γ. An analytic function defined on S is of the form

$$\varphi(z) = u(x, y) + iv(x, y) \quad (2.18)$$

where $i = \sqrt{-1}$ is the imaginary unit, u,v are real and imaginary parts, respectively, and $z = x + iy$.

4 Compliances of Curvilinear-Axis Flexible Hinges

Flexible hinges with curved/circular axis are employed in applications where coupling between axial and bending deformation, as well as between bending and torsion, are necessary. Analytical modeling and design of circular-axis hinges for in-plane mechanism applications with either small or large deformations have been studied by Hsiao and Lin [1], Lee and Ziegert [2], Shisheng et al. [3], Callegari et al. [4], Howell [5] or Jagirda [6], for instance. Similar analysis/design methods have also been developed to characterize the out-of-plane (diaphragm) behavior of circular-axis elastic members in a wide array of applications, including opto-mechanics, precision positioning or robotics – see Trylinski [7], Sydenham [8], Vukobratovich et al. [9], Kyusogin and Sagawa [10], Hermann [11], Mohamad et al. [12], Duong and Kazerounian [13], Shielpiekandula and Youcef-Toumi [14], Yong and Reza-Mohemani [15], Awtar [16], Awtar and Slocum [17], Trease et al. [18], Ishaquddin et al. [19] and Kress et al. [20]. Finite element methods as detailed in Ishaquddin et al. [19], Kress et al. [20], also see Chapter 8 – and compliance matrix-based approaches – as detailed in Lobontiu and Cullin [21], Lobontiu et al. [22], Lobontiu [23–26], Lobontiu et al. [27], Lobontiu [28] – have been utilized to model curvilinear-axis flexible hinges and mechanisms incorporating them.

This chapter formulates the in-plane and out-of-plane compliance matrices of planar flexible hinges that are fully formed of curvilinear-axis segments or combine curvilinear-axis segments with straight-axis segments. By means of translation, addition, rotation and mirroring, the local-frame compliance matrices of the individual segments, like those studied in Chapter 2, are mixed either in series or in parallel to produce the compliance matrices of the final hinge configurations. Flexible-hinge designs, which are symmetric or antisymmetric with respect to an axis, are studied in this chapter by means of compliance matrices of simpler hinge portions. Folded hinges are also analyzed; they comprise curvilinear-axis segments in arrangements that are inscribed in geometric envelopes of straight/curvilinear profile or may be of radial design.

4.1 COMPLIANCE MATRIX TRANSFORMATIONS

In order to formulate the in-plane and out-of-plane compliance matrices of flexible hinges that incorporate curvilinear-axis segments, the local-frame segment compliance matrices need to be transferred to the global frame; this is mainly achieved by matrix translation and rotation, but it can also include mirroring.

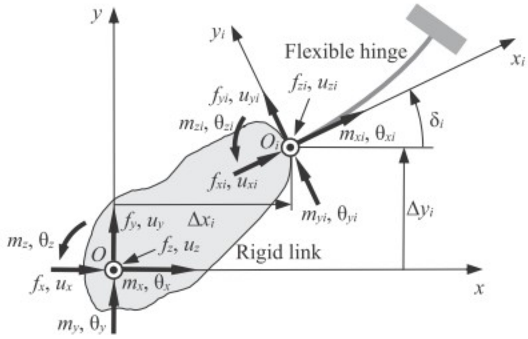

FIGURE 4.1 Rigid link connected to planar curvilinear-axis flexible hinge in global and local reference frames under the action of load displaced from its free end.

Assume that a load formed of f_x, f_y, m_z, m_x, m_y and f_z is applied at a point O that is rigidly connected to the free end O_i of a generic curvilinear-axis flexible hinge, which is fixed at the opposite end, as illustrated in Figure 4.1. The aim is to evaluate the displacements u_x, u_y, θ_z, θ_x, θ_y and u_z in the global reference frame $Oxyz$ in terms of the load at O and to express the flexible-hinge compliance matrices with respect to O based on the hinge native compliance matrices that are formulated in the $O_ix_iy_iz_i$ local frame. The load/displacement vectors are formally separated into in-plane and out-of-plane components.

4.1.1 IN-PLANE COMPLIANCES

The in-plane loads f_x, f_y and m_z statically transfer to O_i from their original location O as:

$$\begin{cases} f_{xi} = f_x \cdot \cos\delta_i + f_y \cdot \sin\delta_i \\ f_{yi} = -f_x \cdot \sin\delta_i + f_y \cdot \cos\delta_i \\ m_{zi} = f_x \cdot \Delta y_i - f_y \cdot \Delta x_i + m_z \end{cases} . \tag{4.1}$$

Equation (4.1) can be written in matrix form as:

$$\left[f^{(i)}_{O_i,ip} \right] = \left[R^{(i)} \right] \left[T^{(i)}_{OO_i,ip} \right] \left[f^{(i)}_{O_i,ip} \right]$$

$$\text{with}: \begin{cases} \left[f^{(i)}_{O_i,ip} \right] = \begin{bmatrix} f_{xi} & f_{yi} & m_{zi} \end{bmatrix}^T; \quad \left[f^{(i)}_{O,ip} \right] = \begin{bmatrix} f_x & f_y & m_z \end{bmatrix}^T \\ \left[R^{(i)} \right] = \begin{bmatrix} \cos\delta_i & \sin\delta_i & 0 \\ -\sin\delta_i & \cos\delta_i & 0 \\ 0 & 0 & 1 \end{bmatrix}; \quad \left[T^{(i)}_{OO_i,ip} \right] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \Delta y_i & -\Delta x_i & 1 \end{bmatrix} \end{cases} . \tag{4.2}$$

where $[R^{(i)}]$ is the rotation matrix and $\left[T^{(i)}_{OO_i,ip}\right]$ is the in-plane translation matrix.

The global-frame displacements u_x, u_y and θ_z are expressed in terms of the local-frame displacements u_{xi}, u_{yi} and θ_{zi} as follows:

$$\begin{cases} u_x = u_{xi} \cdot \cos\delta_i - u_{yi} \cdot \sin\delta_i + \Delta y_i \cdot \theta_{z_i} \\ u_y = u_{xi} \cdot \sin\delta_i + u_{yi} \cdot \cos\delta_i - \Delta x_i \cdot \theta_{z_i} \, . \\ \theta_z = \theta_{x_i} \end{cases} \tag{4.3}$$

Equations (4.3) are rewritten in the matrix form as:

$$\left[u^{(i)}_{O,ip}\right] = \left[T^{(i)}_{OO_i,ip}\right]^T \left[R^{(i)}\right]^T \left[u^{(i)}_{O_i,ip}\right] \text{ with } \begin{cases} \left[u^{(i)}_{O_i,ip}\right] = \begin{bmatrix} u_{xi} & u_{yi} & \theta_{zi} \end{bmatrix}^T \\ \left[u^{(i)}_{O,ip}\right] = \begin{bmatrix} u_x & u_y & \theta_z \end{bmatrix}^T \end{cases} . \tag{4.4}$$

The local-frame loads and displacements are related by means of the hinge in-plane compliance matrix by the known relationship:

$$\left[u^{(i)}_{O_i,ip}\right] = \left[C^{(i)}_{O_i,ip}\right]\left[f^{(i)}_{O_i,ip}\right]. \tag{4.5}$$

Combining Eqs. (4.2), (4.4) and (4.5) yields:

$$\left[u^{(i)}_{O,ip}\right] = \left[C^{(i)}_{O,ip}\right]\left[f^{(i)}_{O,ip}\right] \quad \text{with} \quad \left[C^{(i)}_{O,ip}\right] = \left[T^{(i)}_{OO_i,ip}\right]^T \left[R^{(i)}\right]^T \left[C^{(i)}_{O_i,ip}\right]\left[R^{(i)}\right]\left[T^{(i)}_{OO_i,ip}\right]. \tag{4.6}$$

where $\left[C^{(i)}_{O,ip}\right]$ is the global-frame, in-plane compliance matrix of the generic curvilinear-axis flexible hinge.

4.1.2 OUT-OF-PLANE COMPLIANCES

A similar procedure is applied to determine the relationship between global-frame out-of-plane loads and displacements. The out-of-plane loads m_x, m_y and f_z are statically reduced (moved) to O_i from their original location O as:

$$\begin{cases} m_{xi} = m_x \cdot \cos\delta_i + m_y \cdot \sin\delta_i + f_z \cdot \left(\Delta x_i \cdot \sin\delta_i - \Delta y_i \cdot \cos\delta_i\right) \\ m_{yi} = -m_x \cdot \sin\delta_i + m_y \cdot \cos\delta_i + f_z \cdot \left(\Delta x_i \cdot \cos\delta_i + \Delta y_i \cdot \sin\delta_i\right). \\ f_{zi} = f_x \end{cases} \tag{4.7}$$

which are collected in the matrix form:

$$\left[f^{(i)}_{O_i,op}\right]=\left[R^{(i)}\right]\left[T^{(i)}_{OO_i,op}\right]\left[f^{(i)}_{O,op}\right]$$

$$\text{with}: \begin{cases} \left[f^{(i)}_{O_i,op}\right]=\begin{bmatrix} m_{xi} & m_{yi} & f_{zi} \end{bmatrix}^T; \ \left[f^{(i)}_{O,op}\right]=\begin{bmatrix} m_x & m_y & f_z \end{bmatrix}^T \\ \left[T^{(i)}_{OO_i,op}\right]=\begin{bmatrix} 1 & 0 & -\Delta y_i \\ 0 & 1 & \Delta x_i \\ 0 & 0 & 1 \end{bmatrix} \end{cases}. \tag{4.8}$$

The rotation matrix $[R^{(i)}]$ is calculated in Eq. (4.2) and $\left[T^{(i)}_{OO_i,op}\right]$ is the out-of-plane translation matrix. The displacements θ_x, θ_y and u_z are expressed in terms of the displacements θ_{xi}, θ_{yi} and u_{zi} as:

$$\begin{cases} \theta_x=\theta_{xi}\cdot\cos\delta_i-\theta_{yi}\cdot\sin\delta_i \\ \theta_y=\theta_{xi}\cdot\sin\delta_i+\theta_{yi}\cdot\cos\delta_i \\ u_z=\theta_{xi}\cdot\left(\Delta x_i\cdot\sin\delta_i-\Delta y_i\cdot\cos\delta_i\right)+\theta_{yi}\cdot\left(\Delta x_i\cdot\cos\delta_i+\Delta y_i\cdot\sin\delta_i\right)+u_{zi} \end{cases}. \tag{4.9}$$

Equations (4.9) can also be written in matrix form as:

$$\left[u^{(i)}_{O,op}\right]=\left[T^{(i)}_{OO_i,op}\right]^T\left[R^{(i)}\right]^T\left[u^{(i)}_{O_i,op}\right] \quad \text{with} \quad \begin{cases} \left[u^{(i)}_{O_i,op}\right]=\begin{bmatrix} \theta_{xi} & \theta_{yi} & u_{zi} \end{bmatrix}^T \\ \left[u^{(i)}_{O,ip}\right]=\begin{bmatrix} u_x & u_y & \theta_z \end{bmatrix}^T \end{cases}. \tag{4.10}$$

By definition, the out-of-plane compliance matrix connects the corresponding loads and displacements in the local frame as:

$$\left[u^{(i)}_{O_i,op}\right]=\left[C^{(i)}_{O_i,op}\right]\left[f^{(i)}_{O_i,op}\right]. \tag{4.11}$$

Equations (4.8), (4.10) and (4.11) are combined into:

$$\left[u^{(i)}_{O,op}\right]=\left[C^{(i)}_{O,op}\right]\left[f^{(i)}_{O,op}\right]\text{with}\left[C^{(i)}_{O,op}\right]=\left[T^{(i)}_{OO_i,op}\right]^T\left[R^{(i)}\right]^T\left[C^{(i)}_{O_i,op}\right]\left[R^{(i)}\right]\left[T^{(i)}_{OO_i,op}\right]. \tag{4.12}$$

where $\left[C^{(i)}_{O,op}\right]$ is the global-frame, out-of-plane compliance matrix of the generic curvilinear-axis flexure hinge.

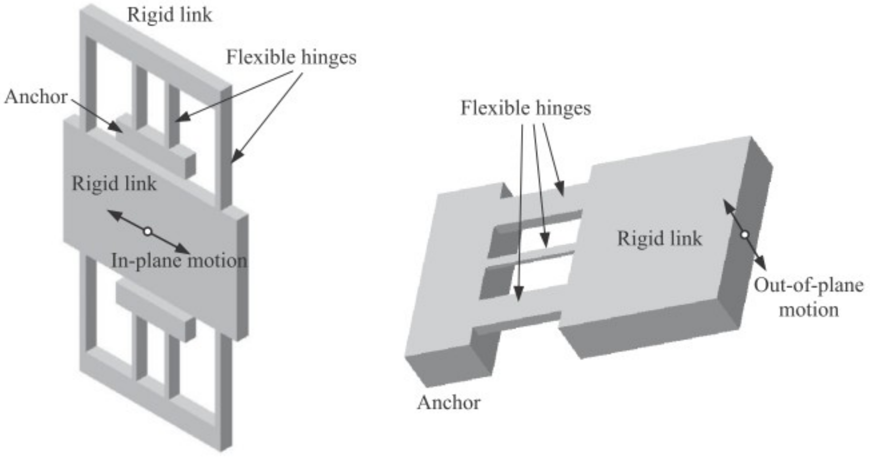
It is important to note that the transformation equations derived in this section for a curvilinear-axis hinge are also valid for a straight-axis hinge. The only difference is that the in-plane and out-of-plane, local-frame compliance matrices of a straight-axis hinge need to be used instead of those of a curvilinear-axis hinge.

1 Introduction

This introductory chapter gives a brief description of flexible hinges and flexure-based compliant mechanisms for macro- and micro-scale applications by highlighting the main traits of these mechanical members/devices. An outline of the subject matter and the associated approach in this book is also sketched here in order to identify and possibly locate the work in the context of similar dedicated information that has already been published.

Derived from the term *compliance*, utilized by Paros and Weisbord [1] to identify the reciprocal of stiffness, the *compliant* qualifier is utilized in this book to identify any mechanical device that comprises at least one elastically deformable joint, called *flexible* (or *flexure*) *hinge*. Such a mechanism usually includes other rigid links, which ensure the necessary rigidity and serve as input/output ports. The flexible-hinge *mechanisms* employ their mobility to perform conversions between electric, thermal, magnetic, etc. and mechanical energies. Many of these mechanisms, which are typically of monolithic architecture, are designed to undergo relatively low levels of rotation/deformation in order to generate accurate, quasi-continuous output motion. This work covers the flexure-based compliant mechanisms possessing all these traits.

Figure 1.1 shows the schematic representation of two microaccelerometers – sensing microdevices used to evaluate external acceleration. Both devices have a planar structure and comprise rigid links (fixed or movable) that are connected by



(a)　(b)

FIGURE 1.1 Flexible-hinge microaccelerometers with: (a) in-plane motion; (b) out-of-the-plane motion.

flexible hinges of (constant) rectangular cross-section. The thinner in-plane cross-sectional dimension of the eight hinges of the microaccelerometer, as shown in Figure 1.1a, also *known as* folded-beam accelerometer (Bhushan [2]), enables the central rigid link (the proof mass) to undergo in-plane, back-and-forth translatory motions when its anchor links are attached to an external vibrating source along the motion direction. Alternatively, in order to sense acceleration along a direction perpendicular to the device plane, the design of Figure 1.1b, named resonant-beam accelerometer (see Tudor et al. [3]), utilizes flexible hinges whose out-of-plane dimension is smaller than the in-plane cross-sectional thickness; consequently, these hinges can bend along an in-plane axis and enable the mobile rigid link (also known as seismic mass) to displace out of the plane. Both devices use additional sensing (capacitive, for instance) to convert the mechanical acceleration into electrical voltage.

Flexible hinges are largely utilized in the auto/aviation industry in applications such as acceleration/speed/position sensors, adaptable seats, airbags, fault-tolerant connectors, single-surface-independent aircraft control devices, actuators for configurable-geometry foils, steering columns, antifriction bearings, suspension systems, satellite small-angle tilting mechanisms, laser-beam communication systems between spacecraft, and flexible couplings. The biomedical industry is also a beneficiary of mechanisms that are based on flexible hinges, and applications in this category include devices for vascular catheters, urethral compression devices, intravascular endoprostheses, cardiac massage apparatuses, orthotic devices and biopsy devices. The computers and fiber optics industries have also applications that incorporate flexible hinges, and the examples in this category include disk drive suspensions, laser systems, optical mirrors, optical disks, microscopes, cameras, print heads, optical scanning equipment, vibrating beam accelerometers, keyboard assemblies, kinematic lens mountings and rotary actuators for disk drives. Various other fields utilize flexible-hinge mechanisms, and a few application examples are coin packaging systems, systems for remotely playing percussion musical instruments, collapsible fishing net mechanisms, table tennis ball-retrieving systems, snow blade attachments, foot propulsion devices for float tube users, bicycle seats, steerable wheels for skate/roller ski, respiratory masks, grinding/polishing machines, fluid jet cutting machines and flywheels. The compliant micro-/nano-electromechanical systems (MEMS/NEMS) are almost entirely based on microdevices that generate their motions by means of flexible hinges. Examples in this industry comprise optical switches, miniature load cells, flexible mounts for imaging masks, load-sensitive resonators, gyroscopes, gravity gradiometers, disk memory head positioners, wire bonding heads, microfluidic devices, accelerometers, scan modules for bar code readers and cantilevers for microscopy.

A flexible hinge is a relatively thin member that provides the relative rotation between two adjacent rigid links mainly through flexing (bending), as sketched in Figure 1.2, where a conventional rotational joint is shown next to a flexible hinge.

In terms of this rotary function, a flexible hinge can be considered the structural correspondent of a bearing with limited rotation capability, as illustrated in

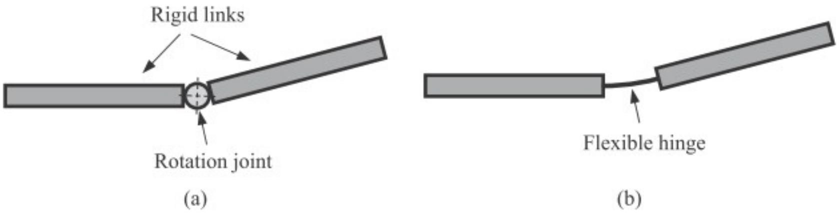


FIGURE 1.2 Joints enabling relative rotation in mechanisms: (a) conventional rotation joint; (b) skeleton representation of a generic flexible hinge.

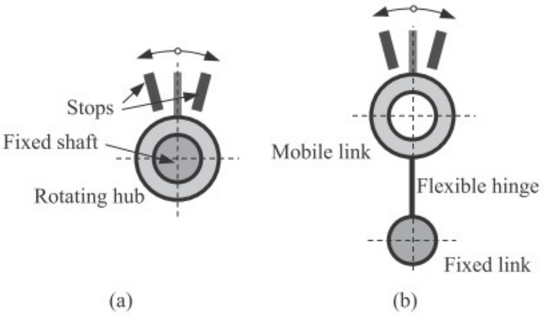

FIGURE 1.3 Functional similarity between rotary bearings and flexible hinges: (a) collocated (concentric) rotation produced by a rotary bearing; (b) non-collocated rotation produced by a flexible hinge.

Figure 1.3. In a classical rotary bearing, the relative rotation takes place between a shaft and its housing, these mating parts are concentrically located, and the rotation can be limited to a specific angular sector, as indicated in Figure 1.3a. A flexible hinge can provide a similar limited rotary output, and the only difference is attributable to the fact that the "centers" of the two adjacent members undergoing the relative rotation are no longer collocated, as shown in Figure 1.3b.

Physically, a flexible hinge can mainly be achieved in two different ways:

- Use an independently fabricated member (like a strip or shim in two-dimensional applications or a cylinder-like part in three-dimensional applications) to connect two rigid members that are designed to undergo a relative rotation;
- Generate the flexible hinge by either subtractive or additive fabrication procedures. In this case, the flexure is integral (or monolithic) to the rigid links it connects.

Among the benefits provided by the flexible hinges, the most notable are:

- No friction losses;
- No need of lubrication;

- No hysteresis;
- Compactness;
- Capacity to be utilized in small-scale applications;
- Ease of fabrication;
- Virtually no maintenance needed;
- No need of repair since the mechanism will operate until something will fail (usually the hinges) because of fatigue or overloading;
- Producing small-increment, quasi-continuous and very precise motion.

Flexible hinges do have limitations, however, and a few examples of such drawbacks are:

- The hinges, particularly the notch ones, provide relatively low levels of rotations due to stress limitations;
- The rotation is not pure because the deformation of a flexible hinge is complex as it is produced by axial loading, shear and torsion in addition to bending;
- The flexible hinge is usually sensitive to temperature variations, and therefore, its dimensions change as a result of thermal expansion/contraction, which leads to modifications in the original hinge elastic properties.

For two-dimensional applications where the flexible hinge is fabricated by removing material from a blank piece, the manufacturing processes that are being utilized for this purpose include end milling, electrodischarge machining (EDM), laser cutting, water/liquid jetting, metal stamping, three-dimensional printing and photolithographic/microfabrication techniques for MEMS/NEMS.

In two-dimensional, planar flexible mechanisms, the hinge is designed to be compliant about a single axis only (the input, compliant or sensitive axis), along which the relative rotation between the adjacent rigid links is taking place, and stiff (as much as possible) about all other axes and motions – see the designs of Figure 1.4a and c. These configurations are also known as *single-axis* flexible hinges. For other hinge architectures that have rotational symmetry (they are revolute and their cross-section is circular), like the one pictured in Figure 1.4b, bending is indiscriminately possible about any axis that is perpendicular to the axial direction, and therefore, the compliant axis can instantaneously be set by the loading/boundary conditions of the three-dimensional compliant mechanism. Consistent with the terminology that has already been utilized such flexible hinges are also called *multi-axis*. Single-axis flexible hinges are specifically intended for two-dimensional compliant mechanisms that have in-plane and out-of-plane motion, whereas multi-axis hinges are implemented in three-dimensional applications in order to take advantage of their capacity to produce relative rotation about two or more compliant axes.

While the designs of Figure 1.4a and b have straight longitudinal axes, flexible hinges with curvilinear longitudinal axis, like the one shown in Figure 1.4c, have also been designed and utilized in various applications.

FIGURE 1.5 Skeleton representation of: (a) straight-axis flexible hinge; (b) curvilinear-axis flexible hinge; (c) flexible hinge with straight- and curvilinear-axis segments.

Oftentimes, it is convenient to use a simplified, skeleton representation of flexible hinges by just drawing the longitudinal axis of the hinge, as illustrated in Figure 1.5.

A considerable number of compliant mechanisms utilize a reduced pool of flexible-hinge configurations. Apart from the constant cross-section (either rectangular or circular) designs that present the inconvenience of high stress concentration at the areas joining the rigid links, two other geometries – the circular design (Paros and Weisbord [1]) and the right circularly corner-filleted configuration (Lobontiu et al. [4]) (these basic configurations are sketched in Figure 1.6) – occupy an ample space of choices for flexible-hinge applications. The simplicity of their geometry and the relative ease of fabrication are two main reasons that prompted the widespread use of these two types of hinges. In

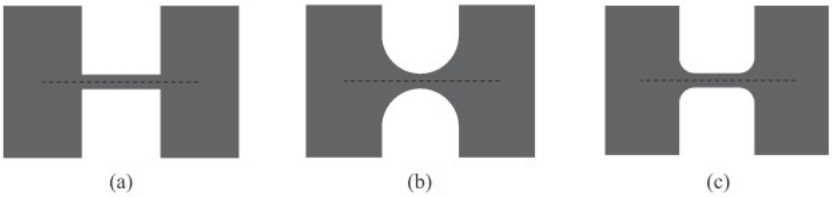

FIGURE 1.6 Commonly utilized flexible-hinge configurations with straight longitudinal axis: (a) constant cross-section; (b) right circular; (c) right circularly corner-filleted.

addition, both configurations come with the advantage of being able to reduce the stress concentration levels through the filleted regions at their corners (ends).

A thorough analytical presentation of single-axis and two-axis circular flexure hinges is provided in Paros and Weisbord [1]. The authors of this paper interchangeably utilized the terms *flexure hinge* and *flexure* to denote a mechanical member, which is "compliant in bending about one axis but rigid about the cross-axes", and mentioned that flexure hinges are incorporated in applications where angular motion is required about an axis – the compliant axis. The key merit of this seminal work consisted in the clear mathematical definition of a flexure hinge as a spring element, which displays two distinct behaviors: it is compliant about one axis, in order to produce the desired rotation, and stiff (as much as possible) in all other motions about the other axes in order to prevent/minimize the respective parasitic motions. This paper provided analytical equations, both exact and approximate, for the spring rates (reciprocal to compliances) of single-axis and two-axis circular symmetric flexures in terms of the motions generated through the consideration of bending and axial effects. The alternative terminology of *flexural pivot* has also been utilized over the years in referring to the same mechanical member. The *notch hinge* has also been employed by several authors; see Smith [5], for instance, especially for single-axis flexible hinges. While the term *flexure* aptly depicts the primary function and operation mode of an elastic joint to flex (bend), there are also hinge configurations whose main intended/functional deformation is torsional. In order to cover all possible deformation modes, the terminology *flexible hinge* is used throughout this book. The term *compliance* (also known as *flexibility*) is utilized here in the original definition given in Paros and Weisbord [1] such that the term refers to the quantity which is the reciprocal of one flexure's spring rate (or stiffness). As a terminology extension from *compliance* – see also previous mention at the beginning of this chapter – the qualifier *compliant* is used in this book to denote the behavior of a mechanical device/mechanism that moves by the elastic deformation of its flexible hinges in order to realize a design objective (actuation or sensing).

Expanding the flexible-hinge design domain with new geometries and configurations is prompted by practical need. The compliant behavior of flexible hinges and flexure-based mechanisms largely depend on the specific geometry of the hinge for a given material. Slight alterations in geometry and dimensions can sensibly modify the elastic response. This aspect is particularly important in mechanisms where precision is a key performance parameter or where a finely tuned, quasi-continuous output is expected in terms of displacement, force or frequency (resonant) response. This book provides compliance equations for a large variety of flexible-hinge configurations that have been developed and reported in the specialty literature over the past years or which are new. It also qualifies and compares the flexible hinges in terms of level and precision of the output motion, sensitivity to parasitic (undesired) loading and stress levels.

The book essentially develops not only a process of discretization through which the compliance (stiffness) is primarily derived, but also studies the inertia and damping characteristics that are derived for a large variety of flexible hinges

both analytically and by means of the finite element technique. With the analytical approach, a distributed-parameter flexible hinge is equivalently transformed into a discrete one with properties defined individually and independently in terms of its degrees of freedom (DOF). For a three-dimensional flexible hinge, one of its ends can move with respect to the other one (presumed fixed) by three translations and three rotations, respectively, as sketched in Figure 1.7. Consequently, a flexible hinge can be modeled as a six-DOF member in the three-dimensional space when only the position of one end relative to the opposite one is of interest.

Planar flexible hinges of rectangular cross-sections can be designed to operate in their original plane, as the microaccelerometer of Figure 1.1a does, or out of their plane, as the case is with the mechanism of Figure 1.1b.

For in-plane operation, a planar flexible hinge, like the curvilinear-axis one shown in Figure 1.8a, has its in-plane dimension thinner than its (constant) out-of-plane dimension w. As a result, the free end O can translate along the x and y axes and rotate around the z axis. The quasi-static behavior of such a hinge, as shown in Chapters 2–4, is characterized by an *in-plane compliance matrix* connecting the load vector formed of the forces f_x and f_y and the moment m_z to the corresponding

displacement vector defined by the translations u_x and u_y and the rotation θ_z. The hinge deformation includes bending around the z axis, axial deformation along the x axis and shear along the y axis. Out-of-plane deformations produced by the other three loads, namely, m_x, m_y and f_z, are undesired and therefore parasitic.

Conversely, the flexible hinge shown in Figure 1.8b, with an out-of-plane dimension w smaller than the in-plane thickness, can easily deform out of its original structural plane; as such, an out-of-plane compliance matrix can be derived to connect the load vector defined by the moments m_x and m_y and the force f_z to the resulting displacement vector formed of the rotations θ_x and θ_y and displacement u_z. This particular hinge mainly deforms in bending around the y axis, torsion around the x axis and shear along the z axis. All other deformations resulting from the in-plane loads f_x, f_y and m_z are undesired (parasitic).

It should be noted again that flexible hinges are approached in this book as members that are subjected to small deformations. This assumption stems from the reality that in numerous engineering applications the flexible hinges actually behave according to this model, which enables utilization of the linear (or first-order) bending theory and derivation of the spring rates for various hinge configurations.

In addition to the compliance-based approach utilized to model the static and dynamic behaviors of flexible-hinge mechanisms, which is a variant of the *force* (or *flexibility matrix*) *method*, this book also studies the flexible hinges and their mechanisms by means of the finite element technique using the classical *displacement* (*stiffness matrix*) *method*. A flexible hinge of either straight or curvilinear/circular axis is modeled as a two- or three-node line element with six DOF per node. A generic finite element formulation is developed by defining the elemental stiffness, mass and damping matrices. Explicit forms of these elemental matrices are derived for a few flexible-hinge configurations. These equations are subsequently utilized to characterize the static or dynamic response of various flexible-hinge mechanism examples.

Several other related topics, including stress concentration, combined stresses and theories of failure, flexible-hinge precision of rotation, layered flexible hinges, temperature effects and piezoelectric actuation/sensing, are also studied in this book.

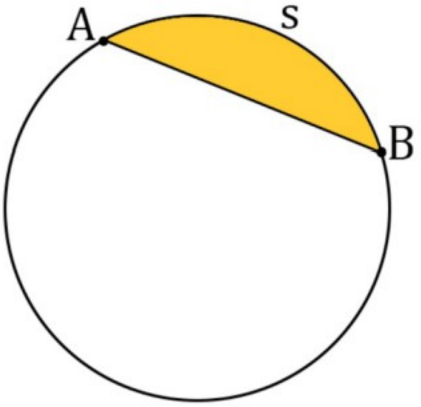
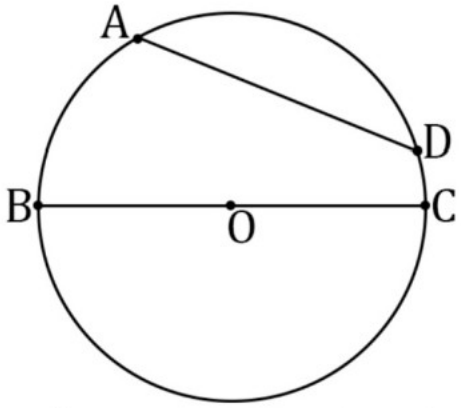
Chords and Circular Segments

This chapter discusses chords, including theorems that relate to intersecting chords, and also explores the area of a circular segment which is formed by a chord.

Chapter 6 Concepts

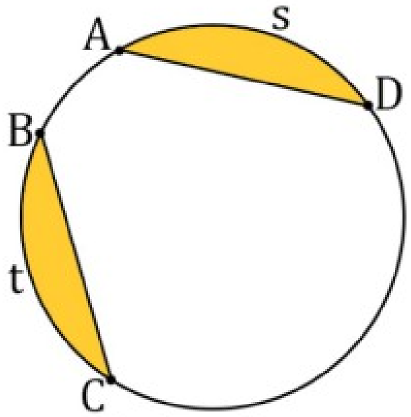
A **chord** (pronounced with a silent "h" so that it sounds like "cord") is a line segment that connects two points that lie on the circumference of a circle. A **circular segment** is a region enclosed by an arc and a chord. For example, in the diagram on the left below, $\overline{AB}$ is a chord and the shaded region between $\overline{AB}$ and arc length s is a circular segment.



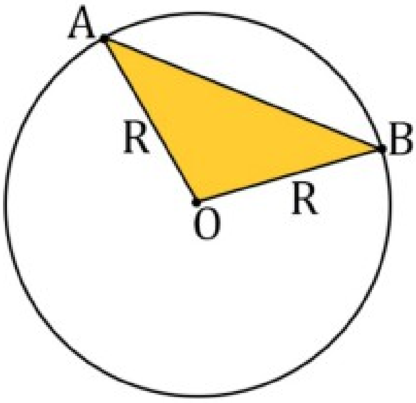


A diameter is a special chord. A **diameter** is a chord that passes through the center of the circle. A chord that does not pass through the center of the circle is shorter than the diameter. For example, in the diagram above on the right, point O lies at the center of the circle, $\overline{BC}$ is a diameter, $\overline{AD}$ is a chord that does not pass through O, and $AD < BC$.

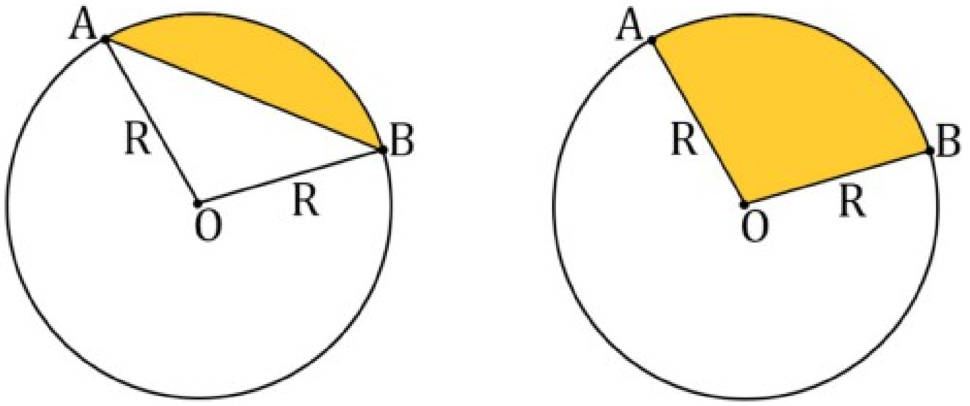
If two **chords** in the same circle are **congruent**, the chords subtend **congruent arcs**. For example, if $\overline{AD} \cong \overline{BC}$ in the diagram below, then arc lengths s and t are equal.



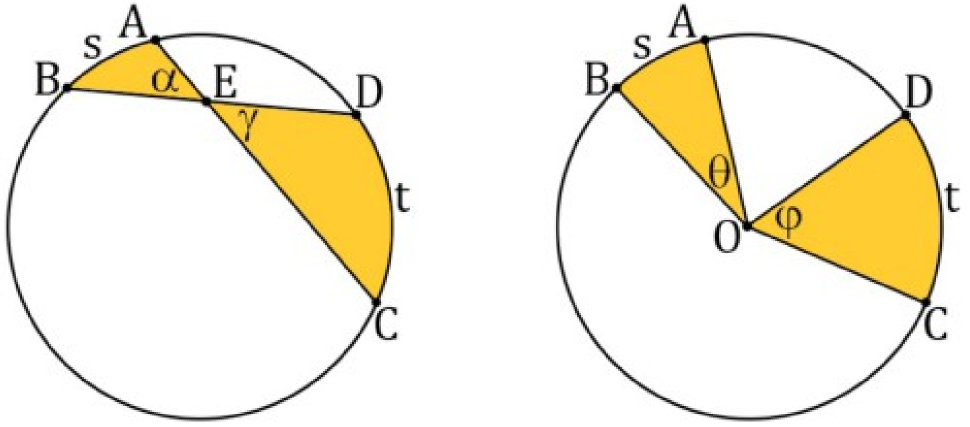
Tip: When working with chords or circular segments, it is often helpful to **draw line segments connecting the endpoints of the chord to the center of the circle**. Since the endpoints of the chord lie on the circumference of the circle, each line segment that connects an endpoint of a chord to the center of a circle is a radius. A triangle bounded by a chord and two radii is an isosceles triangle. For example, in the diagram on the next page, points A and B are the endpoints of chord $\overline{AB}$, point O lies at the center of the circle, $\overline{AO}$ and $\overline{BO}$ are radii, ∠AOB is a central angle, and ΔABO is isosceles.



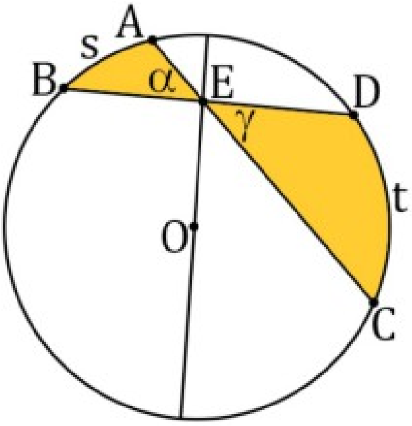
Note the distinction between a **circular segment** and a **sector** (Chapter 3). A circular segment refers to the region between a chord and an arc (left figure on the next page), whereas a sector is a pie slice cut from the center of the circle (right figure on the next page). The **area** of the **circular segment** shown below on the left can be found by subtracting the area of ΔABO from the area of the sector shown on the right. Recall from Chapter 3, Problem 7 that the **area** of a **sector** is $\frac{\theta R^2}{2}$, provided that θ (which is ∠AOB in the diagram below) is expressed in radians. Recall that π rad = 180°. Also recall that the area of a triangle is $\frac{bh}{2}$ (Volume 1, Chapter 6).



When **two chords** of the same circle **intersect**, the angle between the chords is equal to the average value of the two central angles that subtend the same arcs. For example, chords $\overline{AC}$ and $\overline{BD}$ intersect at point E in the diagram below, $\alpha \cong \gamma$ (vertical angles), point O lies at the center of the circle, and central angles θ and φ subtend the same arcs (s and t) as α and γ. Angles α, γ, θ, and φ are related by $\alpha = \gamma = \frac{\theta+\varphi}{2}$.



According to the **intersecting chords theorem**, the distances in the left diagram above are related by the following formula, which involves multiplying distances together: $(AE)(CE) = (BE)(DE) = R^2 - EO^2$. As shown below, EO is the distance from the point where the chords intersect (E) to the center of the circle (O). The radius of the circle is R.

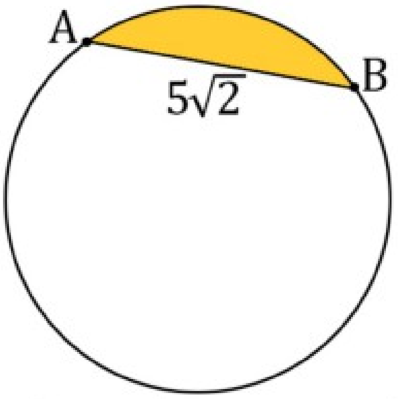


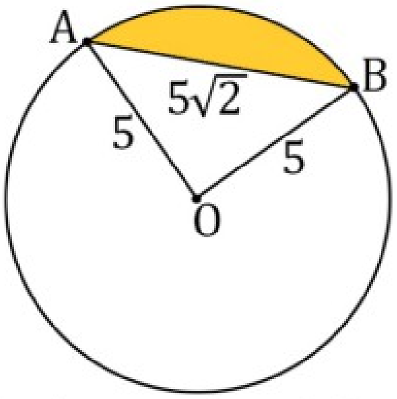
Notation: In this book, a lowercase letter of the English alphabet (like s or q) labeling an arc refers to a distance equal to the **arc length**. This book uses one of the following three common method to indicate an angle: an angle symbol followed by three uppercase English letters (like ∠ABC), an angle symbol followed by a number (like ∠1), or a lowercase Greek letter (like θ). A lowercase English letter (like s or q) in this book can only be a distance.

When reading a book that labels an **angle** on an arc, this is usually the central angle for the arc (even if the central angle is not drawn).

Chapter 6 Examples

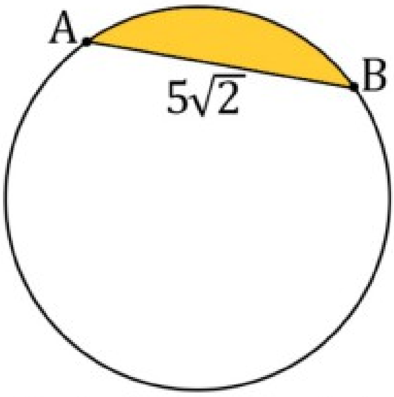
Example 1. In the diagram below, $AB = 5\sqrt{2}$ and the diameter of the circle is 10. Find the central angle that subtends the (minor) arc from A to B.

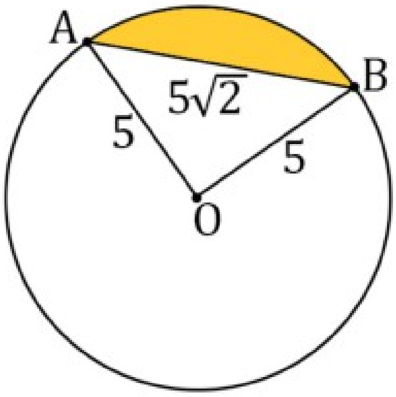




First, draw the center of the circle (point O) and draw line segments $\overline{AO}$ and $\overline{BO}$. Since $D = 10$, the radius is $R = \frac{D}{2} = \frac{10}{2} = 5$. Note that $AO = BO = R = 5$. The sides of ΔABO come in the ratio $AO{:}BO{:}AB = 5{:}5{:}5\sqrt{2} = 1{:}1{:}\sqrt{2}$. (The ratio was reduced by dividing each side by 5.) Since the sides of a 45°-45°-90° triangle come in the ratio $1{:}1{:}\sqrt{2}$ (see Volume 1, Chapter 5), this shows that ΔABO is a 45°-45°-90° triangle. The hypotenuse (AB) is opposite to the right angle. Therefore, $\angle AOB = 90°$.

Example 2. Find the area of the shaded circular segment in the diagram below. As in Example 1, $\text{AB} = 5\sqrt{2}$ and the diameter of the circle is 10.



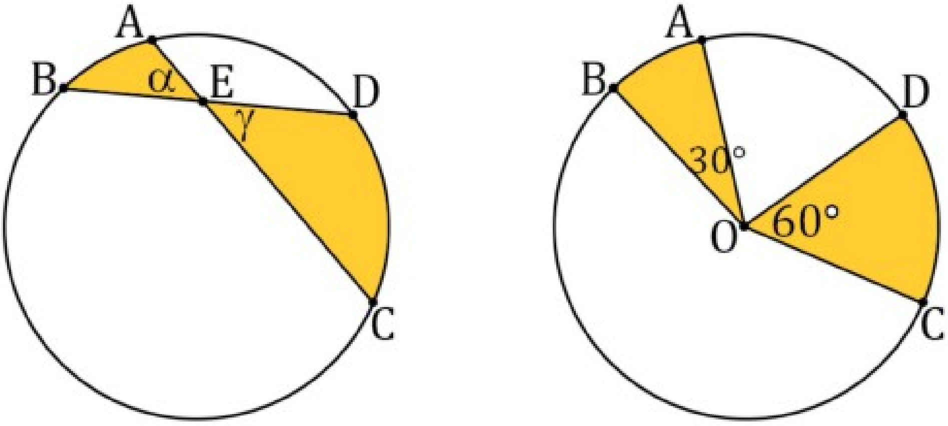


First find the area of the sector (Chapter 3). Recall from Example 1 that $\angle\text{AOB} = 90°$.

Since $360° \div 90° = 4$, the sector has $1/4$ of the area of a full circle: $\frac{\pi R^2}{4} = \frac{\pi 5^2}{4} = \frac{25\pi}{4}$. Since ΔABO is a right triangle, the two legs (AO and BO) serve as the base and height. The area of ΔABO equals $\frac{1}{2}(\text{AO})(\text{BO}) = \frac{1}{2}(5)(5) = \frac{25}{2}$. Subtract the area of ΔABO from the area of the sector to find the area of the circular segment: $A = \frac{25\pi}{4} - \frac{25}{2} = \frac{25}{4}(\pi - 2)$ is the exact area, which was found by factoring out $\frac{25}{4}$. Check the answer by distributing: $\frac{25}{4}(\pi - 2) = \frac{25}{4}\pi - \frac{25}{4}(2) = \frac{25}{4}\pi - \frac{25}{2}$. The area of the circular segment is approximately equal to

$\frac{25}{4}(3.14 - 2) \approx 7.13$ when rounded to three significant figures.

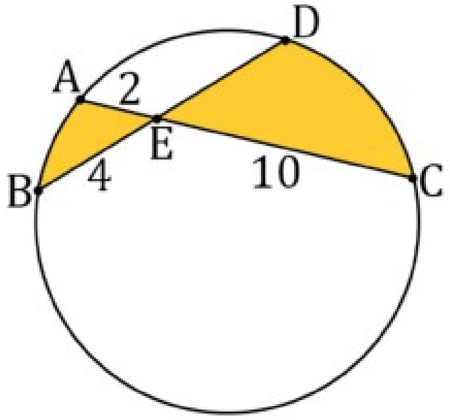
Example 3. The same circle is shown twice below. On the right, point O lies at the center of the circle. Determine α and γ.



First, $\alpha \cong \gamma$ because α and γ are vertical angles. Second, $\overline{AC}$ and $\overline{BD}$ are intersecting chords, which means that α and γ are each equal to the average of the central angles that subtend the same arcs as α and γ.

$$\alpha = \gamma = \frac{\angle AOB + \angle COD}{2} = \frac{30° + 60°}{2} = \frac{90°}{2} = 45°$$

Example 4. In the diagram below, $AE = 2$, $BE = 4$, and $CE = 10$. Find DE.



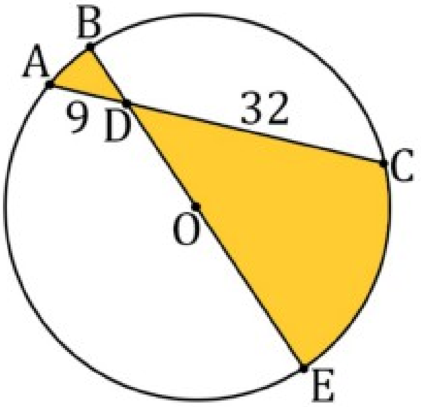
Apply the intersecting chords theorem:

$$(AE)(CE) = (BE)(DE)$$

$$(2)(10) = (4)(DE)$$

$$\frac{20}{4} = 5 = DE$$

Example 5. In the diagram below, $AD = 9$, $CD = 32$, and the radius of the circle equals 22. Find DO.



Apply the intersecting chords theorem:

$$(AD)(CD) = R^2 - DO^2$$

$$(9)(32) = 22^2 - DO^2$$

$$288 = 484 - \mathrm{DO}^2$$

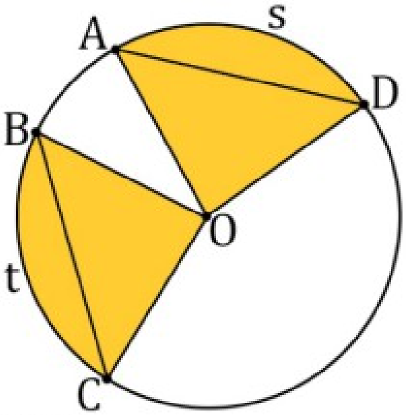
$$\mathrm{DO}^2 + 288 = 484$$

$$\mathrm{DO}^2 = 484 - 288 = 196$$

$$\mathrm{DO} = \sqrt{196} = 14$$

Check: $(\mathrm{BD})(\mathrm{DE}) = (22 - 14)(22 + 14) = (8)(36) = 288$.

Example 6. In the diagram below, point O lies at the center of the circle and $\overline{\mathrm{AD}} \cong \overline{\mathrm{BC}}$. Prove that s ≅ t.

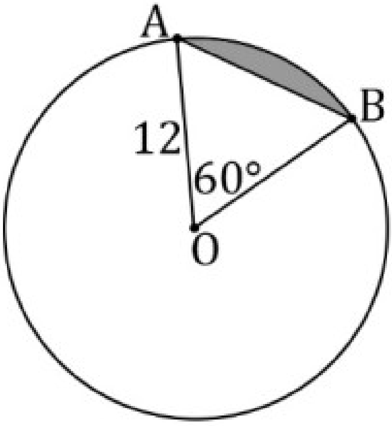


$\overline{\mathrm{AO}} \cong \overline{\mathrm{DO}} \cong \overline{\mathrm{BO}} \cong \overline{\mathrm{CO}}$ because each is a radius and $\overline{\mathrm{AD}} \cong \overline{\mathrm{BC}}$ is given. $\Delta\mathrm{ADO} \cong \Delta\mathrm{BCO}$ according to SSS (recall Volume 1, Chapter 3). $\angle\mathrm{AOD} \cong \angle\mathrm{BOC}$ via the CPCTC. Since arc length equals radius times the central angle (Chapter 3), it follows that s ≅ t (because $\angle\mathrm{AOD}$ and $\angle\mathrm{BOC}$ are the central angles that subtend arc lengths s and t). This proves that if two chords are congruent, the corresponding minor arcs are also congruent.

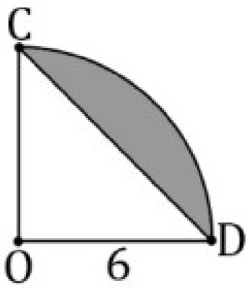
Chapter 6 Problems

Note: The diagrams are not drawn to scale.

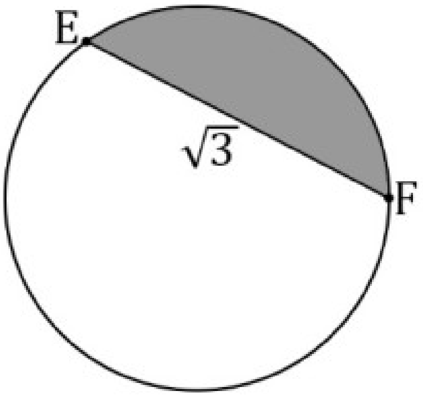
1. In the diagram below, point O lies at the center of the circle, $AO = 12$, and $\angle AOB = 60°$. Determine the length of chord AB and the area of the shaded circular segment.



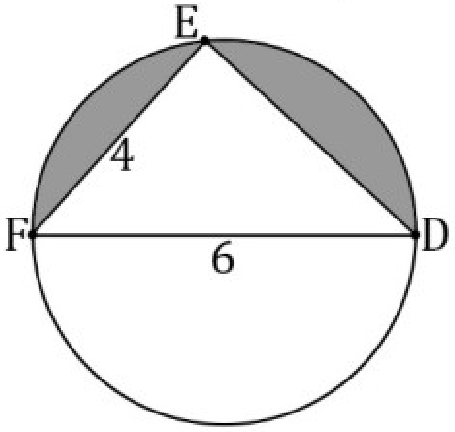
2. The diagram below shows a quarter circle. Determine the length of chord CD and the area of the shaded circular segment.



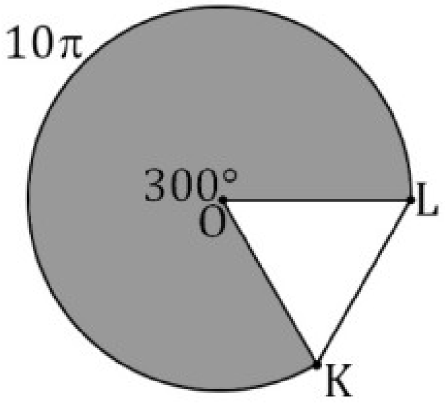
3. In the diagram below, $EF = \sqrt{3}$ and the radius of the circle is 1. Determine the central angle that subtends the minor arc from E to F and the area of the shaded circular segment.



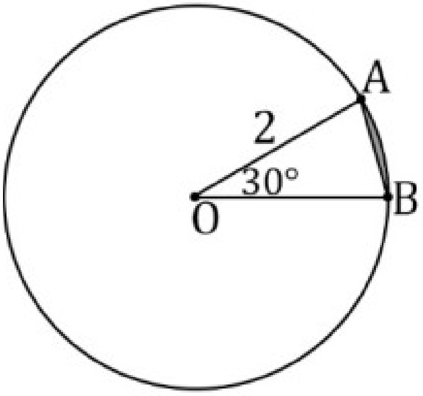
4. In the diagram below, DF is a diameter of the circle. Determine the length of chord DE and the combined area of the two shaded circular segments.



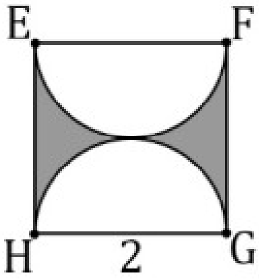
5. In the diagram below, point O lies at the center of the circle and the major arc length from K to L is 10π. Determine the length of chord KL and the area of the shaded region.



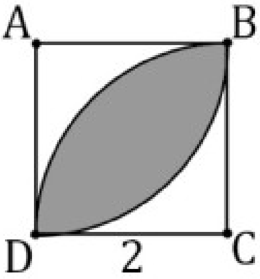
6. In the diagram below, point O lies at the center of the circle, $AO = 2$, and $\angle AOB = 30°$. Determine the length of chord AB and the area of the shaded circular segment. **Tip**: Draw a vertical line segment down from A to make two right triangles. Draw these triangles in a larger diagram off to the side.



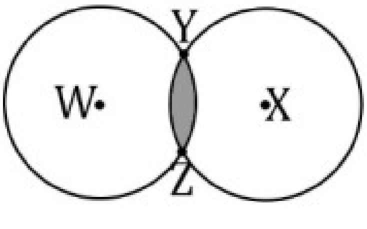
7. The diagram below shows square EFGH and two semicircles that have $\overline{EF}$ and $\overline{GH}$ as diameters. Find the combined area of the shaded regions.



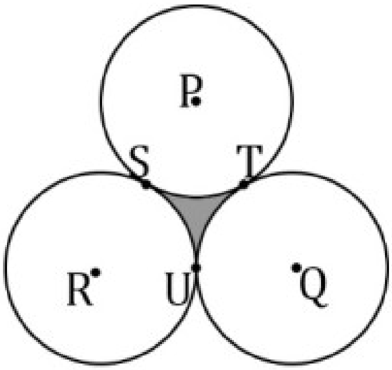
8. The diagram below shows square ABCD and two quarter circles that have points A and C as centers. Find the area of the shaded region.



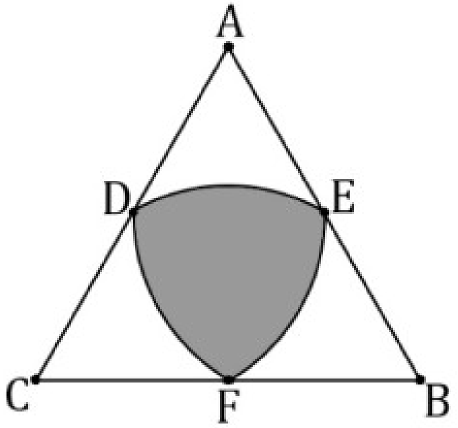
9. In the diagram below, ⊙W and ⊙X intersect at points Y and Z, ⊙W and ⊙X have the same radius (which is 6), and the radius of ⊙W and ⊙X is equal to YZ. Find the area of the shaded region.



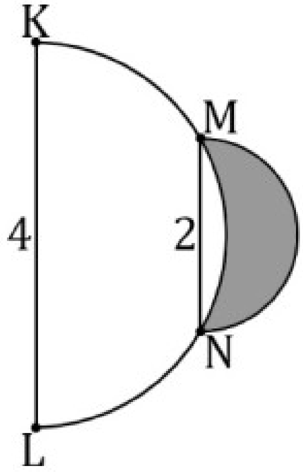
10. In the diagram below, ⊙P, ⊙Q, and ⊙R each have a radius of 3, ⊙P and ⊙Q touch only at point T, ⊙Q and ⊙R touch only at point U, and ⊙P and ⊙R touch only at point S. Find the area of the shaded region.



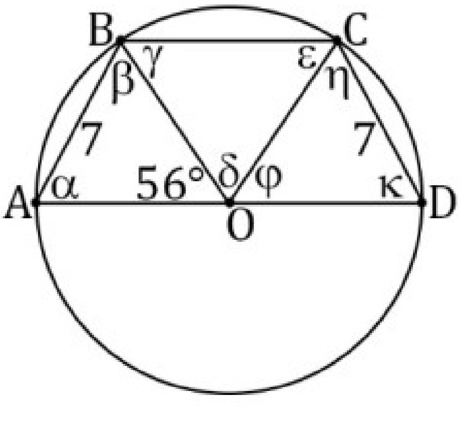
11. The diagram below shows ΔABC and three arcs of circles that have points D, E, and F as centers. Points D, E, and F are midpoints of their respective sides and AB = AC = BC = 2. Find the area of the shaded region.



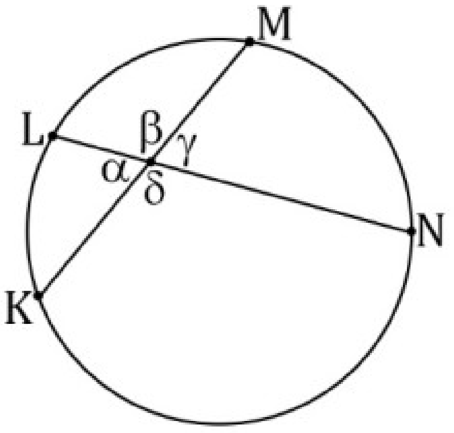
12. The crescent-shaped region formed between two circular arcs such as the shaded region below is called a **lune**. In the diagram below, LK and MN are the diameters of the two semicircles. Find the area of the shaded lune.

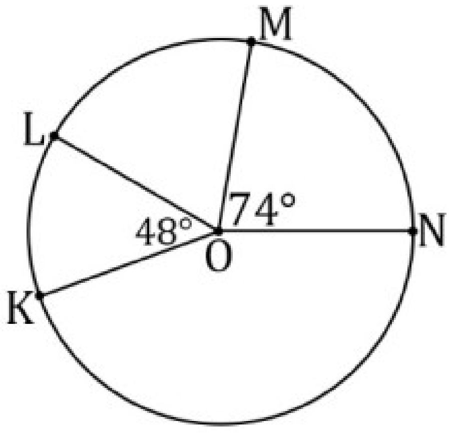


13. In the diagram below, point O lies at the center of the circle, $\overline{AD}$ is a diameter, and $AB = CD = 7$. Determine α, β, γ, δ, ε, φ, η, and κ.

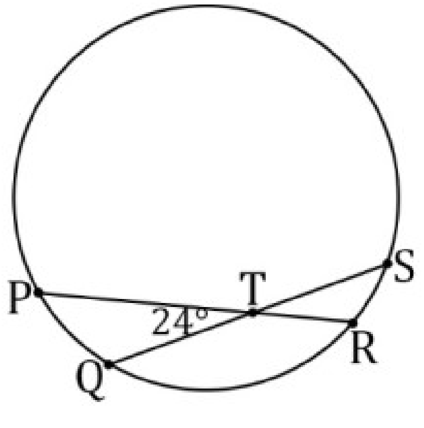


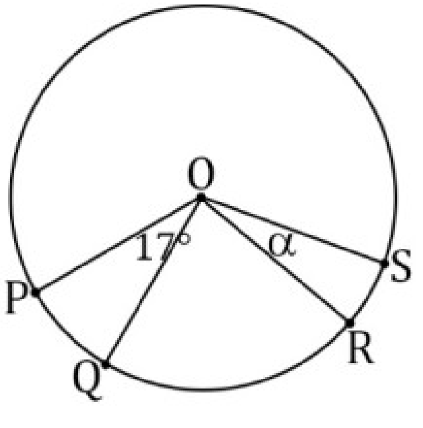
14. The same circle is shown twice below. On the right, point O lies at the center of the circle. Determine α, β, γ, and δ.



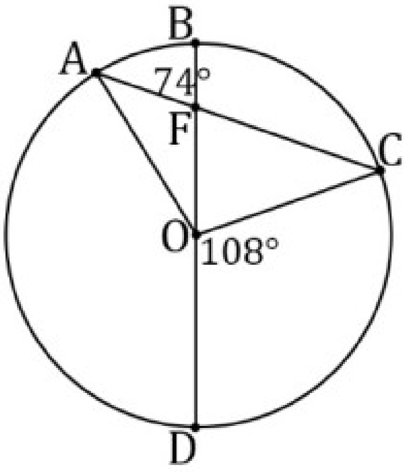


15. The same circle is shown twice below. On the right, point O lies at the center of the circle. Determine α.

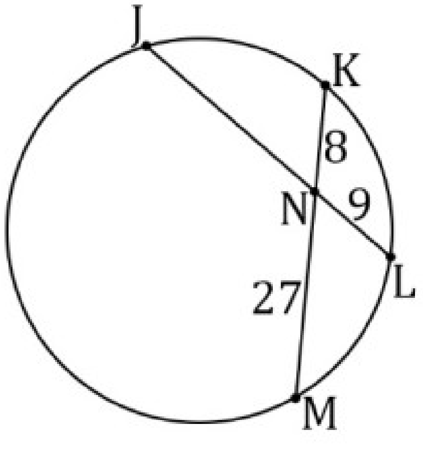




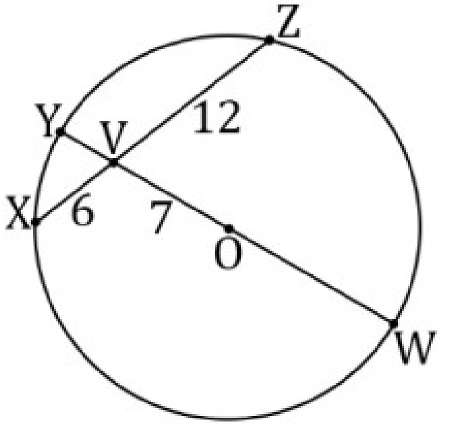
16. In the diagram below, $\angle AFB = 74°$, $\angle COD = 108°$, and point O lies at the center of the circle. Determine $\angle AOF$.



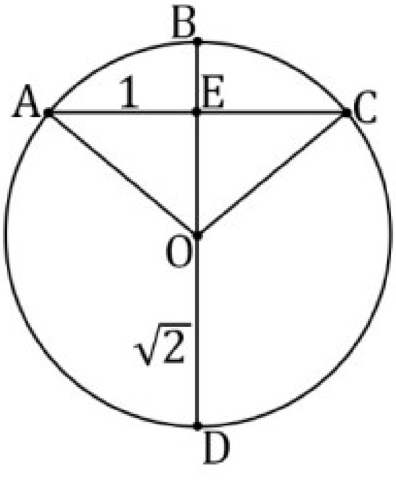
17. In the diagram below, $KN = 8$, $LN = 9$, $MN = 27$, and the diameter of the circle is 36. Find JN and the distance from N to the center of the circle.



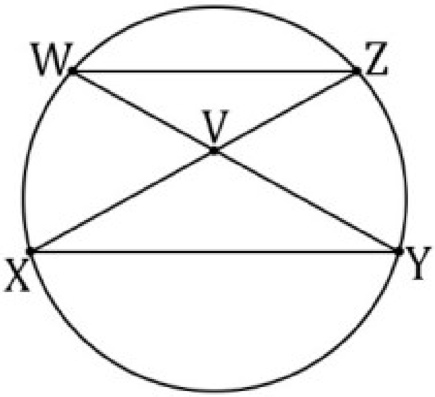
18. In the diagram below, $VX = 6$, $OV = 7$, $VZ = 12$, and point O lies at the center of the circle. Find VY, OY, and WY.



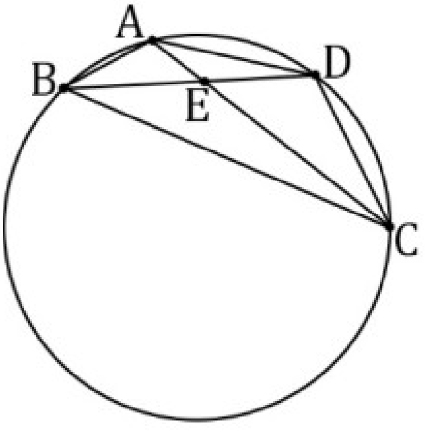
19. In the diagram below, point O lies at the center of the circle, $AE = 1$, $DO = \sqrt{2}$, and $\overline{AC} \perp \overline{BD}$. Find $\angle AOE$, $\angle COD$, AO, EO, and BE without using the formulas below. Use these answers and the information given to verify that $(BE)(DE) = (AE)(CE) = R^2 - EO^2$ and that $\angle BEA = \frac{\angle AOE + \angle COD}{2}$.



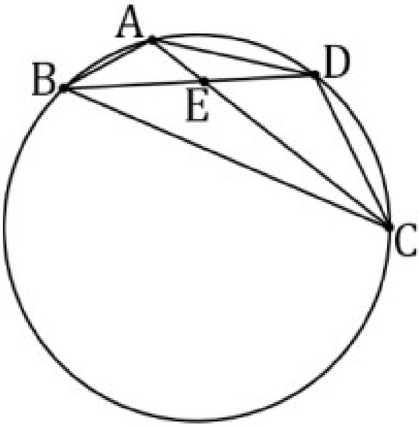
20. In the diagram below, $\overline{VW} \cong \overline{VZ}$. Prove that $\overline{WZ} \parallel \overline{XY}$. Note: Point V does NOT lie at the center of the circle and NONE of the chords shown is a diameter.



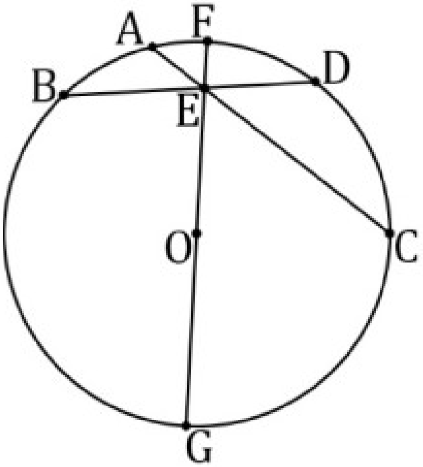
21. Prove that $\Delta ABE \sim \Delta CDE$ and $\Delta ADE \sim \Delta BCE$ in the diagram below. Notes: Point E may NOT lie at the center of the circle. Do NOT assume that any of the chords are parallel. Do NOT use the intersecting chords theorem. Hint: Review Chapter 4.



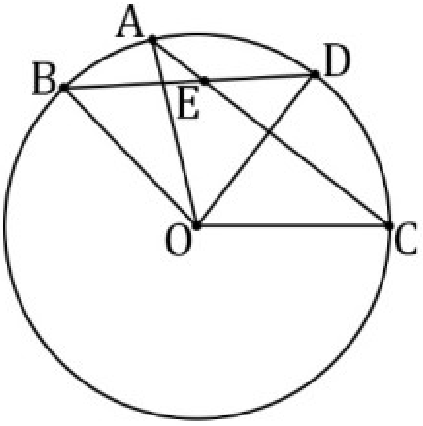
22. Prove that $(\mathrm{AE})(\mathrm{CE}) = (\mathrm{BE})(\mathrm{DE})$ for the diagram below. Notes: Point E may NOT lie at the center of the circle. Do NOT assume that any of the chords are parallel.



23. In the diagram below, point O lies at the center of the circle. Prove that $(\mathrm{AE})(\mathrm{CE}) = (\mathrm{BE})(\mathrm{DE}) = \mathrm{R}^2 - \mathrm{EO}^2$.



24. In the diagram below, point O lies at the center of the circle. Prove that $\angle AEB = \angle CED = \frac{\angle AOB + \angle COD}{2}$.



Chapter 6 Answers

1. $AB = 12$ and $A = 24\pi - 36\sqrt{3} = 12(2\pi - 3\sqrt{3}) \approx 13$. Notes: Since $360° \div 6 = 60°$, the area of the sector is $\frac{\pi R^2}{6} = \frac{\pi 12^2}{6} = \frac{144\pi}{6} = 24\pi$. Since $AO = BO = R$ and $\angle AOB = 60°$, it follows that ΔABO is an equilateral triangle. The edge length of ΔABO is the radius of the circle: $L = R = 12$. Recall from Volume 1, Chapter 6 that the area of an equilateral triangle with edge length L is $\frac{L^2\sqrt{3}}{4} = \frac{12^2\sqrt{3}}{4} = \frac{144\sqrt{3}}{4} = 36\sqrt{3}$. The area of the sector minus the area of the triangle equals the area of the circular segment:

$$A = 24\pi - 36\sqrt{3} = 12(2\pi - 3\sqrt{3})$$

In the last step, 12 was factored out. (Check this by distributing the 12.)

2. $CD = 6\sqrt{2}$ and $A = 9\pi - 18 = 9(\pi - 2) \approx 10.3$. Notes: The area of the quarter circle is $\frac{\pi R^2}{4} = \frac{\pi 6^2}{4} = \frac{36\pi}{4} = 9\pi$. Since $CO = DO = R$ and $\angle COD = 90°$, it follows that ΔCDO is a 45°-45°-90° triangle. The area of ΔCDO is $\frac{1}{2}bh = \frac{1}{2}R^2 = \frac{1}{2}(6)^2 = \frac{36}{2} = 18$. The area of the sector

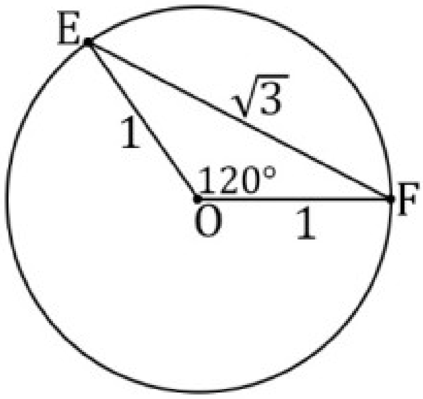
minus the area of the triangle equals the area of the circular segment:

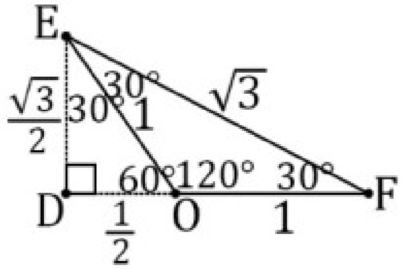
$$A = 9\pi - 18 = 9(\pi - 2)$$

In the last step, 9 was factored out. (Check this by distributing the 9.)

3. $\angle EOF = 120°$ (see the diagram on the next page) and $A = \frac{\pi}{3} - \frac{\sqrt{3}}{4} \approx 0.614$. Notes: Since EO:FO:EF = $1:1:\sqrt{3}$, ΔEOF (where O lies at the center) is a 30°-30°-120° triangle (recall Volume 1, Chapter 5, Problem 12). In the right diagram on the next page, ΔDEO and ΔDEF are 30°-60°-90° triangles. Since the sides of a 30°-60°-90° triangle come in the ratio $1:\sqrt{3}:2$, $DE = \frac{\sqrt{3}}{2}$ (since DE is opposite to 30°, DE must be one-half of EF) and $DO = \frac{1}{2}$ (since DO is opposite to 30°, it must be one-half EO). The base of ΔEFO is $FO = 1$ and the height of ΔEFO is DE $= \frac{\sqrt{3}}{2}$. The area of ΔEFO is $\frac{1}{2}(1)\left(\frac{\sqrt{3}}{2}\right) = \frac{\sqrt{3}}{4}$. Since $360° \div 3 = 120°$, the area of the sector is $\frac{\pi R^2}{3} = \frac{\pi 1^2}{3} = \frac{\pi}{3}$. The area of the sector minus the area of the triangle equals the area of the circular segment:

$$A = \frac{\pi}{3} - \frac{\sqrt{3}}{4}$$





4. $\mathrm{DE} = 2\sqrt{5}$ and $\mathrm{A} = \frac{9\pi}{2} - 4\sqrt{5} \approx 5.19$. Notes: $\Delta\mathrm{DEF}$ is a right triangle according to Thales's theorem (Chapter 5). Use the Pythagorean theorem to check that $\mathrm{DE} = 2\sqrt{5}$:

$$\mathrm{DE}^2 + \mathrm{EF}^2 = \left(2\sqrt{5}\right)^2 + 4^2 = 2^2\left(\sqrt{5}\right)^2 + 4^2$$
$$= 4(5) + 16 = 20 + 16 = 36 = 6^2 = \mathrm{DF}^2$$

The area of $\Delta\mathrm{DEF}$ is $\frac{1}{2}\mathrm{bh} = \frac{1}{2}(\mathrm{DE})(\mathrm{EF}) = \frac{1}{2}\left(2\sqrt{5}\right)(4) = 4\sqrt{5}$. The radius of the circle is $\mathrm{R} = \frac{\mathrm{DF}}{2} = \frac{6}{2} = 3$. The area of the semicircle is $\frac{\pi \mathrm{R}^2}{2} = \frac{\pi 3^2}{2} = \frac{9\pi}{2}$. The area of the sector minus the area of the triangle equals the **combined area** of the **two** circular segments:

$$\mathrm{A} = \frac{9\pi}{2} - 4\sqrt{5}$$

5. $KL = 6$ and $A = 30\pi \approx 94.2$. Notes: $300° = 300° \times \frac{\pi}{180°} = \frac{30\pi}{18} = \frac{5\pi}{3}$ rad (since 30 and 18 are each evenly divisible by 6) is the central angle for the major arc. The given value 10π is the corresponding major arc length: $s = 10\pi$. (The problem clearly states that 10π is an **arc length**, NOT an angle.) Use the arc length formula (Chapter 3).

$$s = R\theta$$

$$10\pi = R\frac{5\pi}{3}$$

$$30\pi = 5\pi R$$

$$6 = R$$

The minor central angle $\angle KOL = 360° - 300° = 60°$. Since $KO = LO = R = 6$ and $\angle KOL = 60°$, ΔKLO is an equilateral triangle. Therefore, $KL = R = 6$. Since $\frac{300°}{360°} = \frac{5}{6}$, the shaded region is $5/6$ of a full circle. The area of the shaded region (which is a **sector**, NOT a circular segment) is $\frac{5\pi R^2}{6} = \frac{5\pi 6^2}{6} = \frac{5\pi 36}{6} = 5\pi 6 = 30\pi$.

6. $AB = \sqrt{8 - 4\sqrt{3}} = 2\sqrt{2 - \sqrt{3}} = \sqrt{6} - \sqrt{2} \approx 1.04$ (all three answers are equivalent, but the form $\sqrt{6} - \sqrt{2}$ is preferred because it does not have nested square roots)

and $A = \frac{\pi}{3} - 1 = \frac{\pi-3}{3} \approx 0.0472$. Notes: ΔABO is isosceles: $AO = BO = R = 2$. (ΔABO is NOT a right triangle.) Draw vertical line segment $\overline{AC}$, as shown on the next page, to create right triangles ΔACO and ΔABC. Since ΔACO is a 30°-60°-90° triangle, $AC{:}CO{:}AO = 1{:}\sqrt{3}{:}2$. Since $CO = \sqrt{3}$ and $BO = 2$, it follows that $BC = 2 - \sqrt{3}$. Use the Pythagorean theorem to find AB.

$$BC^2 + AC^2 = AB^2$$

$$\left(2 - \sqrt{3}\right)^2 + 1^2 = AB^2$$

Apply the "foil" method: $(t - u)^2 = t^2 - 2tu + u^2$.

$$4 - 4\sqrt{3} + 3 + 1 = AB^2$$

$$8 - 4\sqrt{3} = 4\left(2 - \sqrt{3}\right) = AB^2$$

$$\sqrt{8 - 4\sqrt{3}} = 2\sqrt{2 - \sqrt{3}} = AB$$

Following is a clever way to avoid the nested square roots given above.

$$8 - 4\sqrt{3} = 8 - 2(2)\sqrt{3} = 8 - 2\sqrt{4}\sqrt{3} = 6 - 2\sqrt{12} + 2$$

$$= \left(\sqrt{6} - \sqrt{2}\right)^2$$

$$AB = \sqrt{8 - 4\sqrt{3}} = \sqrt{6} - \sqrt{2}$$

Since $\frac{30°}{360°} = \frac{1}{12}$, the area of the sector is $1/12$ the area of a full circle:

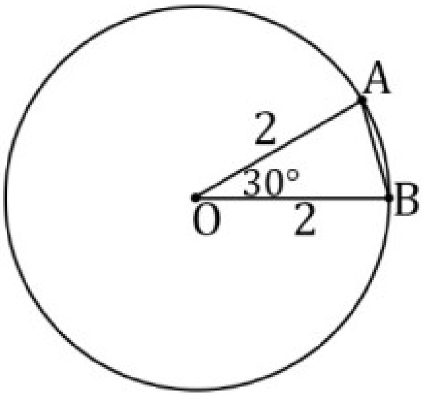
$$\frac{\pi R^2}{12} = \frac{\pi 2^2}{12} = \frac{4\pi}{12} = \frac{\pi}{3}$$

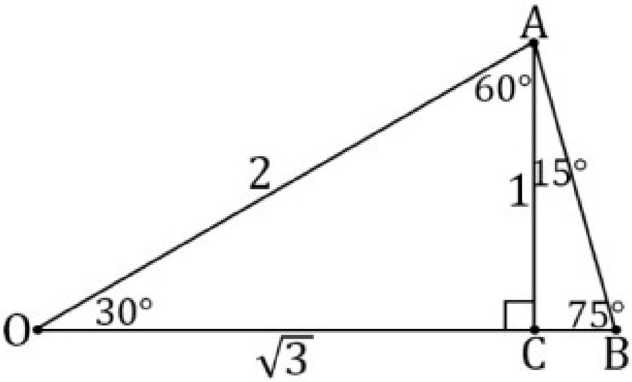
Since ΔABO has a base of BO = 2 and a height of AC = 1, the area of ΔABO is

$$\frac{1}{2}bh = \frac{1}{2}(BO)(AC) = \frac{1}{2}(2)(1) = 1$$

and the area of the circular segment is

$$A = \frac{\pi}{3} - 1 = \frac{\pi - 3}{3}$$

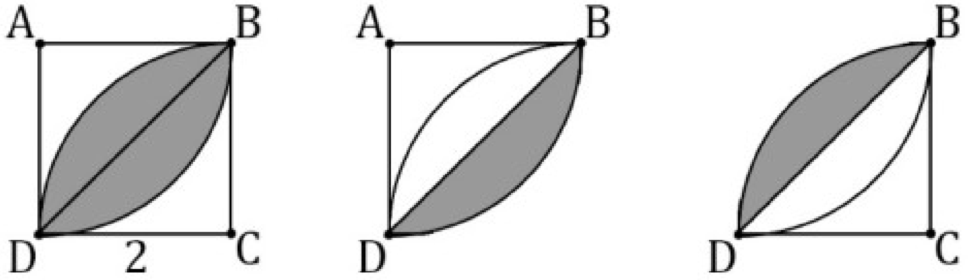




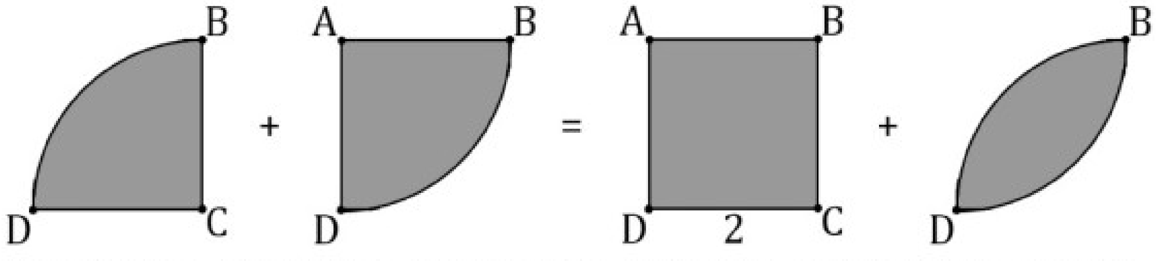
7. $A = 4 - \pi \approx 0.858$. Notes: The area of the square is $2^2 = 4$. The combined area of the two semicircles equals the area of one circle of radius $R = \frac{2}{2} = 1$. The combined area of the two semicircles is $\pi R^2 = \pi 1^2 = \pi$. To find the combined area of the shaded regions, subtract the area of the two semicircles from the area of the square.

8. $A = 2\pi - 4 = 2(\pi - 2) \approx 2.28$. Method 1: Cut the square in half along a diagonal as shown below. Find the

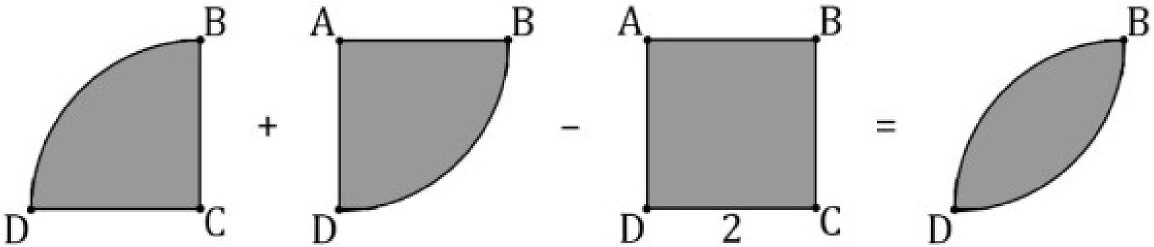
area of each shaded circular segment shown below (recall the solution to Problem 2). The area of the quarter circle is $\frac{\pi R^2}{4} = \frac{\pi 2^2}{4} = \frac{4\pi}{4} = \pi$. The area of the right triangle is $\frac{1}{2} bh = \frac{1}{2} R^2 = \frac{1}{2}(2)^2 = \frac{4}{2} = 2$. The area of the sector minus the area of the triangle equals the area of the circular segment: $\pi - 2$. The two circular segments shown below have equal area. The total area is $A = 2\pi - 4 = 2(\pi - 2)$.



Method 2: The area of the two quarter circles shown below added together equals the area of the square plus the area of the desired shaded region.



Therefore, the area of the two quarter circles minus the area of the square equals the area of the desired shaded region.

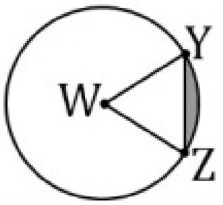


$$\frac{\pi R^2}{4} + \frac{\pi R^2}{4} - R^2 = A$$

$$A = \frac{\pi 2^2}{4} + \frac{\pi 2^2}{4} - 2^2 = \frac{4\pi}{4} + \frac{4\pi}{4} - 4 = 2\pi - 4$$

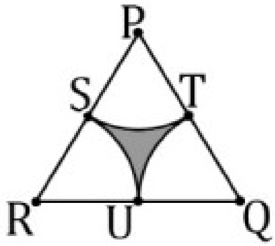
$$= 2(\pi - 2)$$

9. $A = 12\pi - 18\sqrt{3} = 6\left(2\pi - 3\sqrt{3}\right) \approx 6.52$. Notes: $WY = WZ = YZ = XY = XZ = R = 6$. $\Delta WYZ \cong \Delta XYZ$ and both are equilateral triangles. Find the area of the circular segment shown below (like the solution to Problem 1) and then double this. The area of the sector is $\frac{\pi R^2}{6} = \frac{\pi 6^2}{6} = \frac{36\pi}{6} = 6\pi$. Recall from Volume 1, Chapter 6 that the area of an equilateral triangle with edge length L is $\frac{L^2\sqrt{3}}{4} = \frac{6^2\sqrt{3}}{4} = \frac{36\sqrt{3}}{4} = 9\sqrt{3}$. The area of the sector minus the area of the triangle equals the area of the circular segment: $6\pi - 9\sqrt{3} = 3\left(2\pi - 3\sqrt{3}\right)$. Double this to find the total area: $A = 12\pi - 18\sqrt{3} = 6\left(2\pi - 3\sqrt{3}\right)$.



10. $A = 9\sqrt{3} - \frac{9\pi}{2} = 9\left(\sqrt{3} - \frac{\pi}{2}\right) \approx 1.45$. Notes: ΔPQR is an equilateral triangle with edge length $PQ = PR = QR = 2R = 2(3) = 6$. Recall from Volume 1, Chapter 6 that the area of an equilateral triangle with edge length L is $\frac{L^2\sqrt{3}}{4} = \frac{6^2\sqrt{3}}{4} = \frac{36\sqrt{3}}{4} = 9\sqrt{3}$. Each of the three sectors (for vertices P, Q, and R) has a 60° angle (like Problems 1 and 9). Each sector has area $\frac{\pi R^2}{6} = \frac{\pi 3^2}{6} = \frac{9\pi}{6} = \frac{3\pi}{2}$. (Note that the radius of each sector is $R = 3$, whereas the edge length of equilateral triangle ΔPQR is $2R = 6$.) The combined area of the three sectors is $3\left(\frac{3\pi}{2}\right) = \frac{9\pi}{2}$. The area of ΔPQR minus the area of the three sectors equals the area of the shaded region.

$$A = 9\sqrt{3} - \frac{9\pi}{2} = 9\left(\sqrt{3} - \frac{\pi}{2}\right)$$

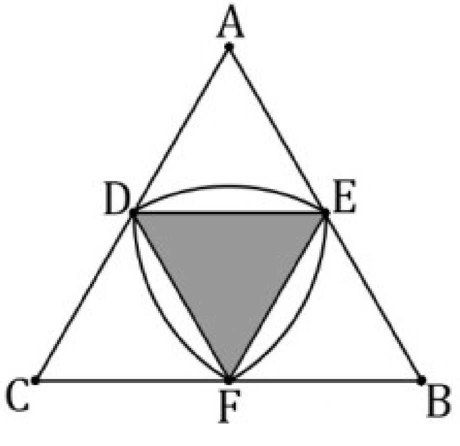


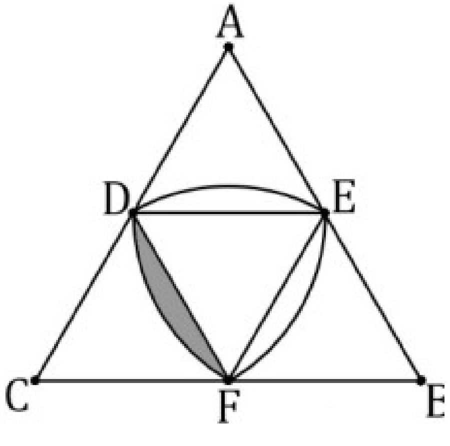
11. $A = \frac{\pi}{2} - \frac{\sqrt{3}}{2} = \frac{\pi - \sqrt{3}}{2} \approx 0.705$. Notes: Draw ΔDEF as shown on the next page. ΔDEF is an equilateral triangle with edge length $DE = DF = EF = \frac{AB}{2} = \frac{AC}{2} = \frac{BC}{2} = \frac{2}{2} = 1$

(recall Volume 1, Chapter 7, "Tips for Working with Medians"). The area of ΔDEF is $\frac{L^2\sqrt{3}}{4} = \frac{1^2\sqrt{3}}{4} = \frac{\sqrt{3}}{4}$ (recall Volume 1, Chapter 6). The area of the **sector** from vertex E that includes both ΔDEF and the shaded circular segment in the diagram on the right below is $\frac{\pi R^2}{6} = \frac{\pi 1^2}{6} = \frac{\pi}{6}$ (like the solution to Problem 1). The area of the sector minus the area of ΔDEF equals the area of the shaded circular **segment** shown in the diagram on the right below: $\frac{\pi}{6} - \frac{\sqrt{3}}{4}$. To find the shaded region given in the problem, add the area of ΔDEF to three times the area of the circular segment shown below on the right.

$$\frac{\sqrt{3}}{4} + 3\left(\frac{\pi}{6} - \frac{\sqrt{3}}{4}\right) = \frac{\sqrt{3}}{4} + \frac{3\pi}{6} - \frac{3\sqrt{3}}{4} = \frac{3\pi}{6} - \frac{2\sqrt{3}}{4}$$

$$= \frac{\pi}{2} - \frac{\sqrt{3}}{2} = \frac{\pi - \sqrt{3}}{2}$$

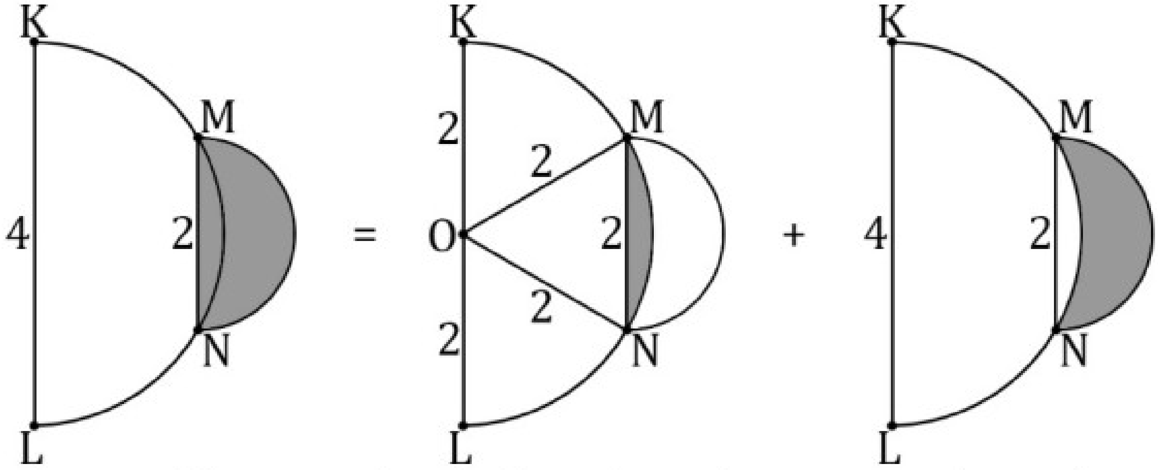




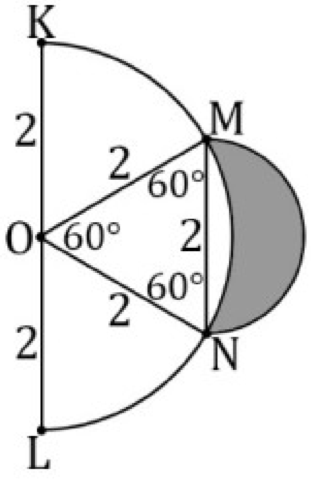
12. $A = \sqrt{3} - \frac{\pi}{6} \approx 1.21$. Notes: The area of the small semicircle shaded in the diagram on the left on the next page minus the area of the circular segment shaded in the middle diagram equals the area of the lune shaded in the diagram on the right. The radius of the small semicircle is $R_{\text{small}} = \frac{2}{2} = 1$. The area of the small semicircle is $\frac{\pi R_{\text{small}}^2}{2} = \frac{\pi 1^2}{2} = \frac{\pi}{2}$. Each sector in the middle diagram on the following page has a 60° central angle, a radius of $R_{\text{large}} = \frac{4}{2} = 2$, and an area of $\frac{\pi R_{\text{large}}^2}{6} = \frac{\pi 2^2}{6} = \frac{4\pi}{6} = \frac{2\pi}{3}$. ΔMNO is an equilateral triangle. The area of ΔMNO is $\frac{L^2\sqrt{3}}{4} = \frac{2^2\sqrt{3}}{4} = \frac{4\sqrt{3}}{4} = \sqrt{3}$ (Volume 1, Chapter 6). Subtract the area of ΔMNO from the area of the sector to find the area of the circular segment shaded in the middle diagram on the following page: $\frac{2\pi}{3} - \sqrt{3}$. To find the area of the lune, subtract the area of the circular segment from the area of the small semicircle shaded in the left diagram.

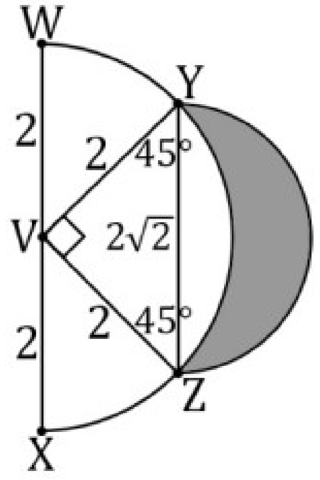
$$\frac{\pi}{2} - \left(\frac{2\pi}{3} - \sqrt{3}\right) = \frac{\pi}{2} - \frac{2\pi}{3} + \sqrt{3} = \sqrt{3} + \frac{3\pi}{6} - \frac{4\pi}{6}$$
$$= \sqrt{3} - \frac{\pi}{6}$$

The minus sign was distributed. For example,
$a - (b - c) = a - b - (-c) = a - b + c$.



This problem involved a lune based on an equilateral triangle (ΔMNO). Don't confuse this lune with another common and important lune, which instead features a 45°-45°-90° triangle. The lune based on the 45°-45°-90° triangle is important because the π's cancel out for that lune. Compare the two lunes shown on the next page. The lune on the left was featured in this problem, and involves an equilateral triangle. The lune on the right involves a 45°-45°-90° triangle. For the lune on the right, the π's cancel out. Try it!





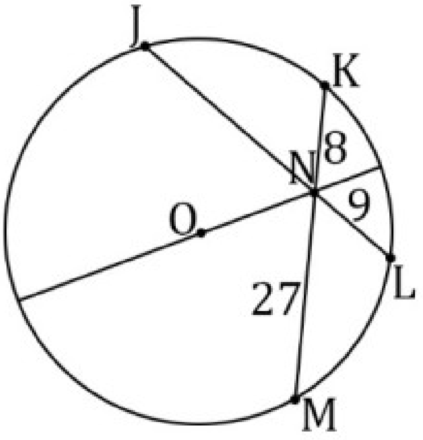
13. $\alpha = 62°$, $\beta = 62°$, $\gamma = 56°$, $\delta = 68°$, $\varepsilon = 56°$, $\varphi = 56°$, $\eta = 62°$, and $\kappa = 62°$. Notes: Central angles that subtend congruent arcs are congruent. Since congruent chords subtend congruent arcs, central angles that subtend congruent chords are congruent. Therefore, since $AB = CD = 7$, $\varphi = 56°$. $AO = BO = CO = DO = R$. Although the value of R is not given, it is clear that ΔABO, ΔBCO, and ΔCDO are isosceles triangles, such that $\alpha = \beta$, $\gamma = \varepsilon$, and $\eta = \kappa$. Checks: $56° + \delta + \varphi = 56° + 68° + 56° = 180°$ (straight angle), $\alpha + \beta + 56° = 62° + 62° + 56° = 180°$, $\delta + \gamma + \varepsilon = 68° + 56° + 56° = 180°$, $\varphi + \eta + \kappa = 56° + 62° + 62° = 180°$. Parallel notes: It turns out that $\overline{BC} \parallel \overline{AD}$ (which is why $\gamma = 56°$ and $\varepsilon = \varphi$ are two pairs of congruent alternate interior angles), but $\overline{BO}$ is NOT parallel to $\overline{CD}$ (η does NOT equal δ) and $\overline{AB}$ is NOT parallel to $\overline{CO}$ (δ does NOT equal β).

14. $\alpha = \gamma = 61°$ and $\beta = \delta = 119°$. Notes: $\alpha = \gamma = \frac{48°+74°}{2} = \frac{122°}{2} = 61°$ (intersecting chords) and $\beta = \delta$ (vertical angles). Check: $\alpha + \beta + \gamma + \delta = 61° + 119° + 61° + 119° = 360°$.

15. $\alpha = 31°$. Check: $\angle PTQ = \angle STR = \frac{\alpha+17°}{2} = \frac{31°+17°}{2} = \frac{48°}{2} = 24°$. Note: To solve for α, first write $24° = \frac{\alpha+17°}{2}$ and then multiply both sides of the equation by 2.

16. $\angle AOF = 40°$. Check: $\angle AFB = \angle CFD = \frac{\angle AOB+\angle COD}{2} = \frac{40°+108°}{2} = \frac{148°}{2} = 74°$. Notes: $\angle AOB \cong \angle AOF$. $\overline{AC}$ and $\overline{BD}$ are the intersecting chords. In this problem, $\overline{BD}$ happens to be a diameter.

17. $JN = 24$ and $NO = 6\sqrt{3}$. Checks: $(JN)(LN) = (24)(9) = 216$, $(KN)(MN) = (8)(27) = 216$, and $R^2 - NO^2 = 18^2 - \left(6\sqrt{3}\right)^2 = 324 - (6)^2\left(\sqrt{3}\right)^2 = 324 - 36(3) = 324 - 108 = 216$.



18. VY = 4, OY = 11, and WY = 22. Checks: (VX)(VZ) = (6)(12) = 72 and $R^2 - OV^2 = 11^2 - 7^2 = 121 - 49 = 72$. Notes: Apply the intersecting chords theorem to $\overline{WY}$ and $\overline{XZ}$. In this problem, $\overline{WY}$ happens to be a diameter. VY + OV = OY = R.

19. ∠AOE = 45°, ∠COD = 135°, AO = $\sqrt{2}$, EO = 1, and BE = $\sqrt{2} - 1$. Notes: AO = BO = CO = DO = R = $\sqrt{2}$. ΔAEO and ΔCEO are 45°-45°-90° triangles. AE:EO:AO = CE:EO:CO = 1:1:$\sqrt{2}$. ∠AOE = ∠COE = 45°. ∠COE + ∠COD = 180°. BE + EO = BO. DO + EO = DE = 1 + $\sqrt{2}$. Checks: (BE)(DE) = $\left(\sqrt{2} - 1\right)\left(1 + \sqrt{2}\right) = \sqrt{2} + 2 - 1 - \sqrt{2} = 2 - 1 = 1$, (AE)(CE) = (1)(1) = 1, $R^2 - EO^2 = \left(\sqrt{2}\right)^2 - 1^2 = 2 - 1 = 1$, and $\frac{\angle AOE + \angle COD}{2} = \frac{45° + 135°}{2} = \frac{180°}{2} = 90° = \angle BEA$.

20. Main ideas: $(\mathrm{VW})(\mathrm{VY}) = (\mathrm{VZ})(\mathrm{VX})$ since $\overline{\mathrm{WY}}$ and $\overline{\mathrm{XZ}}$ are intersecting chords. Since $\overline{\mathrm{VW}} \cong \overline{\mathrm{VZ}}$, this becomes $(\mathrm{VW})(\mathrm{VY}) = (\mathrm{VW})(\mathrm{VX})$, which reduces to $\mathrm{VY} = \mathrm{VX}$. $\Delta\mathrm{WVZ} \sim \Delta\mathrm{VXY}$ according to SAS similarity ($\mathrm{VW}/\mathrm{VZ} = 1$, $\mathrm{VY}/\mathrm{VX} = 1$, and the angle between the sides is congruent; recall Volume 1, Chapter 4). $\angle\mathrm{WZV} \cong \angle\mathrm{VXY}$ are congruent alternate interior angles (because $\Delta\mathrm{WVZ}$ is similar to $\Delta\mathrm{VXY}$ and each triangle is isosceles). Note: Recall from Volume 1 that $\sim$ means similarity, whereas $\cong$ means congruence.

21. Main ideas: $\angle\mathrm{AEB} \cong \angle\mathrm{CED}$ (vertical angles) and $\angle\mathrm{ABD} \cong \angle\mathrm{ACD}$ (these inscribed angles subtend the same arc length from A to D; recall Chapter 4). $\Delta\mathrm{ABE} \sim \Delta\mathrm{CDE}$ according to AA (recall Volume 1, Chapter 4). It can similarly be shown that $\Delta\mathrm{ADE} \sim \Delta\mathrm{BCE}$.

22. Main ideas: $\Delta\mathrm{ABE} \sim \Delta\mathrm{CDE}$ (see the solution to Problem 21). AE:BE = DE:CE because the corresponding sides of similar triangles come in the same proportion (Volume 1, Chapter 4).

$$\frac{\mathrm{AE}}{\mathrm{BE}} = \frac{\mathrm{DE}}{\mathrm{CE}}$$

Cross multiply. (Multiply both sides by BE and by CE.)

$$(\mathrm{AE})(\mathrm{CE}) = (\mathrm{BE})(\mathrm{DE})$$

23. Main ideas: $(AE)(CE) = (BE)(DE)$ was proven in Problem 22. Apply the intersecting chords theorem (proven in Problems 21-22) to chords $\overline{AC}$ and $\overline{FG}$: $(AE)(CE) = (EF)(EG)$. Since $EF + EO = FO = GO = R$, it follows that $EF = R - EO$ and $EG = R + EO$. Therefore, $(AE)(CE) = (EF)(EG)$ may be rewritten as:

$$(AE)(CE) = (R - EO)(R + EO)$$

Apply the "foil" method: $(a + b)(c + d) = ac + ad + bc + bd$.

$$(AE)(CE) = R^2 + R(EO) - (EO)R - EO^2 = R^2 - EO^2$$

24. Main ideas: Draw line segment $\overline{AD}$, as shown on the next page. $\angle AED + \angle DAE + \angle ADE = 180°$ (interior angles of ΔADE). $\angle AED + \angle CED = 180°$ (supplementary angles). $\angle CED = \angle DAE + \angle ADE$ (set the first two equations equal and subtract $\angle AED$ from both sides.) $\angle DAE = \angle DAC = \frac{\angle COD}{2}$ and $\angle ADE = \angle ADB = \frac{\angle AOB}{2}$ (an inscribed angle is one-half of a central angle that subtends the same arc; recall Chapter 4). Plug $\angle DAE = \frac{\angle COD}{2}$ and $\angle ADE = \frac{\angle AOB}{2}$ into $\angle CED = \angle DAE + \angle ADE$ to get $\angle CED = \frac{\angle COD}{2} + \frac{\angle AOB}{2} = \frac{\angle COD + \angle AOB}{2}$.

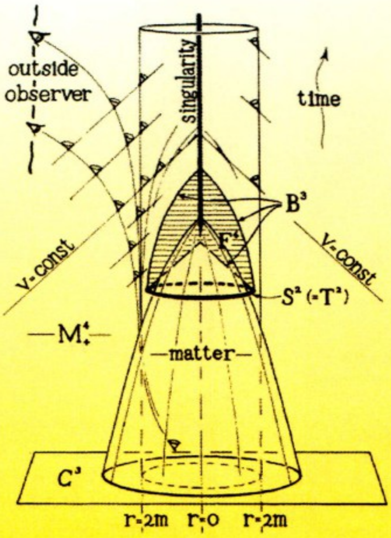
« une belle endormie » qui mobilisait peu.

Dans les années 1960, Roger Penrose a révolutionné la relativité générale en introduisant des techniques de topologie différentielle et de géométrie algébrique (voir l'article suivant). À cette époque, les trous noirs étaient des objets décrits par certaines solutions des équations de la relativité générale et avait fait l'objet de différents modèles décrits par l'astrophysicien allemand Karl Siegmund Schwarzschild (1873–1916), par Roy Kerr et par le physicien américain Julius Robert Oppenheimer (1904–1967). Il n'y avait pas alors de preuve expérimentale ou observationnelle de leur existence.

Le grand apport de Penrose a été d'utiliser la relativité générale pour théoriser la formation de trous noirs par effondrement gravitationnel des étoiles. Il proposait donc, pour la première fois, une histoire de la formation des trous noirs, ce qui pouvait apporter une preuve théorique supplémentaire de leur existence. Il publiait ainsi en 1965 un article dans lequel il démontrait, en utilisant la relativité générale, que les trous noirs pouvaient se former dans des conditions réalistes et qu'il existait, au-delà de l'horizon des évènements, une singularité qui ne pouvait être décrite par les théories physiques actuelles. Avec Stephen Hawking, d'abord son étudiant, puis son collaborateur, les recherches sur les trous noirs connurent des développements continus et importants, marqués aussi par des controverses heuristiques sur l'« entropie des trous noirs » (voir *la Guerre des savants*, Leonard Susskind, Robert Laffont, 2010).

Le diagramme de Penrose

Cette vue cavalière représente une étoile qui s'effondre en deux coordonnées d'espace. Un cercle est une sphère. Le temps s'écoule vers le haut du diagramme : le cercle en bas représente la surface de l'étoile, et son rayon va diminuer (vers le haut) en fonction du temps.



)© Roger Penrose, Physical Review Letters, 1965

À un moment donné, la surface atteint le cercle en gras, qui représente le rayon de Schwarzschild.

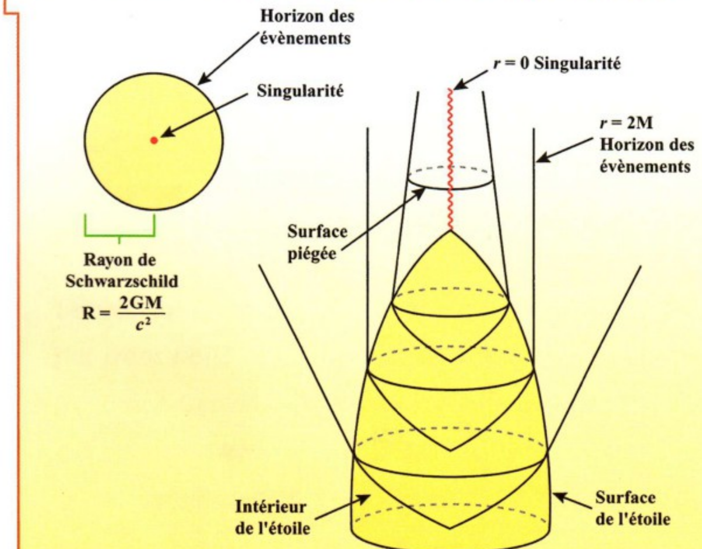
La diminution de la surface continue jusqu'à la singularité formée par la ligne verticale figurée en gras. Ce diagramme montre l'effondrement d'une étoile vers un trou noir.

La théorie de l'effondrement gravitationnel

Roger Penrose démontrait en 1965 un théorème de géométrie qui éclairait l'effondrement gravitationnel non sphérique des étoiles (*Gravitational collapse and space-time singularities*, *Physical Review Letters* 14). Interprété dans le langage de la physique, le résultat est le suivant : tout comme dans un effondrement sphérique, dans un effondrement « réaliste » non sphérique, un stade critique est atteint au-delà duquel aucune communication avec l'extérieur ne peut être établie. Une fois que ce stade est passé, un ou deux évènements peuvent survenir : soit la géométrie de l'espace-temps produit une singularité (cas d'un effondrement sphérique), soit, de manière plus étonnante, l'effondrement met en contact notre univers avec un autre univers dont nous ignorions jusque-là l'existence.

Il y a une différence importante entre la singularité engendrée par un effondrement sphérique et celle qui pourrait être créée lors d'un effondrement non sphérique. Dans le premier cas, lorsqu'elle rencontre la singularité, la matière qui constitue l'étoile est « écrasée » en une densité infinie, dans un volume nul. Dans le cas général, le théorème de Penrose n'affirme rien quant au comportement de la matière d'une étoile en effondrement : cette matière pourrait émerger dans une autre région de l'univers, ou dans un autre univers. Ces résultats sur l'effondrement au-delà du rayon critique sont assez étranges pour inciter certains scientifiques à abandonner la relativité générale d'Einstein au profit d'une théorie qui prédit des phénomènes moins décapants. Penrose a cependant indiqué que la plupart des autres théories géométriques de la gravitation prévoient les mêmes types de phénomènes : son théorème repose principalement sur le mouvement des photons à travers l'espace-temps courbe, et ce mouvement est approximativement le même dans toutes les théories géométriques de la gravitation. Les phénomènes étonnants prédits à l'intérieur du rayon critique ne peuvent pas être vus par un observateur extérieur. C'est pourquoi on peut ignorer ces prédictions. Toutefois, l'évolution de notre univers ressemble

La formation d'une singularité



Tout en bas, le cercle représente la coupe d'une sphère matérielle de rayon r qui commence son effondrement gravitationnel. L'effondrement continue en s'élevant dans le schéma (le temps t augmente). Le rayon r diminue jusqu'à une limite (le *rayon de Schwarzschild*) où la sphère est si dense (et sa gravité si forte) que même la lumière ne peut échapper de sa surface. Un trou noir se forme. La position radiale à partir de laquelle la lumière ne peut plus s'échapper délimite une surface de l'espace-temps, l'*horizon des évènements*. Lorsque $r = 0$, on aboutit à une singularité, point où la matière est infiniment dense et où la courbure de l'espace-temps devient infinie. L'équation du champ d'Einstein cesse d'être valide, la théorie de la relativité générale ne s'applique plus. À l'intérieur de l'horizon des évènements, tout mouvement de matière ou de lumière est dirigé vers la singularité.

É.T.

globalement, et de bien des manières, à une étoile qui s'effondre. Si la densité de l'univers est assez grande, il ne s'étendra pas indéfiniment. Il va tôt ou tard arrêter son expansion et commencer à se contracter. La phase de contraction imiterait assez fidèlement l'effondrement d'une étoile. Par conséquent, on ne peut s'inquiéter du sort ultime de l'univers sans s'intéresser à l'effondrement gravitationnel des étoiles.

✢ La théorie des trous noirs

C'est entre 1967 et 1975 que la théorie des trous noirs progresse vraiment. Un article de Penrose publié en 1972 montre le chemin parcouru vers une compréhension beaucoup plus profonde du phénomène. Pour commencer, l'auteur prend soin de placer l'effondrement gravitationnel et la formation des trous noirs dans le contexte de l'évolution stellaire, soucieux qu'il est de faire sortir les trous noirs du champ de la spéculation pure pour les ancrer dans une réalité astronomique. Revenant ensuite sur le terrain théorique, Penrose introduit le concept de *cône de lumière* (voir encadré) pour décrire la structure de l'espace-temps. Il s'attache ensuite à décrire des solutions de type trou noir plus élaborées que celle trouvée par Schwarzschild : des trous noirs qui ne sont pas exactement sphériques, ou qui possèdent une charge électrique. Il énonce alors le *théorème fondamental de la physique des trous noirs* : le trou noir isolé le plus général est pratiquement dépourvu de propriétés.

Le trou noir isolé le plus général est formellement entièrement décrit par trois paramètres : sa masse M, sa charge électrique Q et son moment angulaire J (son « sens de rotation » : comme une étoile est en rotation, elle possède un moment cinétique, qui est conservé lorsque l'étoile change de volume et dont hérite donc le trou noir *in fine*). En conséquence, il n'existe qu'un nombre réduit de types différents de trous noirs : ceux de Schwarzschild (sphériques, obtenus à partir d'étoiles sans mouvement cinétique, donc sans mouvement de rotation, et sans charge électrique : $J = Q = 0$), ceux de Kerr (non sphériques, avec mouvement de rotation, mais sans charge électrique : $J \neq 0$, $Q = 0$), ceux de Reissner–Nordström (sans rotation et chargés électriquement : $J = 0$, $Q \neq 0$) et ceux de Kerr–Newman (à la fois en rotation et chargés : $J \neq 0$, $Q \neq 0$).
Tout comme la physique quantique, la relativité générale résiste bien aux multiples tests expérimentaux qui sont effectués depuis plusieurs dizaines d'années et qui sont récompensés aujourd'hui par un prix Nobel.

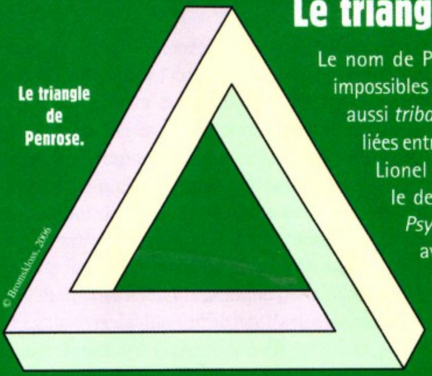
Le triangle de Penrose



Le triangle de Penrose.

© Bromskloss, 2006

Le nom de Penrose est attaché à plusieurs « objets impossibles ». C'est le cas du *triangle de Penrose*, appelé aussi *tribarre* ou *tripoutre*, constitué de trois poutres liées entre elles et représentées en 2D. Avec son père, Lionel Penrose (1898–1972), ils en publièrent le dessin dans un article du *British Journal of Psychology* en février 1958. Roger Penrose en avait eu l'idée après avoir découvert le travail du graveur néerlandais Maurits Cornelis Escher (1898–1972) alors qu'il se trouvait à Amsterdam en 1954 pour le Congrès international des mathématiciens.

Représentation de l'illusion de Reutersvärd (devinez l'astuce mise en œuvre pour la réalisation !).

En fait, c'est l'artiste suédois Oscar Reutersvärd (1915–2002) qui, le premier, a dessiné une série de neuf cubes dans la même configuration. C'était en 1934 pendant un cours de latin où, selon ses dires, il s'ennuyait.

Cette découverte changea le cours de sa vie. Au cours de sa carrière de graphiste, il dessina de très nombreuses « figures impossibles » : il est d'ailleurs parfois surnommé le « père de l'impossible ». Pour lui rendre hommage, la Suède a émis en 1982 une série de timbres. Manifestement, ni les Penrose, ni Escher n'avaient eu connaissance des figures créées, des années auparavant, par Reutersvärd.

L'escalier de Penrose.

L'escalier de Penrose

Une autre « figure impossible » est présente dans l'article écrit par les Penrose en 1958 : l'escalier. Mais, là encore, cette figure avait déjà été décrite par Reutersvärd, en 1937 !

Escher a connaissance de cet objet suite à des échanges avec Roger Penrose. Dès 1960, il en tirera une lithographie restée célèbre, *Montée et Descente*. Andrew Lipson et Daniel Shiu ont réussi à recréer cette œuvre (et bien d'autres, voir leur site, www.andrewlipson.com/lego.htm) avec des briques danoises...

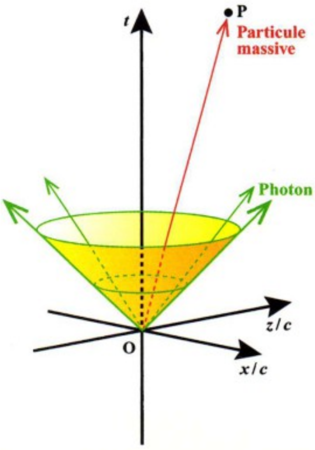
Les singularités
en relativité générale

L'année 1965 marque l'arrivée du premier théorème moderne, dû à Roger Penrose, sur les singularités en relativité générale. Il s'agit d'un résultat géométrique, qui aura d'importantes répercussions concernant l'origine de l'univers et l'effondrement d'étoiles massives.



t
P
Particule massive
Photon
z / c
O
x / c

Demi-cône de lumière dirigé vers le futur. L'ensemble des possibles suite à l'évènement O se situe dans ce demi-cône. Les deux coordonnées d'espace *x* et *z* sont divisées par *c* de sorte que les lignes d'univers des photons soient inclinées à 45°. Une *ligne d'univers* (droite si la particule se déplace à vitesse uniforme, courbe sinon) décrit l'histoire d'une particule tout au long de son existence.

© E. Thomas, 2015

Les équations de la relativité générale (voir encadré) comptent parmi les plus fondamentales de toute la physique moderne. Introduites en 1915 et 1916 par Albert Einstein (1879–1955), on les appelle plus simplement aujourd'hui *l'équation de champ d'Einstein*, au singulier. Cette dernière offre d'innombrables défis mathématiques redoutables de toute beauté (conjecture du cerceau, stabilité non linéaire de la famille de Kerr, conjecture BKL…), dont les fameuses conjectures relatives au phénomène de censure cosmique (voir plus loin) : l'équation est loin d'avoir révélé tous ses secrets !

Du point de vue mathématique, un « espace-temps » est une *variété lorentzienne* muni d'une métrique. Le « chemin le plus court » (pour la métrique considérée) entre deux points de la variété est appelé une *géodésique*. Enfin, la notion de « courbure » de l'espace-temps étudié est encodée et quantifiée à l'aide d'un *tenseur de courbure* (ici, $R_{\mu,\nu}$). Plus l'espace-temps est « courbe », plus les géodésiques vont s'éloigner ou se rapprocher rapidement. Enfin, si $g_{\mu,\nu}(V) > 0$, le vecteur tangent V est *de genre espace*, si $g_{\mu,\nu}(V) = 0$, il est *de genre lumière*, et si $g_{\mu,\nu}(V) < 0$, V est *de genre temps*.

L'arrivée des singularités en physique

Le premier « vrai » théorème sur les singularités porte précisément sur l'équation du champ d'Einstein. Il a été obtenu en 1965 dans un article de moins de trois pages, assez dense, par Sir Roger Penrose. Son importance est telle qu'il a valu à son auteur de recevoir, mardi 6 octobre dernier, le prix Nobel de physique pour *« la découverte que la formation d'un trou noir est une prévision robuste de la théorie de la relativité générale »*. Le célèbre mathématicien britannique partage ce prix à part égale avec le duo formé par l'astrophysicien allemand Reinhard Genzel (né en 1952) et par l'astronome américaine Andrea Mia Ghez (née en 1965), pour leur *« découverte d'un objet compact supermassif au centre de notre galaxie »*, à savoir Sagittarius A*. Découverte qui doit beaucoup aux résultats de Penrose…

Ce sont donc des contributions théoriques (l'introduction de concepts clés en physique mathématique et la démonstration d'un théorème) qui valent au Britannique la fameuse distinction. La démonstration du théorème sur les singularités va conduire dans les années qui suivent à une théorie physique « mûre », dotée de résultats puissants.

L'existence d'« irrégularités catastrophiques » en relativité générale, appelées *singularités*, n'avait pas été anticipée par Albert Einstein. Pourtant, dès 1916 (voir plus loin), les premiers résultats théoriques relatifs à une masse centrale (le Soleil) de Karl Schwarzschild, sans aller jusqu'à imaginer des « trous noirs », ouvrent la voie à de nouvelles explorations. En 1922, le mathématicien russe Alexandre Friedmann (1888–1925), suivi en 1927 par l'astrophysicien belge Georges Lemaître (1894–1966), obtiennent des résultats accréditant l'hypothèse d'un univers en expansion, posant dès lors la question de son « point de départ ». En 1955, Amal Kumar Raychaudhuri (1923–2005) prouve une sorte de théorème de singularité pour certaines poussières stellaires, qui sera généralisé l'année suivante par Arthur Komar (1931–2011). Les singularités ont le vent en poupe.

Un théorème de géométrie

En 1965, Roger Penrose est un expert du calcul tensoriel et de l'équation du champ d'Einstein. Travaillant sur les singularités, il prouve que les écarts ou déviations par rapport à la symétrie sphérique ne peuvent pas empêcher, à eux seuls, la formation de singularités au sein de la relativité générale. Le résultat ne fait pas intervenir les hypothèses d'homogénéité ou de symétrie de ses prédécesseurs : il surprend par sa généralité. Il affirme que si un espace-temps est « suffisamment régulier » (au sens que $g_{\mu,\nu}$ est deux fois continûment différentiable) et qu'il vérifie trois conditions, alors il contient une géodésique causale mais *incomplète* (que l'on ne peut pas prolonger à $\mathbb{R}$ tout entier). C'est un résultat de pure géométrie.

Les hypothèses sont de nature géométrique pour l'une (sur la courbure de l'espace-temps : la densité totale de masse et d'énergie ne doit jamais être négative), causale pour la deuxième (« le futur doit toujours être distinct du passé », afin d'éviter les boucles temporelles), et analytique pour la troisième (condition initiale ou condition de bord : l'espace-temps doit avoir un volume infini avant que l'effondrement ne commence). Les deux premières sont « réalistes » sur le plan de la physique. La troisième pose encore problème : on ignore en effet si notre espace-temps a un volume infini. La plupart des théoriciens de la relativité conjecturent cependant que le théorème de Penrose est valide, que l'espace-temps soit infini ou non. Mais le résultat reste à généraliser et à prouver dans le cas d'un volume fini. •

L'équation du champ d'Einstein

Dans son apparence la plus classique, l'équation d'Einstein prend la forme suivante :

$$\mathrm{R}_{\mu,v} - \frac{1}{2}\mathrm{R}g_{\mu,v} + \Lambda g_{\mu,v} = \frac{8\pi}{c^4}\mathrm{G}\mathrm{T}_{\mu,v}.$$

Elle fait intervenir $\mathrm{R}_{\mu,\nu}$ le *tenseur de Ricci* (tenseur d'ordre 2 qui encode la déformation de l'espace-temps) ; R la *courbure scalaire* (un nombre qui mesure la courbure de l'espace-temps, c'est la trace de $\mathrm{R}_{\mu,\nu}$) ; $g_{\mu,\nu}$ le *tenseur métrique*, à savoir un tenseur d'ordre 2 qui permet d'associer un produit scalaire à deux vecteurs quelconques en chaque point de l'espace-temps (il est de signature (+, –, –, –), caractéristique de la géométrie lorentzienne) ; $\mathrm{T}_{\mu,\nu}$ le *tenseur énergie–impulsion*, qui permet de caractériser la répartition de masse et d'énergie dans l'espace-temps ; Λ une constante physique fondamentale (la *constante cosmologique*), G la constante gravitationnelle ($\mathrm{G} = 6{,}67430 \times 10^{-11}\ \mathrm{m}^3\ \mathrm{kg}^{-1}\ \mathrm{s}^{-2} \pm 0{,}00015 \times 10^{-11}\ \mathrm{m}^3\ \mathrm{kg}^{-1}\ \mathrm{s}^{-2}$) et c la vitesse de la lumière dans le vide ($c = 299\,792\,458\ \mathrm{m\ s}^{-1}$).

L'étude mathématique de l'équation du champ d'Einstein est très ardue. Déjà, comment en saisir la signification ? Les *tenseurs* sont des applications multilinéaires qui, à des vecteurs et covecteurs d'un espace vectoriel, associent un scalaire. Ce qu'il convient de comprendre, c'est que l'équation du champ d'Einstein permet de connaître le tenseur métrique ($g_{\mu,\nu}$, indispensable pour mesurer des longueurs et des angles dans l'espace-temps) étant donnée une distribution de matière et d'énergie (exprimée sous la forme du tenseur énergie–impulsion $\mathrm{T}_{\mu,\nu}$). La géométrie de l'espace-temps (décrite par $g_{\mu,\nu}$) est déterminée localement par son contenu en énergie–impulsion (donné par $\mathrm{T}_{\mu,\nu}$) ; l'espace-temps dit à la matière comment se déplacer (*via* $\mathrm{R}_{\mu,\nu}$) ; la matière dit à l'espace-temps comment se courber (*via* R).

L'espace-temps de Gödel

En 1949 et 1952, le célèbre logicien Kurt Gödel (1906–1978), qui s'intéresse alors à la relativité générale, démontre que la rotation de l'espace-temps à elle seule peut suffire à empêcher la formation de singularités. *L'espace-temps de Gödel* est l'un des rares exemples d'une solution *régulière* (c'est-à-dire sans singularité) aux équations d'Einstein. Il est par ailleurs en rotation et *géodésiquement complet* (au sens que le paramètre définissant un point courant de ses géodésiques est défini sur $\mathbb{R}$ tout entier, ce qui équivaut à dire, par le théorème de Hopf–Rinow, que les parties fermées et bornées sont compactes). De fait, il contient, mathématiquement parlant, des *courbes de genre temps fermées*, ce qui signifie, du point de vue de la physique, que le voyage dans le temps y serait permis. Il s'agit donc d'une solution « artificielle », avec boucles temporelles. Or, si l'on pose le principe de causalité comme prérequis à tout modèle physique, il ne saurait y avoir de boucles temporelles. L'espace-temps de Gödel conserve toutefois d'intéressantes vertus pédagogiques.

Kurt Gödel.

Penrose introduit l'idée d'incomplétude pour les géodésiques afin de décrire d'éventuels espaces-temps singuliers. Il introduit également la notion de surface fermée S *piégée* (au sens que deux familles de rayons lumineux émergeant de manière orthogonale de S et dirigées vers le futur convergent initialement : elles se trouvent « piégées » et ne *peuvent s'échapper de S), une contribution qui* s'avérera fondamentale pour toute la physique des champs gravitationnels. De fait, ses idées ont infusé en géométrie différentielle, en analyse, en géométrie algébrique et en topologie différentielle. Une singularité n'appartient pas « physiquement » à l'espace-temps considéré, il s'agit d'une pure abstraction mathématique (en effet, par définition, un espace-temps physique est constitué de points réguliers). Il s'agit d'une demi-géodésique, de genre temps ou de genre lumière, dirigée vers le futur, et qui est *incomplète* (son intervalle de définition est borné) : l'histoire d'une particule de cette semi-géodésique commence à un temps fini (le Big Bang) et s'achève en un temps fini (en pénétrant dans un trou noir).

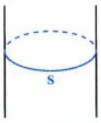
Le théorème sur les singularités de 1965 accrédite l'hypothèse d'un état final singulier d'une étoile massive. Étendant ce résultat, les travaux de Hawking en 1966 et de Hawking–Penrose en 1970 indiquent qu'une singularité dans le passé était inévitable en relativité générale : l'hypothèse d'un Big Bang se trouve confortée. En 1972 enfin, Stephen Hawking développe une théorie des trous noirs : il devient en effet nécessaire de compléter la théorie de la relativité générale par des considérations issues de la physique quantique lorsqu'une gravité extrême est en jeu.

C'est cosmique !

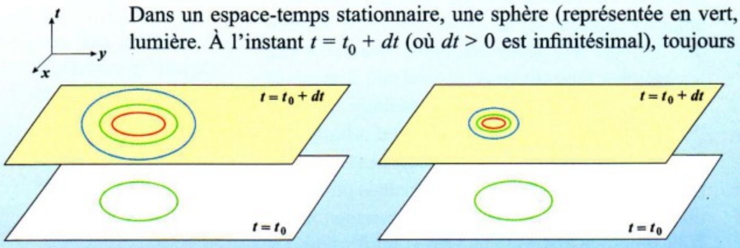
Les théorèmes sur les singularités en relativité générale, qui stipulent tous que, pour une raison non spécifiée, soit l'observateur disparaît, soit le rayon lumineux s'arrête, ne marquent pas la fin de l'histoire. En effet, ils ne caractérisent pas la *singularité. De quelle nature est cette géodésique* causale incomplète ? Est-elle localisée ? Est-elle unique ? Survient-elle dans le passé ou dans le futur ? Surtout, d'un point de vue « pratique » : peut-on observer une singularité ?

Dans la solution exacte à l'équation du champ d'Einstein obtenue en 1916 par Schwarzschild, une singularité a été mise au jour ; elle se niche au sein d'une étoile ; elle n'est donc pas visible. Dans cette solution, on fait entre autres l'hypothèse que l'espace-temps possède une symétrie sphérique

La notion de surface piégée



La notion de surface fermée piégée (ci-contre, à gauche, représentée comme un cercle), introduite par Penrose, formalise l'idée intuitive d'une surface fermée bordant une région de l'espace dont la lumière ne peut s'échapper. C'est une notion délicate dans la mesure où l'idée intuitive fait référence à un espace absolu qui ne saurait exister dans un contexte relativiste général. Dans le schéma qui suit, la dimension d'espace z n'est pas représentée.



Espace-temps stationnaire **Espace-temps en contraction**

Dans un espace-temps stationnaire, une sphère (représentée en vert, en coupe, à l'instant $t = t_0$) émet des rais de lumière. À l'instant $t = t_0 + dt$ (où $dt > 0$ est infinitésimal), toujours en coupe (dans le même plan), on observe la sphère initiale (en vert), une deuxième sphère (en bleu) correspondant au lieu défini par les rais de lumière émis vers l'extérieur de la sphère initiale, et une troisième sphère (en rouge) correspondant au lieu défini par les rais de lumière émis vers l'intérieur de la sphère initiale. L'aire A_0 de la sphère originale reste constante dans le temps. L'aire de la sphère bleue, supérieure à A_0, augmente avec le temps. L'aire de la sphère rouge, inférieure à A_0, diminue avec le temps.

Dans un univers en contraction, les sphères bleue et rouge peuvent avoir une aire constamment inférieure à A_0, y compris celle de la sphère bleue, bien qu'elle croisse en permanence ! Cette sphère est alors un exemple d'une *surface fermée piégée dans le futur*.

parfaite et on fixe $\Lambda = 0$ dans l'équation du champ d'Einstein. Dès lors, l'apparition d'une singularité aurait pu résulter d'hypothèses très contraignantes et peu réalistes. Il n'en est rien : le théorème sur les singularités de 1965 a prouvé que des situations bien plus générales forcent l'émergence de singularités au sein d'étoiles ou de trous noirs. Penrose a alors posé les questions naturelles suivantes :

- Les singularités produites à la suite d'un effondrement gravitationnel sont-elles toujours cachées au sein d'une étoile ou d'un trou noir, derrière un horizon des évènements ? (*censure cosmique faible*)
- Peut-on exclure que, à l'exception du Big Bang, les singularités produites à la suite d'un effondrement gravitationnel sont de genre temps ? (*censure cosmique forte*)

Ces questions posent en fait le problème de l'adéquation entre une formulation mathématique précise et rigoureuse (l'étude de l'équation du champ d'Einstein) et le phénomène astrophysique d'un effondrement gravitationnel. Faut-il prendre en compte la nature quantique du champ gravitationnel ? Dans la négative, on est conduit à réaliser des approximations, qui cessent d'être valides à proximité d'une singularité de l'espace-temps (à cause de la courbure très grande de ce dernier).

Si les réponses aux deux questions posées par Penrose sont négatives (on parle de *singularité nue*, d'où le terme humoristique de « censure »), alors les effets de la gravité quantique seraient visibles en situation d'effondrement gravitationnel, et la gravité quantique deviendrait nécessaire pour comprendre la nature profonde des singularités.

C'est ainsi que sont nées, sous la plume de Penrose, la *conjecture faible de la censure cosmique* dès 1969 et la *conjecture forte* en 1976. La censure cosmique est un phénomène physique hypothétique donnant naissance à une singularité nue. Selon ces conjectures, il n'existerait pas d'autre singularité nue que celle associée au Big Bang.

Mathématiquement parlant, les deux « conjectures » sont indépendantes et ne sont pas énoncées de manière extrêmement précise ; il s'agit plus de programmes de recherche. Il n'existe pas de singularité de genre temps dans un espace-temps globalement hyperbolique. Dans un tel espace-temps, la conjecture de la censure cosmique forte est automatiquement vérifiée. L'idée de la version « forte » est alors que l'ensemble E des données initiales qui conduisent à un espace-temps globalement hyperbolique remplit tout l'espace-temps (E ne peut pas être étendu sous des conditions génériques).

Cette conjecture est l'une des plus fameuses de toute la théorie des équations aux dérivées partielles. Elle est également très difficile à attaquer, sauf à introduire des hypothèses simplificatrices de type symétrie de l'espace-temps.

Pour l'étudier, Penrose a introduit l'*inégalité de Penrose*. Il s'agit d'une sorte d'inégalité isopérimétrique, selon laquelle (dans les notations de l'équation du champ d'Einstein) l'aire de l'horizon apparent S d'une hypersurface de Cauchy Σ de masse totale M, de moment angulaire J et de charge électrique Q est inférieure à $16\pi\left(\frac{GM}{c^2}\right)^2$, soit $4\pi(r_{\text{Sch}})^2$ avec $r_{\text{Sch}} = \frac{2GM}{c^2}$ le *rayon de Schwarschild*.

L'*horizon apparent* S est la surface externe de Σ piégée. L'« aire de S » désigne en fait l'aire minimale de toute surface de Σ contenant S.

Pour un trou noir, on a $Q \leq \frac{G}{c}M$ ou $J \leq \frac{G}{c}M^2$.

Pour une singularité nue,
on a $Q > \frac{G}{c}M$ ou $J > \frac{G}{c}M^2$.

Comme l'inégalité de Penrose ne dépend que de Σ, qui est un objet mathématique, elle peut être étudiée géométriquement pour elle-même et généralisée en toute dimension.

Une violation de l'inégalité de Penrose entraînerait la visibilité d'effets quantiques dans le phénomène macroscopique d'effondrement gravitationnel (et donc une absence de prédictibilité de la relativité générale telle qu'elle est développée actuellement). Ce serait un contre-exemple à la conjecture faible de la censure cosmique.

À ce jour, l'inégalité de Penrose a été prouvée dans certains cas particuliers, mais elle n'a été ni confirmée, ni infirmée dans le cas général.

É.T.

Relativité générale : les contributions de Penrose

En dehors de ses théorèmes sur les singularités (celui de 1965, et ceux qui suivront, en particulier avec Stephen Hawking), Sir Roger Penrose a durablement marqué la relativité générale de son empreinte. Les *diagrammes de Penrose* ou *de Penrose–Carter* sont des diagrammes bidimensionnels facilitant l'étude des propriétés causales d'un espace-temps ; ils permettent de représenter plusieurs métriques spatio-temporelles en supprimant systématiquement deux dimensions d'espace (voir un exemple dans le précédent article). Ils sont *conformes* : les lignes horizontales sont du genre espace, les lignes verticales sont du genre temps, la lumière (géodésique de genre nul) se déplace sur les *lignes de lumière*, orientées à 45° et –45°. Le *formalisme de Penrose* ou *de Newman–Penrose* est un ensemble de notations introduites pour traiter la relativité générale en termes de notations avec des spineurs, qui remplace certaines variables réelles par des variables complexes. Enfin, Penrose travaille avec acharnement, depuis plus d'un demi-siècle, à une grande théorie géométrique, la *théorie des twisteurs*, qui permettrait de formaliser sur des bases solides une gravité quantique. L'espace-temps y serait remplacé par l'*espace des twisteurs*, un espace géométrique très sophistiqué dans lequel le déplacement des photons serait représenté à l'aide de quatre nombres complexes.

Des Nobel de physique et des maths

Le plus célèbre des lauréats du prix Nobel de physique est sans doute Albert Einstein, récompensé en 1921 pour des travaux autour de l'effet photoélectrique – et non pour sa fameuse théorie de la relativité. À ses côtés, dans la liste des lauréats, on retrouve plusieurs scientifiques ayant œuvré du côté des mathématiques. L'un des domaines d'étude largement représentés parmi eux est la physique quantique, pour laquelle ont été mis à l'honneur Max Karl Ernst Ludwig Planck en 1918 *« pour la découverte des quanta d'énergie »*, Werner Heisenberg en 1932 *« pour la création de la mécanique quantique »*, puis Wolfgang Pauli en 1945, Max Born en 1954 ou encore Julian Seymour Schwinger et Richard Phillips Feynman en 1965.

Par ailleurs, bon nombre de ces aventuriers nobélisés ont été récompensés pour des découvertes en physique atomique ou subatomique, comme Niels Bohr en 1922, Louis de Broglie en 1929, Erwin Schrödinger et Paul Adrien Maurice Dirac en 1933, ou encore Eugene Paul Wigner en 1963.

On recense également des prix Nobel décernés à Hendrik Antoon Lorentz en 1902 pour des travaux en électromagnétisme, à John William Strutt Rayleigh en 1904 pour des études en physique des gaz, à Wilhelm Wien en 1911 pour de la thermodynamique, à Lev Davidovitch Landau en 1962 pour des découvertes en physique de la matière condensée ou à Subrahmanyan Chandrasekhar en 1983 pour des travaux en astrophysique. Une telle variété souligne, au-delà de la pluridisciplinarité des lauréats, l'intrication profonde des mathématiques et de la physique.

en bref

Penrose et l'affaire Kleenex

Dans les années 1970, Roger Penrose avait déposé des brevets pour un certain nombre de ses pavages apériodiques (!) et il avait créé une société, Pentaflex, chargée de gérer les droits de ces brevets.

En 1997, il découvre que des rouleaux de papier hygiénique de la firme Kleenex, achetés par son épouse, portent des motifs inspirés de l'un de ses pavages, sans son accord. Il porte l'affaire en justice et attaque la firme américaine Kimberly-Clark Corporation, détentrice de la marque déposée Kleenex.

L'issue du procès est incertaine. Selon certaines sources, Penrose gagna le procès et obligea la firme à retirer ses rouleaux en vente et à changer de décoration ; selon d'autres sources, il trouva un arrangement financier avec le fabricant. De fait, un motif géométrique peut-il être soumis à des droits d'auteur ?

En 1995, un informaticien américain, Roger Schlafly, déposa un brevet pour deux nombres premiers (US Patent 5 373 560), l'un de cent cinquante chiffres et l'autre de trois cents chiffres, utilisables dans des procédés de codage. Penrose lui-même considéra qu'un tel dépôt de brevet était abusif.

Un engagement dans la diffusion des connaissances

Sir Roger Penrose est un vulgarisateur hors pair, à l'écrit comme à l'oral. Son ouvrage *l'Esprit, l'Ordinateur et les Lois de la physique* (Interéditions, 1993) est ainsi un modèle du genre et permet de comprendre finement la pensée originale et les idées scientifiques de l'auteur.

On sait moins que Penrose est très impliqué dans l'Archive Trust for Research in Mathematical Sciences and Philosophy (**https://v1.archmathsci.org**), dont il est l'un des présidents d'honneur depuis sa création. Cette fondation caritative britannique fondée en 2007 repose sur un projet que porte son directeur, le physicien Michael Wright, depuis 1973. L'objet est de créer des archives sonores et vidéo de milliers de conférences, colloques, séminaires, cours, discussions et entretiens (formels ou informels), assurés par des universitaires de tout premier plan, et qui ont été inlassablement filmés, par Wright et son équipe parcourant le monde, depuis près de cinquante ans.

À ce jour, l'Archive Trust compte plus de quarante mille tels documents, accompagnés de plus de deux cent cinquante mille pages de transcriptions, notes de cours et correspondances. Les mathématiques pures et la physique théorique forment l'essentiel du fonds documentaire, qui couvre également la philosophie, la cosmologie, l'histoire des sciences… Au moins vingt pour cent des archives sont en français.

Le travail de numérisation, de catalogage et de référencement par des métadonnées pertinentes est considérable et nécessite des moyens financiers substantiels. À terme, l'intégralité de l'archive est destinée à être mise à disposition gracieusement auprès de la communauté des chercheurs.

Appendix II.D The Liouville space

The Liouville (line) space $\mathcal{L}$ (see also Refs. [11,67]) is defined as the product $\mathcal{H} \otimes \mathcal{H}^+$ where $\mathcal{H}$ is the Hilbert space and $\mathcal{H}^+$ is its associated dual space.

Vectors in $\mathcal{L}$. If the ket vectors $|\alpha\rangle$ (and associated bra's $\langle\alpha|$) form a basis of $\mathcal{H}$, the $|\alpha\rangle\langle\beta|'$s, denoted $|\alpha\beta\rangle\rangle$, (and $\langle\langle\alpha\beta| \equiv |\beta\rangle\langle\alpha|$) which are operators in $\mathcal{H}$, form a basis in $\mathcal{L}$. The product of two vectors of $\mathcal{L}$ is defined by:

$$\langle\langle A'|A\rangle\rangle = \mathrm{Tr}[A'A], \tag{II.D1}$$

where Tr[...] designates the trace. One thus has:

$$\langle\langle\alpha'\beta'|\alpha\beta\rangle\rangle = \mathrm{Tr}[|\beta'\rangle\langle\alpha'|\alpha\rangle\langle\beta|] = \sum_{\gamma}\langle\gamma|\beta'\rangle\langle\alpha'|\alpha\rangle\langle\beta|\gamma\rangle. \tag{II.D2}$$

Hence, if the $|\alpha\rangle'$s form an orthonormalized basis of $\mathcal{H}$ (i.e., $\langle\alpha'|\alpha\rangle = \delta_{\alpha,\alpha'}$), the $|\alpha\beta\rangle\rangle'$s are also orthonormalized in $\mathcal{L}$, since Eq. (II.D2) straightforwardly leads to:

$$\langle\langle\alpha'\beta'|\alpha\beta\rangle\rangle = \delta_{\alpha,\alpha'}\delta_{\beta,\beta'}. \tag{II.D3}$$

Furthermore, one also has the following "closure" relation:

$$\sum_{\alpha,\beta}|\alpha\beta\rangle\rangle\langle\langle\alpha\beta| = 1. \tag{II.D4}$$

If A designates an operator in $\mathcal{H}$, and hence a vector in $\mathcal{L}$, one has:

$$\begin{aligned}|A\rangle\rangle &= \sum_{\alpha,\beta}\langle\langle\alpha\beta|A\rangle\rangle \times |\alpha\beta\rangle\rangle = \sum_{\alpha,\beta}\mathrm{Tr}[|\beta\rangle\langle\alpha|A] \times |\alpha\beta\rangle\rangle = \sum_{\alpha,\beta,\gamma}\langle\gamma|\beta\rangle\langle\alpha|A|\gamma\rangle \times |\alpha\beta\rangle\rangle \\ &= \sum_{\alpha,\beta}\langle\alpha|A|\beta\rangle \times |\alpha\beta\rangle\rangle,\end{aligned} \tag{II.D5}$$

yielding:

$$\langle\langle\alpha\beta|A\rangle\rangle = \langle\alpha|A|\beta\rangle. \tag{II.D6}$$

Operators in $\mathcal{L}$. If $\hat{O}$ is a (super) operator in $\mathcal{L}$, constructed from the operator O of $\mathcal{H}$, the action of $\hat{O}$ on any vector $|A\rangle\rangle$ of $\mathcal{L}$ is given by (A being an operator in $\mathcal{H}$):

$$\hat{O}|A\rangle\rangle = [O, A], \tag{II.D7}$$

where [,] is the commutator. One can then define the matrix elements in the Liouville space. Indeed, Eq. (II.D5) leads to:

$$\hat{O}|\alpha\beta\rangle\rangle = [O, |\alpha\rangle\langle\beta|] = O|\alpha\rangle\langle\beta| - |\alpha\rangle\langle\beta|O, \tag{II.D8}$$

leading, from Eq. (II.D6), to:

$$\langle\langle\alpha'\beta'|\hat{O}|\alpha\beta\rangle\rangle = \langle\alpha'|O|\alpha\rangle\langle\beta|\beta'\rangle - \langle\alpha|\alpha'\rangle\langle\beta|O|\beta'\rangle. \tag{II.D9}$$

Hence, if O is a Hermitian operator in $\mathcal{H}$ and the $|\alpha\rangle$'s are its orthonormalized eigenvectors with associated eigenvalues o_α, one has:

$$\langle\langle\alpha'\beta'|\hat{O}|\alpha\beta\rangle\rangle = (o_\alpha - o_\beta) \times \delta_{\alpha,\alpha'}\delta_{\beta,\beta'}. \tag{II.D10}$$

This equation is often used in the present book in the particular case of the operator $\hat{O} = L_a$ of $\mathcal{L}$ constructed from the operator $O = H_a/\hbar$, where H_a is the Hamiltonian describing the internal states of the radiator. If $|i\rangle$ and $|f\rangle$ designate eigenvectors of H_a associated with the (energy) eigenvalues E_i and E_f, then the matrix element:

$$\langle\langle fi|L_a|fi\rangle\rangle = (E_f - E_i)/\hbar \equiv \omega_{fi}, \tag{II.D11}$$

directly gives the frequency ω_{fi} [or, in wavenumbers, $\sigma_{fi} = \omega_{fi}/(2\pi c)$] of the line associated with the f←i optical transition.

Evolution operators in $\mathcal{L}$. In the Hilbert space, the Heisenberg representation of the time evolution of an operator O is given by:

$$O(t) = U^{+}(t)OU(t), \tag{II.D12}$$

where U(t) is the evolution operator (U^{+} being its adjoint), given by:

$$U(t) = e^{-iHt/\hbar}, \tag{II.D13}$$

H being the total Hamiltonian for the considered system. Let us introduce the Liouville operator L constructed from $H/\hbar$. Note that, due to Eq. (II.D7), the use of L in the equation giving the evolution of the density operator $\rho(t)$, that is:

$$i\hbar\frac{\partial}{\partial t}\rho(t) = [H, \rho], \tag{II.D14}$$

leads to the following compact form:

$$i\frac{\partial}{\partial t}\rho(t) = L\rho, \tag{II.D15}$$

which naturally calls for the introduction of the Liouville operator $\hat{U}(t)$, defined by:

$$\hat{U}(t) = e^{-iLt}. \tag{II.D16}$$

From Eq. (II.D12) and the definition of L, it is then straightforward to show that:

$$O(t) = \hat{U}(t)^{+}O. \tag{II.D17}$$

One thus has, successively using Eqs. (II.D17), (II.D4), and (II.D6):

$$\begin{aligned}\langle\langle\beta'\alpha'|O(t)\rangle\rangle &= \langle\langle\beta'\alpha'|\hat{U}^{+}(t)O\rangle\rangle = \sum_{\alpha,\beta}\langle\langle\beta'\alpha'|\hat{U}^{+}(t)|\beta\alpha\rangle\rangle\langle\langle\beta\alpha|O\rangle\rangle \\ &= \sum_{\alpha,\beta}\langle\langle\beta'\alpha'|\hat{U}^{+}(t)|\beta\alpha\rangle\rangle\langle\beta|O|\alpha\rangle.\end{aligned} \tag{II.D18}$$

From Eqs. (II.D6) and (II.D12), and the closure relation in the Hilbert space, one can write:

$$\begin{aligned}\langle\langle\beta'\alpha'|O(t)\rangle\rangle &= \langle\beta'|O(t)|\alpha'\rangle = \langle\beta'|U^{+}(t)OU(t)|\alpha'\rangle \\ &= \sum_{\alpha,\beta}\langle\beta'|U^{+}(t)|\beta\rangle\langle\beta|O|\alpha\rangle\langle\alpha|U(t)|\alpha'\rangle.\end{aligned} \tag{II.D19}$$

Identifying Eqs. (II.D18) and (II.D19) leads to:

$$\langle\langle\beta'\alpha'|\hat{U}^{+}(t)|\beta\alpha\rangle\rangle = \langle\beta'|U^{+}(t)|\beta\rangle\langle\alpha|U(t)|\alpha'\rangle = \langle\beta|U(t)|\beta'\rangle^{*}\langle\alpha|U(t)|\alpha'\rangle. \tag{II.D20}$$

This shows that $\langle\langle fi|\hat{U}^{+}(t)|f'i'\rangle\rangle = \langle f'|U(t)|f\rangle^{*}\langle i'|U(t)|i\rangle$, and, finally:

$$\langle\langle f'i'|\hat{U}(t)|fi\rangle\rangle = \langle f'|U(t)|f\rangle\langle i'|U(t)|i\rangle^{*}, \tag{II.D21}$$

in agreement with Eq. (II.45).

Appendix II.E The resolvent approach

II.E1 Spectral-shape expression

The starting point of the Fano and Ben-Reuven formalism[44–46,137] is Eqs. (II.7) and (II.8), which define the spectral density $F(\omega)$ as the Fourier transform of the autocorrelation function $\Phi(t)$ of the radiator dipole moment $\vec{d}$ (when considering, of course, electric dipole absorption spectra):

$$F(\omega) = \frac{1}{\pi}\mathrm{Re}\left\{\int_{0}^{\infty} dt e^{i\omega t}\mathrm{Tr}_{S_M}\left[\rho_M(0)e^{+iH_M t/\hbar}\vec{d}^{+}e^{-iH_M t/\hbar}\vec{d}\right]dt\right\}. \tag{II.E1}$$

Here, H_M and $\rho_M(0)$ are the Hamiltonian and the initial density operator of the system S_M composed of one radiator in a bath of N_p perturbers. Note that, implicit in Eq. (II.E1), is the assumption that the translational motion of the radiating molecule can be

4 Complex projective spaces

> In the house of mathematics there are many mansions and of these the most elegant is projective geometry.
>
> *Morris Kline*

An attentive reader of Chapter 3 will have noticed that there must exist a Hopf fibration of any odd-dimensional sphere; it is just that we studiously avoided to mention what the resulting base space is. In this chapter it will be revealed that

$$\mathbb{C}\mathbf{P}^n = \mathbf{S}^{2n+1}/\mathbf{S}^1. \tag{4.1}$$

The space on the left-hand side is called *complex projective space* or – when it is used as a space of pure states in quantum mechanics – *projective Hilbert space*. It is not a sphere unless $n = 1$. The study of projective spaces was actually begun by artists during the Renaissance, and this is how we begin our story.

4.1 From art to mathematics

Painters, engaged in projecting the ground (conveniently approximated as a flat plane) onto a flat canvas, discovered that parallel lines on the ground intersect somewhere on a *vanishing line* or *line at infinity* that exists on the canvas but not on the ground, where parallel lines do not meet. Conversely, a line exists on the ground (right below the artist) that does not appear on the canvas at all. When the subject was taken over by mathematicians this led to the theory of the *projective plane* or *real projective 2-space* $\mathbb{R}\mathbf{P}^2$. The idea is to consider a space whose points consists of the one-dimensional subspaces of a three-dimensional vector space $\mathbb{R}^3$. Call them *rays*. The origin is placed at the eye of the artist, and the rays are his lines of sight. The ground and the canvas serve as two *affine coordinate planes* for $\mathbb{R}\mathbf{P}^2$. A *projective line* is a certain one parameter family of points in the projective plane, and is defined as the space of rays belonging to some two-dimensional subspace $\mathbb{R}^2$. In itself, this is the real projective 1-space $\mathbb{R}\mathbf{P}^1$. To see how all this works out in formulae, we observe that any triple of real numbers defines a one-dimensional subspace of $\mathbb{R}^3$. But the latter does not determine the triple of numbers uniquely. Hence

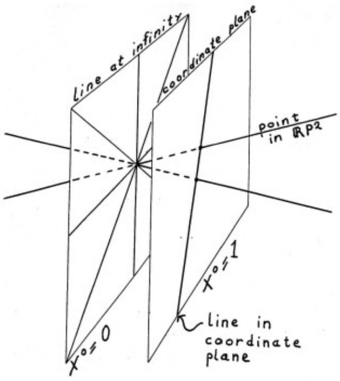

Figure 4.1. Affine coordinates for (almost all of) the projective plane.

a point of $\mathbb{R}\mathbf{P}^2$ is given by an equivalence class

$$(X^0, X^1, X^2) \sim k(X^0, X^1, X^2)\ ; \qquad k \in \mathbb{R} \quad k \neq 0\ . \tag{4.2}$$

The numbers X^α are known as *homogeneous coordinates* on $\mathbb{R}\mathbf{P}^2$. If we want to use true coordinates, one possibility is to choose a plane in $\mathbb{R}^3$ such as $X^0 = 1$, representing an infinite canvas, say. We think of this plane as an affine plane (a vector space except that the choice of origin and scalar product is left open). We can then label a ray with the coordinates of the point where it intersects the affine plane. This is an affine coordinate system on the projective plane; it does not cover the entire projective plane since the rays lying in the plane $X^0 = 0$ are missing. But this plane is a vector space $\mathbb{R}^2$, and the space of rays lying in it is the projective line $\mathbb{R}\mathbf{P}^1$. Hence the affine coordinates display the projective plane as an infinite plane to which we must add an extra projective line 'at infinity'.

Why did we define our rays as one-dimensional subspaces, and not as directed lines from the origin? The answer does not matter to the practising artist, but for the mathematician our definition results in simple *incidence properties* for points and lines. The projective plane will now obey the simple axioms that

(1) Any two different points lie on a unique line.
(2) Any two different lines intersect in a unique point.

There are no exceptional cases (such as parallel lines) to worry about. That axiom (2) holds is simply the observation that two planes through the origin in $\mathbb{R}^3$ always intersect, in a unique line.

There is nothing special about the line at infinity; the name is just an artefact of a special choice of affine coordinates. Every projective line is the space of rays in some two-dimensional subspace of $\mathbb{R}^3$, and it has the topology of a circle – to its image in the affine plane we must add one point 'at infinity'.

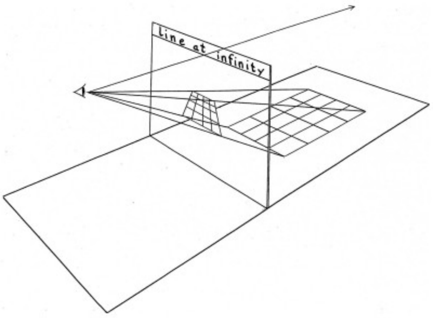

Figure 4.2. Renaissance painter, engaged in changing affine coordinates.

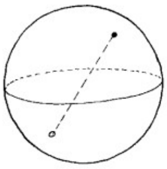

Figure 4.3. Real projective space is the sphere with antipodal points identified.

It is interesting to observe that the space of all lines in $\mathbb{R}\mathbf{P}^2$ is another $\mathbb{R}\mathbf{P}^2$ since one can set up a one-to-one correspondence between rays and planes through the origin in $\mathbb{R}^3$. In fact there is a complete *duality* between the space of points and the space of lines in the projective plane. The natural way to select a specific one-to-one correspondence between $\mathbb{R}\mathbf{P}^2$ and the dual $\mathbb{R}\mathbf{P}^2$ is to introduce a metric in the underlying vector space, and to declare that a ray in the vector space is dual to that plane through the origin to which it is orthogonal. But once we think of the vector space as a metric space as well as a linear one we will be led to the round metric as the natural metric to use on $\mathbb{R}\mathbf{P}^2$. Indeed a moment's reflection shows that $\mathbb{R}\mathbf{P}^n$ can be thought of as the sphere $\mathbf{S}^n$ with antipodal points identified,

$$\mathbb{R}\mathbf{P}^n = \mathbf{S}^n/\mathbb{Z}_2 \ . \tag{4.3}$$

This is one of the reasons why the real projective plane is so famous: it is a space of constant curvature where every pair of geodesics intersect once (as opposed to twice, as happens on a sphere). In fact all of Euclid's axioms for points and straight lines are valid, except the fifth, which shows that the parallel axiom is independent of the others.

In general a specific one-to-one map between a projective space and its dual is known as a *polarity*, and choosing a polarity singles out a particular metric on the projective space as being the most natural one.

There are other geometrical figures apart from points and lines. A famous example is that of the *conic section*. Consider a (circular, say) cone of rays

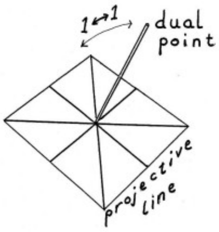

Figure 4.4. Polarity: a metric for the projective plane.

with its vertex at the origin of $\mathbb{R}^3$. In one affine coordinate system the points of intersection of the cone with the affine plane will appear as a circle, in another as a hyperbola. Hence circles, ellipses and hyperbolae are projectively equivalent. In homogeneous coordinates such a conic section appears as

$$(X^1)^2 + (X^2)^2 = (X^0)^2 \ . \tag{4.4}$$

This equation defines a submanifold of $\mathbb{R}\mathbf{P}^2$ because it is homogeneous in the X^α, and therefore unaffected by scaling. If we use affine coordinates for which $X^0 = 1$ it appears as a circle, but if we use affine coordinates for which $X^1 = 1$ it appears as a hyperbola. We can use this fact to give us some further insight into the somewhat difficult topology of $\mathbb{R}\mathbf{P}^2$: if we draw our space as a disc with antipodal points on the boundary identified – this would be the picture of the topology implied by Figure 4.3 – then we see that the hyperbola becomes a topological circle because we are adding two points at infinity. Its interior is an ordinary disc while its exterior is a *Möbius strip* because of the identifications at the boundary – if you glue a disc to the boundary of a Möbius strip you obtain a projective plane. By the way $\mathbb{R}\mathbf{P}^2$, unlike $\mathbb{R}\mathbf{P}^1$, is a *non-orientable* space; this means that a 'right-handed' basis in the tangent space can be turned into a 'left-handed' one by moving it around so that in fact the distinction between right- and left-handedness cannot be upheld. See Figure 4.5.

If you think a little bit further about the $\mathbb{R}\mathbf{P}^2$ topology you will also notice a – possibly reassuring – fact, namely that there is a topological difference between projective lines and conic sections. Although they are both circles intrinsically, the conic sections have the property that they can be continually deformed to a point within the projective plane, while the lines cannot. Indeed if you cut the projective plane open along a projective line it remains connected, while it splits into two pieces if you cut along a conic section.

We could go on to discuss n-dimensional real projective spaces $\mathbb{R}\mathbf{P}^n$, but we confine ourselves to two topological remarks: that $\mathbb{R}\mathbf{P}^n = \mathbf{S}^n/\mathbb{Z}_2$ (obvious), and that $\mathbb{R}\mathbf{P}^{2n+1}$ is orientable while $\mathbb{R}\mathbf{P}^{2n}$ is not (easy to prove).

We can change our *field* from the real numbers $\mathbb{R}$ to rational, complex or quaternionic numbers. In fact one can also use finite fields, such as the integers modulo p where p is some prime number. If we repeat the construction of

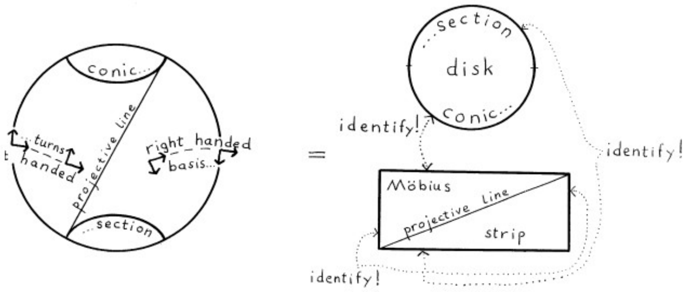

Figure 4.5. The topology of the real projective plane. For a different view, see Figure 4.12.

the projective plane starting from a three-dimensional vector space over the field of integers modulo p then we will obtain a projective plane with exactly $p+1$ points on each line. This is an interesting construction, but like real and quaternionic projective spaces it is of only secondary importance in quantum mechanics, where complex projective space occupies the centre of the stage.

4.2 Complex projective geometry

Complex projective space is in some respects easier to study than is its real cousin, mainly because the complex numbers form a *closed field* (that is to say, every polynomial equation has a root). The most effective presentation of $\mathbb{C}\mathbf{P}^n$ starts directly in the vector space $\mathbb{C}^N = \mathbb{C}^{n+1}$, known as *Hilbert space* in quantum mechanics; our convention is always that $N = n+1$. By definition $\mathbb{C}\mathbf{P}^n$ is the space of rays in $\mathbb{C}^{n+1}$, or equivalently the space of equivalence classes of $n+1$ complex numbers, not all zero, under

$$(Z^0, Z^1, \dots, Z^n) \sim \lambda(Z^0, Z^1, \dots, Z^n) \ ; \qquad \lambda \in \mathbb{C} \qquad \lambda \neq 0 \ . \tag{4.5}$$

We will use Greek indices to label the homogeneous coordinates. We can cover $\mathbb{C}\mathbf{P}^n$ with affine coordinate patches like

$$Z^\alpha = (1, z^1, \dots, z^n) \ , \qquad Z^\alpha = (z^{n'}, 1, z^{1'}, \dots, z^{(n-1)'}) \tag{4.6}$$

and so on. This leads to two important observations. The first is that one coordinate patch covers all of $\mathbb{C}\mathbf{P}^n$ except that subset which has (say)

$$Z^\alpha = (0, Z^1, \dots, Z^n) \ . \tag{4.7}$$

But the set of all such rays is a $\mathbb{C}\mathbf{P}^{n-1}$. Hence we conclude that topologically $\mathbb{C}\mathbf{P}^n$ is like $\mathbb{C}^n$ with a $\mathbb{C}\mathbf{P}^{n-1}$ attached 'at infinity'. Iterating this observation we obtain the *cell decomposition*

$$\mathbb{C}\mathbf{P}^n = \mathbb{C}^n \cup \mathbb{C}^{n-1} \cup \dots \cup \mathbb{C}^0 \ . \tag{4.8}$$

Evidently $\mathbb{C}\mathbf{P}^0$ is topologically a point and $\mathbb{C}\mathbf{P}^1$ is a 2-sphere, while for $n > 1$

we get something new that we will have to get used to as we proceed. The second observation is that in a region where the coordinate systems overlap, they are related by (say)

$$z^{a'} = \frac{Z^{a+1}}{Z^1} = \frac{Z^0}{Z^1}\frac{Z^{a+1}}{Z^0} = \frac{z^{a+1}}{z^1} \, , \tag{4.9}$$

which is clearly an analytic function on the overlap region. Hence $\mathbb{C}\mathbf{P}^n$ is a complex manifold.

The *linear subspaces* of $\mathbb{C}\mathbf{P}^n$ are of major importance. They are defined as the images of the subspaces of $\mathbb{C}^{n+1}$ under the natural map from the vector space to the projective space. Equivalently they are given by a suitable number of linear equations in the homogeneous coordinates. Thus the *hyperplanes* are $(n-1)$-dimensional submanifolds of $\mathbb{C}\mathbf{P}^n$ defined by the equation

$$P_\alpha Z^\alpha = 0 \tag{4.10}$$

for some fixed set of $n+1$ complex numbers P_α. This definition is unaffected by a change of scale for the homogeneous coordinates, and also by a change of scale in P_α. Hence the $n+1$ complex numbers P_α themselves are homogeneous coordinates for a $\mathbb{C}\mathbf{P}^n$; in other words the hyperplanes in a projective n-space can be regarded as the points of another projective n-space which is dual to the original.

If we impose a set of $m \leq n$ independent linear equations on the Z^α we obtain a linear subspace of complex dimension $n-m$ which is itself a $\mathbb{C}\mathbf{P}^{n-m}$. Geometrically this is the intersection of m hyperplanes. The space whose points consist of all such $(n-m)$-dimensional subspaces of $\mathbb{C}\mathbf{P}^n$ is known as a *Grassmannian* – it is only in the case of hyperplanes (and the trivial case of points) that the Grassmannian is itself a $\mathbb{C}\mathbf{P}^n$. A linear subspace of complex dimension one is known as a *complex projective line*, a linear subspace of dimension two is a complex projective plane and so on, while $\mathbb{C}\mathbf{P}^0$ is just a point. The complex projective line is a $\mathbb{C}\mathbf{P}^1$ – topologically this is a sphere and this may boggle some minds, but it is a line in the sense that one can draw a unique line between any pair of points (this is essentially the statement that two vectors in $\mathbb{C}^{n+1}$ determine a unique two-dimensional subspace). It also behaves like a line in the sense that two projective lines in a projective space intersect in a unique point if they intersect at all (this is the statement that a pair of two-dimensional subspaces are either disjoint or they share one common ray or they coincide). In general the intersection of two linear subspaces A and B is known as their *meet* $A \cap B$. We can also define their *join* $A \cup B$ by taking the linear span of the two subspaces of the underlying vector space to which A and B correspond, and then go back down to the projective space. These two operations – meet and join – turn the set of linear subspaces into a partially ordered structure known as a *lattice*, in which every pair of elements has a greatest lower bound (the meet) and a least upper bound (the join). This is the starting point of the subject known as quantum logic (Jauch, 1968; Varadarajan, 1985). It is also the second time we encounter a lattice – in Section 1.1 we came across the lattice of faces of a convex body.

In Chapter 8 we will find a convex body whose lattice of faces agrees with the lattice of subspaces of a vector space. By then it will be a more interesting lattice, because we will have an inner product on $\mathbb{C}^N$, so that a given subspace can be associated with its orthogonal complement.

But we have not yet introduced any inner product in $\mathbb{C}^N$, or any metric in $\mathbb{C}\mathbf{P}^n$. In fact we will continue to do without it for some time; projective geometry is precisely that part of geometry that can be done without a metric. There is an interesting group theoretical view of this, originated by Felix Klein. All statements about linear subspaces – such as when two linear subspaces intersect – are invariant under general linear transformations of $\mathbb{C}^N$. They form the group $GL(N, \mathbb{C})$, but only a subgroup acts *effectively* on $\mathbb{C}\mathbf{P}^n$. (Recall that $N = n+1$. A transformation is said to act effectively on some space if it moves at least one point.) Changing the matrix with an overall complex factor does not change the transformation effected on $\mathbb{C}\mathbf{P}^n$, so we can set its determinant equal to one and multiply it with an extra complex Nth root of unity if we wish. The *projective group* is therefore $SL(n+1, \mathbb{C})/\mathbb{Z}_N$.

According to Klein's conception projective geometry is completely characterized by the projective group; its subgroups include the group of affine transformations that preserves the $\mathbb{C}\mathbf{P}^{n-1}$ at infinity and this subgroup characterizes affine geometry. A helpful fact about the projective group is that any set of $n+2$ points can be brought to the standard position $(1, 0, \ldots, 0)$, $\ldots$, $(0, \ldots, 0, 1)$, $(1, 1, \ldots, 1)$ by means of a projective transformation. For $\mathbb{C}\mathbf{P}^1$ this is the familiar statement that any triple of points on the complex plane can be transformed to 0, 1, and ∞ by a Möbius transformation.

4.3 Complex curves, quadrics and the Segre embedding

The equation that defines a subspace of $\mathbb{C}\mathbf{P}^n$ does not have to be linear; any homogeneous equation in the homogeneous coordinates Z^α gives rise to a well-defined submanifold. Hence in addition to the linear subspaces we have *quadrics, cubics, quartics* and so on, depending on the degree of the defining polynomial. The locus of a number of homogeneous equations

$$w_1(Z) = w_2(Z) = \cdots = w_m(Z) = 0 \tag{4.11}$$

is also a subspace known as an *algebraic* (or projective) *variety*, and we move from projective to *algebraic* geometry.[1] *Chow's theorem* states that every non-singular algebraic variety is a complex submanifold of $\mathbb{C}\mathbf{P}^n$, and conversely every compact complex submanifold is the locus of a set of homogeneous equations. On the other hand it is not true that every complex manifold can be embedded as a complex submanifold in $\mathbb{C}\mathbf{P}^n$.

There are two kinds of submanifolds that are of immediate interest in quantum mechanics. One of them is the *complex curve*; by definition this is a map of $\mathbb{C}\mathbf{P}^1$ into $\mathbb{C}\mathbf{P}^n$. In real terms it is a 2-surface in a $2n$-dimensional space. This does not sound much like a curve, but once it is accepted that $\mathbb{C}\mathbf{P}^1$ deserves the name of line it will be admitted that the name curve is reasonable here. Let us first choose $n = 2$, so that we are looking for a complex curve in the projective plane. Using (u, v) as homogeneous coordinates on $\mathbb{C}\mathbf{P}^1$ we clearly get a map into $\mathbb{C}\mathbf{P}^2$ if we set

---

[1] A standard reference, stressing the setting of complex manifolds, is Griffiths and Harris (1978). For an alternative view see the book by Harris alone (Harris, 1992).

$$(u, v) \quad \rightarrow \quad (u^2, uv, v^2) \ . \tag{4.12}$$

(In Section 6.4 we will adjust conventions a little.) This is a well-defined map because the expression is homogeneous in the u and v. Evidently the resulting complex curve in $\mathbb{C}\mathbf{P}^2$ obeys the equation

$$Z^0 Z^2 \ = \ Z^1 Z^1 \ . \tag{4.13}$$

Hence it is a quadric hypersurface as well, and indeed any quadric can be brought to this form by projective transformations. In the projective plane a quadric is also known as a conic section.

In higher dimensions we encounter complex curves that are increasingly difficult to grasp since they are not quadrics. The next simplest case is the *twisted cubic* curve in $\mathbb{C}\mathbf{P}^3$, defined by

$$(u, v) \quad \rightarrow \quad (u^3, u^2 v, uv^2, v^3) \ . \tag{4.14}$$

We leave it aside for the moment though.

A class of submanifolds that is of particular interest in quantum mechanics arises in the following way. Suppose that the complex vector space is given as a *tensor product*

$$\mathbb{C}^{n+1} \otimes \mathbb{C}^{m+1} \ = \ \mathbb{C}^{(n+1)(m+1)} \ . \tag{4.15}$$

Then there should be an embedded submanifold

$$\mathbb{C}\mathbf{P}^n \times \mathbb{C}\mathbf{P}^m \ \in \ \mathbb{C}\mathbf{P}^{(n+1)(m+1)-1} \ . \tag{4.16}$$

Indeed this is true. In terms of homogeneous coordinates the submanifold can be parametrized as

$$Z^\alpha = Z^{\mu\mu'} = P^\mu Q^{\mu'}, \tag{4.17}$$

in a fairly obvious notation – the P^μ and $Q^{\mu'}$ are homogeneous coordinates on $\mathbb{C}\mathbf{P}^n$ and $\mathbb{C}\mathbf{P}^m$, respectively. The construction is known as the *Segre embedding.* The submanifold is a Cartesian product with (complex) dimension $n+m$, and it follows from Chow's theorem that it can be defined as the locus of nm homogeneous equations in the large space. Indeed it is easy to see from the definition that the submanifold will be the intersection of the quadrics

$$Z^{\mu\mu'} Z^{\nu\nu'} - Z^{\mu\nu'} Z^{\nu\mu'} = 0 \ . \tag{4.18}$$

In quantum mechanics – and in Section 15.2 – the Segre submanifold reappears as the set of separable states of a composite system.

Let us consider the simplest case

$$\mathbb{C}\mathbf{P}^1 \times \mathbb{C}\mathbf{P}^1 \ \in \ \mathbb{C}\mathbf{P}^3 \ , \tag{4.19}$$

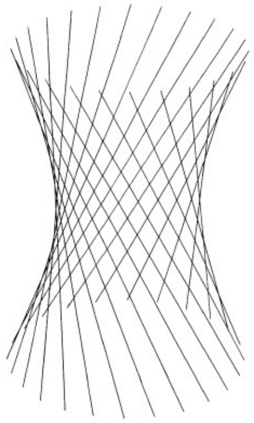

Figure 4.6. The real Segre embedding: a hyperboloid ruled by straight lines.

when only one equation is needed. Write

$$(Z^0, Z^1, Z^2, Z^3) = (Z^{00'}, Z^{01'}, Z^{10'}, Z^{11'}) \ . \tag{4.20}$$

Then the submanifold $\mathbb{C}\mathbf{P}^1 \times \mathbb{C}\mathbf{P}^1$ is obtained as the quadric surface

$$Z^0Z^3 - Z^1Z^2 = 0 \ . \tag{4.21}$$

In general the non-degenerate quadrics in $\mathbb{C}\mathbf{P}^3$ are in one-to-one correspondence to all possible embeddings of $\mathbb{C}\mathbf{P}^1 \times \mathbb{C}\mathbf{P}^1$. It is interesting to consider the projection map from the product manifold to one of its factors. This means that we hold $Q^{\mu'}$ (say) fixed and vary P^μ. Then the fibre of the map – the set of points on the quadric that are projected to the point on $\mathbb{C}\mathbf{P}^m$ that is characterized by that particular $Q^{\mu'}$ – will be given by the equations

$$\frac{Z^{00'}}{Z^{01'}} = \frac{P^0Q^{0'}}{P^0Q^{1'}} = \frac{Q^{0'}}{Q^{1'}} = \frac{P^1Q^{0'}}{P^1Q^{1'}} = \frac{Z^{10'}}{Z^{11'}} \ . \tag{4.22}$$

Since $Q^{\mu'}$ is fixed this implies that there is a complex number λ such that

$$Z^0 = \lambda Z^1 \quad \text{and} \quad Z^2 = \lambda Z^3 \ . \tag{4.23}$$

This pair of linear equations defines a projective line in $\mathbb{C}\mathbf{P}^3$. Projecting down to the other factor leads to a similar conclusion. In this way we see that the quadric is ruled by lines, or in other words that through any point on the quadric there goes a pair of straight lines lying entirely in the quadric.

For visualization, let us consider the real Segre embedding

$$\mathbb{R}\mathbf{P}^1 \times \mathbb{R}\mathbf{P}^1 \in \mathbb{R}\mathbf{P}^3 \ . \tag{4.24}$$

This time we choose to diagonalize the quadric; define

$$Z^0 = X + U \ , \quad Z^1 = X - U \ , \quad Z^2 = V + Y \ , \quad Z^3 = V - Y \ . \tag{4.25}$$

We then obtain

$$Z^0Z^3 - Z^1Z^2 = X^2 + Y^2 - U^2 - V^2 = 0 \ . \qquad (4.26)$$

Now let us choose affine coordinates by dividing through with V. The quadric becomes

$$x^2 + y^2 - u^2 \ = \ 1 \ . \qquad (4.27)$$

This is a hyperboloid of one sheet sitting in a three-dimensional real space. The fact that such a surface can be *ruled* by straight lines is a surprising fact of elementary geometry (first noted by Sir Christopher Wren).

4.4 Stars, spinors and complex curves

The *stellar representation* is a delightful way of visualizing $\mathbb{C}\mathbf{P}^n$ in real terms. It works for any n and simplifies some problems in a remarkable way.[2] Here we will develop it a little from a projective point of view, while Chapter 7 discusses the same construction with the added benefit of a metric. The idea is that vectors in $\mathbb{C}^{n+1}$ are in one-to-one correspondence with the set of nth degree polynomials in one complex variable z, such as

$$w(z) = Z^0z^n + Z^1z^{n-1} + \cdots + Z^n \ . \qquad (4.28)$$

(The important point is that we have a polynomial of the nth degree; in Chapter 7 we will have occasion to polish the conventions a little.) We can rescale the vector Z^α so that $Z^0 = 1$; therefore points in $\mathbb{C}\mathbf{P}^n$ will be in one-to-one correspondence with unordered sets of n complex numbers, namely with the complex roots of the equation

$$Z^0z^n + Z^1z^{n-1} + \cdots + Z^{n+1} = 0 = Z^0(z - z_1)(z - z_2)\ldots(z - z_n) \ . \qquad (4.29)$$

Multiple roots are allowed. If $Z^0 = 0$ then infinity counts as a root (of multiplicity m if $Z^1 = \cdots = Z^{m-1} = 0$). Finally, by means of a stereographic projection the roots can be represented as unordered sets of n points on an ordinary 2-sphere – the points are called 'stars' and thus we have arrived at the stellar representation, in which points in $\mathbb{C}\mathbf{P}^n$ are represented by n unordered stars on a 'celestial' sphere. As a mathematical aside it follows that $\mathbb{C}\mathbf{P}^1 = \mathbf{S}^2$, $\mathbb{C}\mathbf{P}^2 = \mathbf{S}^2 \times \mathbf{S}^2/S_2$ and in general that $\mathbb{C}\mathbf{P}^n = \mathbf{S}^2 \times \mathbf{S}^2 \times \cdots \times \mathbf{S}^2/S_n$, where S_n is the *symmetric group* of permutations of n objects.

There is a piece of notation that is conveniently introduced at this juncture. Let us denote the homogeneous coordinates on $\mathbb{C}\mathbf{P}^1$ by

$$\zeta^A = (u, v) \ . \qquad (4.30)$$

So we use a capital Latin letter for the index and we will refer to ζ^A as a

---

[2] The first reference appears to be to Majorana (1932). The result has been rediscovered many times within (Bacry, 1974) and without (Penrose, 1960) the context of quantum mechanics.

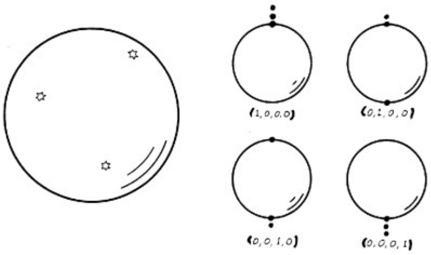

Figure 4.7. Any state from $\mathbb{C}\mathbf{P}^3$ may be represented by three stars on the sphere. Some special cases, where the stars coincide, are shown on the right.

spinor. The overall scale of the spinor is irrelevant to us, so we can introduce an affine coordinate z by

$$z = \frac{v}{u} \ : \qquad \zeta^A \sim (1, z) \ . \tag{4.31}$$

A spinor for which $u = 0$ then corresponds to the south pole on the Riemann sphere. We will use the totally anti-symmetric tensor ϵ_{AB} (the symplectic structure on $\mathbf{S}^2$, in fact) to raise and lower indices according to

$$\zeta_A \equiv \zeta^B \epsilon_{BA} \qquad \Leftrightarrow \qquad \zeta^A = \epsilon^{AB} \zeta_B \ . \tag{4.32}$$

Due to the fact that ϵ_{AB} is anti-symmetric there is a definite risk that sign errors will occur when one uses its inverse ϵ^{AB}. Simply stick to the convention just made and all will be well. Note that $\zeta_A \zeta^A = 0$. So far then a spinor simply denotes a vector in $\mathbb{C}^2$. We do not think of this as a Hilbert space yet because there is no inner product. On the contrary the formalism is manifestly invariant under the full projective group $SL(2, \mathbb{C})/\mathbb{Z}^2$. A special linear transformation on $\mathbb{C}^2$ gives rise to a *Möbius transformation* on the sphere;

$$\zeta^A \rightarrow \begin{bmatrix} u' \\ v' \end{bmatrix} = \begin{bmatrix} \alpha & \beta \\ \gamma & \delta \end{bmatrix} \begin{bmatrix} u \\ v \end{bmatrix} \qquad \Rightarrow \qquad z \rightarrow z' = \frac{\alpha z + \beta}{\gamma z + \delta} \ , \tag{4.33}$$

where $\alpha\delta - \beta\gamma = 1$ is the condition (on four complex numbers) that guarantees that the matrix belongs to $SL(2, \mathbb{C})$ and that the transformation preserves ϵ_{AB}. The group of Möbius transformations is exactly the group of projective transformations of $\mathbb{C}\mathbf{P}^1$.

We can go on to consider totally symmetric *multispinors*

$$\Psi^{AB} = \Psi^{(AB)} \ , \qquad \Psi^{ABC} = \Psi^{(ABC)} \tag{4.34}$$

and so on. (The brackets around the indices mean that we are taking the totally symmetric part.) It is easy to see that when the index ranges from zero to one then the number of independent components of a rank n totally symmetric multispinor is $n + 1$, just right so that the multispinor can serve as homogeneous coordinates for $\mathbb{C}\mathbf{P}^n$. To see that this works, consider the equation

$$\Psi_{AB\dots M}\zeta^A\zeta^B\dots\zeta^M = 0 \ . \tag{4.35}$$

If we now choose the scale so that $\zeta^A = (1, z)$ then the above equation turns into an nth degree polynomial in z, having n complex roots. We can use this fact together with Eq. (4.29) to translate between the $\Psi^{AB\dots M}$ and the Z^α, should this be needed. We can also use the fundamental theorem of algebra to rewrite the polynomial as a product of n factors. In analogy with Eq. (4.29) we find that

$$\Psi_{AB\dots M}\zeta^A\zeta^B\dots\zeta^M = 0 = (\alpha_0 + \alpha_1 z)(\beta_0 + \beta_1 z)\dots(\mu_0 + \mu_1 z) \ . \tag{4.36}$$

The conclusion is that a rank n multispinor can be written – uniquely except for an overall factor of no interest to us – as a symmetrized product of n spinors:

$$\Psi_{AB\dots M}\zeta^A\zeta^B\dots\zeta^M = \alpha_A\zeta^A\beta_B\zeta^B\dots\mu_M\zeta^M \quad \Rightarrow \quad \Psi_{AB\dots M} = \alpha_{(A}\beta_B\dots\mu_{M)} \ . \tag{4.37}$$

The factors are known as *principal spinors*, and they are of course the n unordered points (note the symmetrization) on the sphere in slight disguise.

The stellar representation, or equivalently the spinor notation, deals with linear subspaces in an elegant way. Consider a complex projective line (a $\mathbb{C}\mathbf{P}^1$) in $\mathbb{C}\mathbf{P}^2$ for definiteness. A general point in $\mathbb{C}\mathbf{P}^2$ is described by a pair of unordered points on the 2-sphere, or equivalently as a spinor

$$\Psi^{AB} = \alpha^{(A}\beta^{B)} \equiv \frac{1}{2}\big(\alpha^A\beta^B + \alpha^B\beta^A\big) \ . \tag{4.38}$$

Evidently we get a complex projective line by holding one of the points fixed and letting the other vary, that is by holding one of the principal spinors (say β^A) fixed and letting the other vary.

The spinor notation also deals elegantly with complex curves in general. Thus we get a conic section in $\mathbb{C}\mathbf{P}^2$ as the set of points for which the principal spinors coincide. That is to say that

$$\Psi^{AB} = \Psi^A\Psi^B \tag{4.39}$$

for some spinor Ψ^A. Through any point on the quadric (for which $\Psi^A = \alpha^A$ say) there goes a complex projective line

$$\Psi^{AB} = \zeta^{(A}\alpha^{B)} \tag{4.40}$$

(where ζ^A varies). This line is *tangent* to the quadric since it touches the quadric in a unique point $\alpha^A\alpha^B$. It is moreover rather easy to see that a pair of tangent lines always intersect in a unique point. See Figure 4.8.

4.5 The Fubini–Study metric

Now we want a notion of distance, and indeed a Riemannian metric, in $\mathbb{C}\mathbf{P}^n$. How do we do it? Pick an arbitrary pair of points. The distance between them

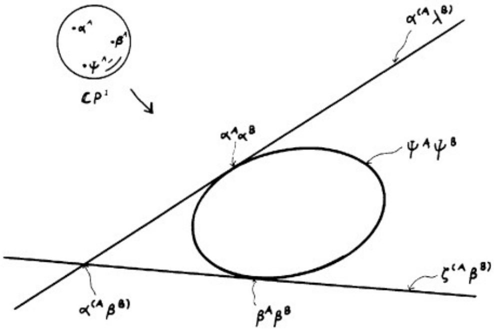

Figure 4.8. A conic section in $\mathbb{C}\mathbf{P}^2$ and a pair of tangent lines.

will be the length of the geodesic curve connecting them. On the other hand we know that there is a unique projective line connecting them; topologically this is $\mathbb{C}\mathbf{P}^1 = \mathbf{S}^2$. Suppose that we insist that this 2-sphere is a round 2-sphere, with the ordinary round metric. Let us also insist that the metric on $\mathbb{C}\mathbf{P}^n$ is such that the projective lines are *totally geodesic*. Technically a submanifold is said to be totally geodesic if a geodesic with respect to the induced metric on the submanifold is also a geodesic with respect to the metric on the embedding space, or equivalently if a geodesic that starts out parallel to the submanifold stays in the submanifold. But a geodesic on a complex projective line is simply a great circle on a 2-sphere, so we have found a way to define geodesics between two arbitrary points in $\mathbb{C}\mathbf{P}^n$. The resulting notion of distance is called the *Fubini–Study distance.*[3]

It only remains to make this definition of the metric on $\mathbb{C}\mathbf{P}^n$ explicit. Since the geodesic lives on some complex projective line, we can write down its equation using nothing but the results of Chapter 3. Let us recall Eq. (3.85) for a geodesic on an odd-dimensional sphere:

$$Z^\alpha(\sigma) = Z^\alpha(0)\cos\sigma + \dot{Z}^\alpha(0)\sin\sigma \ , \tag{4.41}$$

where

$$Z(0)\cdot\bar{Z}(0) = \dot{Z}(0)\cdot\dot{\bar{Z}}(0) = 1 \ , \qquad Z(0)\cdot\dot{\bar{Z}}(0) + \dot{Z}(0)\cdot\bar{Z}(0) = 0 \ . \tag{4.42}$$

If $\dot{Z}^\alpha(0) = \mathrm{i}Z^\alpha(0)$ this is a Hopf circle, and projects to a point on $\mathbb{C}\mathbf{P}^1$ $\mathbb{C}\mathbf{P}^1 = \mathbf{S}^2$. In general we can write

$$Z^\alpha(0) \equiv m^\alpha \ , \qquad \dot{Z}^\alpha(0) = m^\alpha\cos a + n^\alpha\sin a \ , \qquad m\cdot\bar{n} = 0 \ . \tag{4.43}$$

Since the constant vectors m^α and n^α have been chosen orthogonal, they lie antipodally on the particular complex projective line that they span. We can now appeal to the fibre bundle perspective (Section 4.8) to see that this curve is horizontal, and hence projects to a geodesic on $\mathbb{C}\mathbf{P}^1$, if and only if

---

[3] It was first studied by two leading geometers from a century ago; Fubini (1903) and Study (1905).

$\dot{Z} \cdot \bar{Z} = 0$, that is to say if and only if $\cos a = 0$. Alternatively we can use a direct calculation to show that for general a they project to latitude circles, and to great circles if and only if $\cos a = 0$. Either way, we conclude that our definition implies that a geodesic on $\mathbb{C}\mathbf{P}^n$ is given by

$$Z^\alpha(\sigma) = m^\alpha \cos\sigma + n^\alpha \sin\sigma \ , \qquad m \cdot \bar{m} = n \cdot \bar{n} = 1 \ , \ m \cdot \bar{n} = 0 \ . \qquad (4.44)$$

More precisely, this is the horizontal lift of a geodesic on $\mathbb{C}\mathbf{P}^n$ to the odd-dimensional sphere $\mathbf{S}^{2n+1}$, in the fibre bundle $\mathbb{C}\mathbf{P}^n = \mathbf{S}^{2n+1}/\mathbf{S}^1$.

We will now use this set-up to define the Fubini–Study distance D_{FS} between any two points on $\mathbb{C}\mathbf{P}^n$. Since everything takes place within a complex projective line, which lifts to a 3-sphere, we can use the expression for the distance arrived at in our discussion of the Hopf fibration of $\mathbf{S}^3$, namely Eq. (3.95). The Fubini–Study distance D_{FS} must be given by

$$\cos^2 D_{\text{FS}} \ = \ \kappa \ , \qquad (4.45)$$

where the *projective cross-ratio* between two points P^α and Q^α is given by

$$\kappa \ = \ \frac{P \cdot \bar{Q}\ Q \cdot \bar{P}}{P \cdot \bar{P}\ Q \cdot \bar{Q}} \ . \qquad (4.46)$$

We give the same formula in standard quantum mechanical notation in Eq. (5.16). There is one new feature: in Section 3.5 we assumed that $P \cdot \bar{P} = Q \cdot \bar{Q} = 1$, but this assumption has now been dropped. As in Section 4.1 there is a polarity – that is to say a map from the space of points to the space of hyperplanes – hidden here: the polarity maps the point P^α to that special hyperplane consisting of all points Q^α with

$$Q \cdot \bar{P} \ \equiv \ Q^\alpha \bar{P}_\alpha \ = \ 0 \ . \qquad (4.47)$$

Interestingly complex conjugation appears here for the first time. Another interesting fact is that our definitions imply that $\mathbb{C}\mathbf{P}^n$ is a C_π manifold: all geodesics are closed, and have the same circumference. This is a quite exceptional property, related to the fact that the isotropy group – the subgroup of isometries leaving a given point invariant – is so large that it acts transitively on the space of directions there. Spheres have this property too. The circumference of a geodesic on $\mathbb{C}\mathbf{P}^n$ equals π because $\mathbb{C}\mathbf{P}^1$ is a 2-sphere of radius $1/2$; the geodesic on $\mathbf{S}^{2n+1}$ has circumference 2π and doubly covers the geodesic on $\mathbb{C}\mathbf{P}^n$. We also note that the maximal distance between two points is equal to $\pi/2$ (when the two vectors are orthogonal), and that all geodesics meet again at a point of maximal distance from their point of origin.

To obtain the line element in a local form we assume that

$$Q^\alpha \ = \ P^\alpha + \mathrm{d}P^\alpha \qquad (4.48)$$

and expand to second order in the vector $\mathrm{d}P^\alpha$ (and to second order in D_{FS}). The result is the *Fubini–Study metric*

$$\mathrm{d}s^2 = \frac{\mathrm{d}P \cdot \mathrm{d}\bar{P}\ P \cdot \bar{P} - \mathrm{d}P \cdot \bar{P}\ P \cdot \mathrm{d}\bar{P}}{P \cdot \bar{P}\ P \cdot \bar{P}} \ . \qquad (4.49)$$

Before we are done we will become very familiar with this expression.

It is already clear that many formulae will be simplified if we normalize our vectors so that $P \cdot \bar{P} = 1$. In quantum mechanics, where the vectors are the usual Hilbert space state vectors, this is usually done. In this chapter we will use normalized vectors now and then in calculations, but on festive occasions – say when stating a definition – we do not.

An important definition follows immediately, namely that of the 2-form

$$\Omega \;=\; \mathrm{i}\, \frac{P \cdot \bar{P}\; \mathrm{d}P \cdot \wedge \mathrm{d}\bar{P} - \mathrm{d}P \cdot \bar{P} \wedge P \cdot \mathrm{d}\bar{P}}{P \cdot \bar{P}\, P \cdot \bar{P}} \;. \tag{4.50}$$

This is clearly a relative of the metric and the suggestion is that it is a (closed) symplectic form and that $\mathbb{C}\mathbf{P}^n$ is a Kähler manifold for all n. And this is true. To prove the Kähler property it is helpful to use the affine coordinates from Section 4.2. When expressed in terms of them the Fubini–Study metric becomes

$$\mathrm{d}s^2 = \frac{1}{1+|z|^2}\left(\mathrm{d}z^a \mathrm{d}\bar{z}_a - \frac{\bar{z}_a \mathrm{d}z^a \mathrm{d}\bar{z}_b z^b}{1+|z|^2}\right) \equiv 2 g_{a\bar{b}}\; \mathrm{d}z^a \mathrm{d}\bar{z}^{\bar{b}} \;, \qquad |z|^2 \equiv z^a \bar{z}_a \;. \tag{4.51}$$

(We are using $\delta_{a\bar{b}}$ to change $\bar{z}^{\bar{a}}$ into $\bar{z}_a$.) Now

$$2 g_{a\bar{b}} = \frac{1}{1+|z|^2}\left(\delta_{a\bar{b}} - \frac{\bar{z}_a z_{\bar{b}}}{1+|z|^2}\right) = \partial_a \partial_{\bar{b}} \ln\left(1+|z|^2\right) \;. \tag{4.52}$$

Or more elegantly

$$g_{a\bar{b}} \;=\; \frac{1}{2} \partial_a \partial_{\bar{b}} \ln Z \cdot \bar{Z} \;, \tag{4.53}$$

where it is understood that the homogeneous coordinates should be expressed in terms of the affine ones. As we know from Section 3.3 this proves that $\mathbb{C}\mathbf{P}^n$ is a Kähler manifold. Every complex submanifold is Kähler too. For $n = 1$ we recognize the metric on $\mathbf{S}^2$ written in stereographic coordinates.

We will use a different choice of coordinate system to explore the space in detail, but the affine coordinates are useful for several purposes, for instance if one wants to perform an explicit check that the curve (4.44) is indeed a geodesic, or when one wants to compute the Riemann curvature tensor. Thus:

$$g^{a\bar{b}} = 2(1+|z|^2)(\delta^{a\bar{b}} + z^a \bar{z}^{\bar{b}}) \tag{4.54}$$

$$\Gamma_{bc}{}^{a} \;=\; -\frac{1}{1+|z|^2}\left(\delta^a_b \bar{z}_c + \delta^a_c \bar{z}_b\right) \tag{4.55}$$

$$R_{a\bar{b}c\bar{d}} \;=\; -2(g_{a\bar{b}} g_{c\bar{d}} + g_{a\bar{d}} g_{c\bar{b}}) \tag{4.56}$$

$$R_{a\bar{b}} \;=\; 2(n+1) g_{a\bar{b}} \;. \tag{4.57}$$

All components not related to these through index symmetries or complex conjugation are zero. From the expression for the Ricci tensor $R_{a\bar{b}}$ we see that its traceless part vanishes; the Fubini–Study metric solves the Euclidean Einstein equations with a cosmological constant. The form of the full Riemann tensor $R_{a\bar{b}c\bar{d}}$ shows that the space has constant holomorphic sectional curvature (but it does not show that the curvature is constant, and in fact it is not – our result is weaker basically because $g_{a\bar{b}}$ is just one 'block' of the metric tensor). There is an important theorem that says that a simply connected complex manifold of constant holomorphic sectional curvature is necessarily isometric with $\mathbb{C}\mathbf{P}^n$ or else it has the topology of an open unit ball in $\mathbb{C}^n$, depending on the sign of the curvature. (If it vanishes the space is $\mathbb{C}^n$.) The situation is clearly analogous to that of simply connected two-dimensional manifolds of constant sectional curvature, which are either spheres, flat spaces, or hyperbolic spaces with the topology of a ball.

We observe that both the Riemannian and the symplectic geometry relies on the Hermitian form $Z \cdot \bar{Z} = Z^\alpha \bar{Z}_\alpha$ in $\mathbb{C}^N$. Therefore distances and areas are invariant only under those projective transformations that preserve this form. These are precisely the unitary transformations, with anti-unitary transformations added if we allow the transformations to flip the sign of the symplectic form. In quantum mechanics this theorem goes under the name of Wigner's theorem (Wigner, 1959):

Theorem 4.1 (Wigner's) *All isometries of* $\mathbb{C}\mathbf{P}^n$ *arise from unitary or anti-unitary transformations of* $\mathbb{C}^N$.

Since only a part of the unitary group acts effectively the connected component of the isometry group is in fact $SU(N)/\mathbb{Z}_N$. For $N = 2$ we are dealing with a sphere and $SU(2)/\mathbb{Z}_2 = SO(3)$, that is the group of proper rotations. The full isometry group $O(3)$ includes reflections and arises when anti-unitary transformations are allowed.

We obtain an infinitesimal isometry by choosing an Hermitian matrix – a generator of $U(N)$ – and writing

$$\mathrm{i}\,\dot{Z}^\alpha = H^\alpha{}_\beta Z^\beta\ . \tag{4.58}$$

This equation – to reappear as the *Schrödinger equation* in Section 5.1 – determines a Killing flow on $\mathbb{C}\mathbf{P}^n$. A part of it represents 'gauge', that is changes in the overall phase of the homogeneous coordinates. Therefore we write the projective equation

$$\mathrm{i}Z^{[\alpha}\dot{Z}^{\beta]} = Z^{[\alpha}H^{\beta]}{}_\gamma Z^\gamma\ , \tag{4.59}$$

where the brackets denote anti-symmetrization. This equation contains all the information concerning the Killing flow on $\mathbb{C}\mathbf{P}^n$ itself, and is called the *projective Schrödinger equation* (Hughston, 1995, p. 59). The fixed points of the flow occur when the right-hand side vanishes. Because of the anti-symmetrized indices this happens when Z^α is an eigenvector of the Hamiltonian,

$$H^\alpha{}_\beta Z^\beta = EZ^\alpha\ . \tag{4.60}$$

A picture will be given later.

There are other ways of introducing the Fubini–Study metric. We usually understand $\mathbb{C}\mathbf{P}^1$, that is the 2-sphere, as a subset embedded in $\mathbb{R}^3$. Through the Hopf fibration we can also understand it as the base space of a fibre bundle whose total space is either $\mathbf{S}^3$ or $\mathbb{C}^2$ with the origin excluded. Both of these pictures can be generalized to $\mathbb{C}\mathbf{P}^n$ for arbitrary n. The fibre bundle picture will be discussed in more detail later. The embedding picture relies on an embedding into $\mathbb{R}^{(n+1)^2-1}$. The dimension is rather high but we will have to live with this. To see how it works, use homogeneous coordinates to describe $\mathbb{C}\mathbf{P}^n$ and form the matrix

$$\rho^{\alpha}{}_{\beta} \ \equiv \ \frac{Z^{\alpha}\bar{Z}_{\beta}}{Z \cdot \bar{Z}} \ . \tag{4.61}$$

This is a useful way to represent a point in $\mathbb{C}\mathbf{P}^n$ since the reduncancy of the homogeneous coordinates has disappeared. The resulting matrix is Hermitian and has trace unity. Hence we have an embedding of $\mathbb{C}\mathbf{P}^n$ into the space of Hermitian $N \times N$ matrices with trace unity, which has the dimension advertised, and can be made into a flat space in a natural way. We simply set

$$D^2(A,B) \ = \ \frac{1}{2}\mathrm{Tr}(A-B)^2 \ . \tag{4.62}$$

This expression defines a distance D between the matrices A and B (equal to the *Hilbert–Schmidt distance* introduced in Chapter 8). It is analogous to the chordal distance between two points on the sphere when embedded in a flat space in the standard way.

To see that the embedding gives rise to the Fubini–Study metric we take two matrices representing different points of $\mathbb{C}\mathbf{P}^n$, such as

$$\rho^{\alpha}_{P\ \beta} = \frac{P^{\alpha}\bar{P}_{\beta}}{P \cdot \bar{P}} \qquad \rho^{\alpha}_{Q\ \beta} = \frac{Q^{\alpha}\bar{Q}_{\beta}}{Q \cdot \bar{Q}} \ , \tag{4.63}$$

and compute

$$D^2(\rho_P, \rho_Q) = 1 - \kappa = 1 - \cos^2 D_{\mathrm{FS}} \ , \tag{4.64}$$

where κ is the projective cross-ratio (4.46) and D_{FS} is the Fubini–Study distance between P and Q along a curve lying within the embedded $\mathbb{C}\mathbf{P}^n$. If the points are very close we can expand the square of the cosine to second order and obtain

$$D \ = \ D_{\mathrm{FS}} + \text{higher order terms} \ . \tag{4.65}$$

This proves our point. The Riemannian metric

$$\mathrm{d}s^2 = \frac{1}{2}\,\mathrm{Tr}\ \mathrm{d}\rho\,\mathrm{d}\rho, \tag{4.66}$$

is precisely the Fubini–Study metric, provided that it is evaluated at a point where the matrix ρ is an outer product of two vectors – and $\mathrm{d}\rho$ is the 'infinitesimal' difference between two such matrices, or more precisely a tangent vector to $\mathbb{C}\mathbf{P}^n$. This embedding will reappear in Chapter 8 as the embedding of pure states into the space of density matrices.

4.6 $\mathbb{C}\mathbf{P}^n$ illustrated

At this point we still do not know what $\mathbb{C}\mathbf{P}^n$ 'looks like', even in the modest sense that we feel that we know what an n-sphere 'looks like' for arbitrary n. There is a choice of coordinate system that turns out to be surprisingly helpful in this regard (Barros e Sá, 2001a; Bengtsson, Brännlund and Życzkowski, 2002). Define

$$(Z^0, Z^1, \ldots, Z^n) = (n_0, n_1 \mathrm{e}^{\mathrm{i}\nu_1}, \ldots, n_n \mathrm{e}^{\mathrm{i}\nu_n}) \ , \tag{4.67}$$

where $0 \leq \nu_i < 2\pi$ and the real numbers n_0, n_i are non-negative, $n_0 \geq 0$, $n_i \geq 0$, and obey the constraint

$$n_0^2 + n_1^2 + \cdots + n_n^2 = 1 \ . \tag{4.68}$$

We call such coordinates *octant coordinates*, because $n_0, n_1, \ldots$ clearly form the positive hyperoctant of an n-sphere. The phases ν_i form an n-torus, so we already see a picture of the topology of $\mathbb{C}\mathbf{P}^n$ emerging: we have a set of tori parametrized by the points of a hyperoctant, with the proviso that the picture breaks down at the edges of the hyperoctant, where the phases are undefined.[4]

To go all the way to a local coordinate system we can set

$$\begin{cases} n_0 &= \cos\vartheta_1 \sin\vartheta_2 \sin\vartheta_3 \ \ldots \ \sin\vartheta_n \\ n_1 &= \sin\vartheta_1 \sin\vartheta_2 \sin\vartheta_3 \ \ldots \ \sin\vartheta_n \\ n_2 &= \qquad \cos\vartheta_2 \sin\vartheta_3 \ \ldots \ \sin\vartheta_n \\ \ \vdots & \ \vdots \qquad\qquad \vdots \\ n_n &= \qquad\qquad \cos\vartheta_n \end{cases} \qquad 0 < \vartheta_i < \frac{\pi}{2} \ . \tag{4.69}$$

This is just like Eq. (1.13), except that the range of the coordinates has changed. We can also use n_i as orthographic coordinates. Alternatively we can set

$$y_i \ = \ n_i^2 \tag{4.70}$$

and use the n coordinates y_i. This looks contrived at this stage but will suggest itself later. If we also define $y_0 = n_0^2$ we clearly have

$$y_0 + y_1 + \cdots + y_n = 1 \ . \tag{4.71}$$

A probability interpretation is not far behind ... .

To see how it all works, let us consider $\mathbb{C}\mathbf{P}^2$. The point is that octant coordinates are quite well adapted to the Fubini–Study metric, which becomes

$$\begin{aligned} \mathrm{d}s^2 = {} & \mathrm{d}n_0^2 + \mathrm{d}n_1^2 + \mathrm{d}n_2^2 \\ & + n_1^2(1 - n_1^2)\,\mathrm{d}\nu_1^2 + n_2^2(1 - n_2^2)\,\mathrm{d}\nu_2^2 - 2n_1^2 n_2^2 \ \mathrm{d}\nu_1\,\mathrm{d}\nu_2 \ . \end{aligned} \tag{4.72}$$

The first piece here, given Eq. (4.68), is recognizable as the ordinary round metric on the sphere. The second part is the metric on a flat torus, whose shape depends on where we are on the octant. Hence we are justified in thinking of

---

[4] There is an entire branch of mathematics called 'toric geometry' whose subject matter, roughly speaking, consists of spaces that can be described in this way. See Ewald (1996) for more on this.

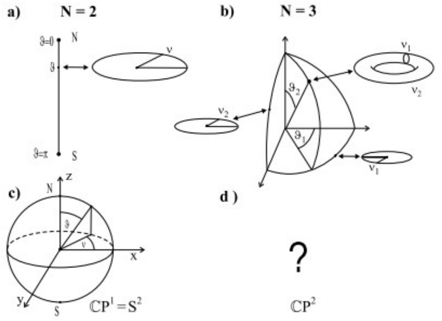

Figure 4.9. $\mathbb{C}\mathbf{P}^2$ may be visualized as the positive octant of a 2-sphere. Each point inside the octant represents a torus T^2 spanned by the phases $(\nu_1,\ \nu_2)$ (b). Each point at the edges of the octant denotes a circle, so each of three edges representes a 2-sphere. For comparison we plot $\mathbb{C}\mathbf{P}^1$ in the same manner, in panel (a). A realistic view of $\mathbb{C}\mathbf{P}^1$ is shown in panel (c); an analogous view of $\mathbb{C}\mathbf{P}^2$ would be more difficult (d).

$\mathbb{C}\mathbf{P}^2$ as a set of flat 2-tori parametrized by a round octant of a 2-sphere. There is an evident generalization to all n, and in fact we can draw accurate pictures of $\mathbb{C}\mathbf{P}^3$ if we want to.

For $n = 1$ we obtain a one parameter family of circles that degenerate to points at the end of the interval; a moment's thought will convince the reader that this is simply a way to describe a 2-sphere. Just to make sure, use the angular coordinates and find that Eq. (4.72) becomes

$$\mathrm{d}s^2 = \mathrm{d}\vartheta_1^2 + \frac{1}{4}\sin^2(2\vartheta_1)\,\mathrm{d}\nu_1^2 = \frac{1}{4}\left(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2\right)\,, \tag{4.73}$$

where we used $\theta = 2\vartheta_1$ and $\phi = \nu_1$ in the second step.

To make the case $n = 2$ quite clear we make a map of the octant, using a stereographic or a gnomonic projection (Section 3.1). The latter is quite useful here and it does not matter that only half the sphere can be covered since we need to cover only one octant anyway. It is convenient to centre the projection at the centre of the octant and adjust the coordinate plane so that the coordinate distance between a pair of corners of the resulting triangle equals one. The result is shown in Figure 4.10.

This takes care of the octant. We obtain a picture of $\mathbb{C}\mathbf{P}^2$ when we remember that each interior point really represents a flat torus, conveniently regarded as a parallelogram with opposite sides identified. The shape of the parallelogram – discussed in Section 3.3 – is relevant. According to Eq. (4.72) the lengths of the sides are

$$L_1 = \int_0^{2\pi} \mathrm{d}s = 2\pi n_1\sqrt{1-n_1^2} \quad \text{and} \quad L_2 = 2\pi n_2\sqrt{1-n_2^2}\,. \tag{4.74}$$

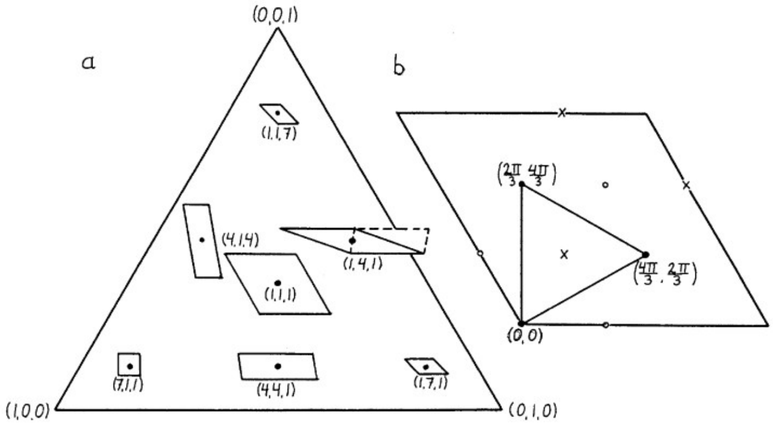

Figure 4.10. In (a) we indicate how the torus lying over each interior point changes with position in the octant. The position in the octant is given by an unnormalized vector. At the edges the tori degenerate to circles so edges are complex projective lines. The corners of the octant represent orthogonal points. It may be convenient to perform some cutting and gluing of the parallelogram before thinking about the shape of the torus it defines, as indicated with dashed lines for the torus lying over the point $(1, 4, 1)$. The size of the octant relative to that of the tori is exaggerated in the picture. To bring this home we show, in (b), the largest torus – the one sitting over $(1, 1, 1)$ – decorated with three times three points (marked with crosses and filled or unfilled dots). Each such triple corresponds to an orthogonal basis. The coordinates (ν_1, ν_2) are given for one of the triples.

The angle between them is given by

$$\cos\theta_{12} = -\frac{n_1 n_2}{\sqrt{1-n_1^2}\,\sqrt{1-n_2^2}} \ . \tag{4.75}$$

The point is that the shape depends on where we are on the octant. So does the total area of the torus,

$$A = L_1 L_2 \sin\theta_{12} = 4\pi^2 n_0 n_1 n_2 \ . \tag{4.76}$$

The 'biggest' torus occurs at the centre of the octant. At the boundaries the area of the tori is zero. This is because there the tori degenerate to circles. In effect an edge of the octant is a one parameter family of circles, in other words it is a $\mathbb{C}\mathbf{P}^1$.

It is crucial to realize that there is nothing special going on at the edges and corners of the octant, whatever the impression left by the map may be. Like the sphere, $\mathbb{C}\mathbf{P}^n$ is a homogeneous space and looks the same from every point. To see this, note that any choice of an orthogonal basis in a three-dimensional Hilbert space gives rise to three points separated by the distance $\pi/2$ from each other in $\mathbb{C}\mathbf{P}^2$. By an appropriate choice of coordinates we can make any

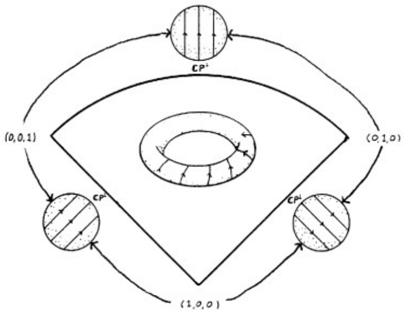

Figure 4.11. Killing vector flows on $\mathbb{C}\mathbf{P}^2$. Stereographic coordinates are used for the octant.

such triplet of points sit at the corners of an octant in a picture identical to the one shown in Figure 4.11.

To get used to the picture we begin by looking at some one real dimensional curves in it. We choose to look at the flow lines of an isometry – a Killing field. Since the isometries are given by unitary transformations of $\mathbb{C}^N$, we obtain an infinitesimal isometry by choosing an Hermitian matrix. Any such matrix can be diagonalized, so we can choose a basis in which the given Hermitian 3×3 matrix takes the form

$$H^{\alpha}{}_{\beta} = \begin{bmatrix} E_0 & 0 & 0 \\ 0 & E_1 & 0 \\ 0 & 0 & E_2 \end{bmatrix} . \tag{4.77}$$

We can therefore arrange our octant picture so that the fixed points of the flow – determined by the eigenvectors – occur at the corners. If we exponentiate Eq. (4.58) we find that the isometry becomes

$$\begin{bmatrix} n^0 \\ n^1 \mathrm{e}^{\mathrm{i}\nu_1} \\ n^2 \mathrm{e}^{\mathrm{i}\nu_2} \end{bmatrix} \quad \rightarrow \quad \begin{bmatrix} \mathrm{e}^{-\mathrm{i}E_0 t} & 0 & 0 \\ 0 & \mathrm{e}^{-\mathrm{i}E_1 t} & 0 \\ 0 & 0 & \mathrm{e}^{-\mathrm{i}E_2 t} \end{bmatrix} \begin{bmatrix} n^0 \\ n^1 \mathrm{e}^{\mathrm{i}\nu_1} \\ n^2 \mathrm{e}^{\mathrm{i}\nu_2} \end{bmatrix} \tag{4.78}$$

where t is a parameter along the flow lines. Taking out an overall phase, we find that this implies that

$$n^I \rightarrow n^I , \quad \nu_1 \rightarrow \nu_1 + (E_0 - E_1)t , \quad \nu_2 \rightarrow \nu_2 + (E_0 - E_2)t . \tag{4.79}$$

Hence the position on the octant is preserved by the Killing vector flow; the movement occurs on the tori only. At the edges of the octant (which are spheres, determined by the location of the fixed points) the picture is the expected one. At a generic point the orbits wind around the tori and, unless the frequencies are rational multiples of each other, they will eventually cover the tori densely. Closed orbits are exceptional.

We go on to consider some submanifolds. Every pair of points in the complex projective plane defines a unique complex projective line, that is a $\mathbb{C}\mathbf{P}^1$,

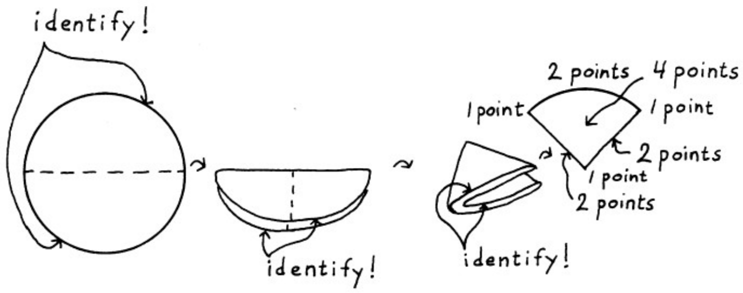

Figure 4.12. Using stereographic coordinates we show how the octant picture of the real submanifold $\mathbb{R}\mathbf{P}^2$ is related to the standard description as a hemisphere with antipodal points on the equator identified.

containing the pair of points. Conversely a pair of complex projective lines always intersect at a unique point. Through every point there passes a 2-sphere's worth of complex projective lines, conveniently parametrized by the way they intersect the line at infinity, that is the set of points at maximal distance from the given point. This is easily illustrated provided we arrange the picture so that the given point sits in a corner, with the line at infinity represented by the opposite edge. An interesting fact about $\mathbb{C}\mathbf{P}^2$ follows from this, namely that it contains *incontractible* 2-spheres – a complex projective line can be deformed so that its radius grows, but it cannot be deformed so that its radius shrinks because it has to intersect the line at infinity in a point. (The topological reasons for this can be seen in the picture.)

Another submanifold is the real projective plane $\mathbb{R}\mathbf{P}^2$. It is defined in a way analogous to the definition of $\mathbb{C}\mathbf{P}^2$ except that real rather than complex numbers are used. The points of $\mathbb{R}\mathbf{P}^2$ are therefore in one-to-one correspondence with the set of lines through the origin in a three-dimensional real vector space and also with the points of $\mathbf{S}^2/\mathbb{Z}_2$, that is to say the sphere with antipodal points identified. In its turn this is a hemisphere with antipodal points on the equator identified. $\mathbb{R}\mathbf{P}^2$ is clearly a subset of $\mathbb{C}\mathbf{P}^2$. It is illuminating to see how the octant picture is obtained, starting from the stereographic projection of a hemisphere (a unit disc) and folding it twice.

Next choose a point. Adjust the picture so that it sits at a corner of the octant. Surround the chosen point with a 3-sphere consisting of points at constant distance from that point. In the picture this will appear as a curve in the octant, with an entire torus sitting over each interior point on the curve. This makes sense: from the Hopf fibration we know that $\mathbf{S}^3$ can be thought of as a one parameter family of tori with circles at the ends. The 3-sphere is round if the tori have a suitable rectangular shape. But as we let our 3-sphere grow, its tori get more and more 'squashed' by the curvature of $\mathbb{C}\mathbf{P}^2$, and the roundness gradually disappears. When the radius reaches its maximum value of $\pi/2$ the 3-sphere has collapsed to a 2-sphere, namely to the projective line

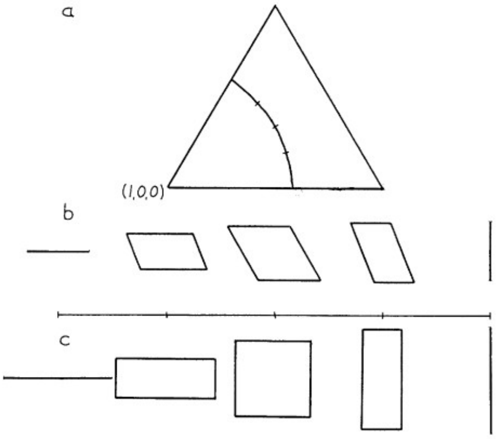

Figure 4.13. The set of points at constant distance from a corner form a squashed 3-sphere. In (a) we show how such a submanifold appears in the octant. All points in the torus lying over a point on the curve are included. In (b) we show how the size and shape of the torus change as we move along the curve in the octant; at the ends of the interval the tori collapse to circles. For comparison, in (c) we show the corresponding picture for a round 3-sphere.

at infinity. In equations, set

$$n_1 = \sin r \cos \frac{\theta}{2} , \quad n_2 = \sin r \sin \frac{\theta}{2} , \quad \tau = \nu_1 + \nu_2 , \quad \phi = \nu_1 - \nu_2 , \quad (4.80)$$

where $0 \leq r \leq \pi/2$, $0 \leq \theta \leq \pi$. When we express the Fubini–Study metric in these coordinates we find that they are geodesic polar coordinates with the coordinate r measuring the distance from the origin – curves with affine parameter equal to r are manifestly geodesics. Indeed

$$\mathrm{d}s^2 \;=\; \mathrm{d}r^2 + \sin^2 r \, (\Theta_1^2 + \Theta_2^2 + \cos^2 r \, \Theta_3^2) \; , \quad (4.81)$$

where the Θ_I are the invariant forms introduced in Section 3.7; our squashed spheres at constant distance are Berger spheres, as defined in the same section.

Finally, a warning: the octant picture distorts distances in many ways. For instance, the distance between two points in a given torus is shorter than it looks, because the shortest path between them is not the same as a straight line within the torus itself. Note also that we have chosen to exaggerate the size of the octant relative to that of the tori in the pictures. To realize how much room there is in the largest torus we note that one can find four sets of orthonormal bases in the Hilbert space $\mathbb{C}^3$ such that the absolute value of the scalar product between members of different bases is $1/\sqrt{3}$ – a kind of sphere packing problem in $\mathbb{C}\mathbf{P}^2$. If one basis is represented by the corners of the octant, the remaining 3×3 basis vectors are situated in the torus over the centre of the octant,[5] as illustrated in Figure 4.10. The message is that the biggest torus is really big.

4.7 Symplectic geometry and the Fubini–Study measure

So far the symplectic form has not been illustrated, but the octant coordinates are very useful for this purpose too. If we use $n_1, n_2, \ldots, n_n$ as orthographic coordinates on the octant we find that the symplectic form (4.50) is

$$\Omega \;=\; 2(n_1 \mathrm{d}n_1 \wedge \mathrm{d}\nu_1 + \cdots + n_n \mathrm{d}n_n \wedge \mathrm{d}\nu_n) \; . \tag{4.82}$$

Even better, we can use $y_i = n_i^2$ as coordinates. Then Ω takes the canonical form

$$\Omega = \mathrm{d}y_1 \wedge \mathrm{d}\nu_1 + \cdots + \mathrm{d}y_n \wedge \mathrm{d}\nu_n \; . \tag{4.83}$$

In effect (y_i, ν_i) are action-angle variables.

Given a symplectic form we can construct a phase space volume by wedging it with itself enough times. This is actually simpler than to compute the determinant of the metric tensor, and the two notions of volume – symplectic and metric – agree because we are on a Kähler manifold. Thus, in form language, the *Fubini–Study volume element* on $\mathbb{C}\mathbf{P}^n$ is

$$\mathrm{d}\tilde{\Omega}_n \;=\; \frac{1}{n!}\,(\frac{1}{2}\Omega) \wedge (\frac{1}{2}\Omega) \wedge \cdots \wedge (\frac{1}{2}\Omega) \; , \tag{4.84}$$

where we take n wedge products. Equivalently we compute the square root of the determinant of the metric. We have decorated the volume element with a tilde because in Section 7.6 we will divide it with the total volume of $\mathbb{C}\mathbf{P}^n$ to obtain the *Fubini–Study measure* $\mathrm{d}\Omega_n$, which is a probability distribution whose integral over $\mathbb{C}\mathbf{P}^n$ equals unity. Any measure related to the Fubini–Study volume element by a constant is distinguished by the fact that it gives the same volume to every ball of given radius, as measured by the Fubini–Study metric, and by the fact that it is unitarily invariant, in the sense that $\mathrm{vol}(A) = \mathrm{vol}\big(U(A)\big)$ for any subset A of $\mathbb{C}\mathbf{P}^n$.

It is a volume element worth studying in several coordinate systems. Using octant coordinates we obtain

$$\mathrm{d}\tilde{\Omega}_n \;=\; n_0 n_1 \ldots n_n \, \mathrm{d}V_{\mathbf{S}^n} \, \mathrm{d}\nu_1 \ldots \mathrm{d}\nu_n \; , \qquad 0 < \nu_i < 2\pi \tag{4.85}$$

where $\mathrm{d}V_{\mathbf{S}^n}$ is the measure on the round n-sphere. If we use orthographic coordinates on the round octant, remember that $\sqrt{g} = 1/n_0$ in these coordinates, and use the coordinates $y_i = n_i^2$, we obtain

$$\mathrm{d}\tilde{\Omega}_n = n_1 \ldots n_n \, \mathrm{d}n_1 \ldots \mathrm{d}n_n \, \mathrm{d}\nu_1 \ldots \mathrm{d}\nu_n = \frac{1}{2^n} \, \mathrm{d}y_1 \ldots \mathrm{d}y_n \, \mathrm{d}\nu_1 \ldots \mathrm{d}\nu_n \; . \tag{4.86}$$

---

[5] It is not known to what extent this property generalizes to arbitrary Hilbert space dimension. Ivanović (1981) and Wootters and Fields (1989) have shown that $N + 1$ orthonormal bases with the modulus of the scalar product between members of different bases always equal to $1/\sqrt{N}$ can be found if the dimension $N = p^k$, where p is a prime number.

All factors in the measure have cancelled out! As far as calculations of volumes are concerned $\mathbb{C}\mathbf{P}^n$ behaves like a Cartesian product of a flat simplex and a flat torus of a fixed size.

The angular coordinates ϑ can also be used on the octant. We just combine Eqs. (4.85) with Eq. (1.14) for the measure on the round octant. Computing the total volume of $\mathbb{C}\mathbf{P}^n$ with respect to its Fubini–Study volume element then leads to an easy integral:

$$\mathrm{vol}(\mathbb{C}\mathbf{P}^n) = \int_{\mathbb{C}\mathbf{P}^n} \mathrm{d}\tilde{\Omega}_n = \prod_{i=1}^{n} \int_0^{\frac{\pi}{2}} \mathrm{d}\vartheta_i \int_0^{2\pi} \mathrm{d}\nu_i \, \cos\vartheta_i \, \sin^{2i-1}\vartheta_i = \frac{\pi^n}{n!} \ . \quad (4.87)$$

We fixed the linear scale of the space by the requirement that a closed geodesic has circumference π. Then the volume goes to zero when n goes to infinity. Asymptotically the volume of $\mathbb{C}\mathbf{P}^n$ even goes to zero somewhat faster than that of $\mathbf{S}^{2n}$, but the comparison is not fair unless we rescale the sphere until the great circles have circumference π. Having done so we find that the volume of $\mathbb{C}\mathbf{P}^n$ is always larger than that of the sphere (except when $n = 1$, when they coincide).

It is curious to observe that

$$\mathrm{vol}(\mathbb{C}\mathbf{P}^n) = \mathrm{vol}(\Delta_n) \times \mathrm{vol}(\mathbf{T}^n) = \frac{\mathrm{vol}(\mathbf{S}^{2n+1})}{\mathrm{vol}(\mathbf{S}^1)} \ . \quad (4.88)$$

The first equality expresses the volume as the product of the volumes of a flat simplex and a flat torus and is quite surprising, while the second is the volume of $\mathbf{S}^{2n+1}$, given in Eq. (1.17), divided by the volume 2π of a Hopf circle as one would perhaps expect from the Hopf fibration. The lesson is that the volume does not feel any of the more subtle topological properties involved in the fibre bundle construction of $\mathbb{C}\mathbf{P}^n$.

4.8 Fibre bundle aspects

Although we did not stress it so far, it is clear that $\mathbb{C}\mathbf{P}^n$ is the base manifold of a bundle whose total space is $\mathbf{S}^{2n+1}$ or even $\mathbb{C}^N = \mathbb{C}^{n+1}$ with its origin deleted. The latter bundle is known as the *tautological bundle* for fairly obvious reasons. A lightning review of our discussion of fibre bundles in Chapter 3 consists, in effect, of the observation that our expression for the Fubini–Study metric is invariant under

$$\mathrm{d}P^\alpha \ \rightarrow \ \mathrm{d}P^\alpha + zP^\alpha \ , \quad (4.89)$$

where $z = x + \mathrm{i}y$ is some complex number. But the vector xP^α is orthogonal to the sphere, while $\mathrm{i}yP^\alpha$ points along its Hopf fibres. Because it is unaffected by changes in these directions the Fubini–Study metric really is a metric on the space of Hopf fibres. In some ways it is convenient to normalize our vectors to $Z \cdot \bar{Z} = 1$ here because then we are dealing with a principal bundle. The tautological bundle is not a principal bundle; technically it is called a *Hermitian line bundle*.

A fibre bundle can always be equipped with a connection that allows us to lift curves in the base manifold to the bundle space in a unique manner. Here the preferred choice is

$$\omega \;=\; \frac{\mathrm{i}}{2}\,\frac{Z\cdot \mathrm{d}\bar{Z} - \mathrm{d}Z\cdot\bar{Z}}{Z\cdot\bar{Z}} \;=\; -\mathrm{i}\,\mathrm{d}Z\cdot\bar{Z}\ . \tag{4.90}$$

In the last step we used normalized vectors. The equation $\omega = 0$ now expresses the requirement that $\mathrm{d}Z^\alpha$ be orthogonal to Z^α, so that the lifted curve will be perpendicular to the fibres of the bundle. A minor calculation confirms that

$$\mathrm{d}\omega \;=\; \Omega\ , \tag{4.91}$$

where Ω is the symplectic 2-form defined in Eq. (4.50).

Let us lift some curves on $\mathbb{C}\mathbf{P}^n$ to Hilbert space. We have already done so for a geodesic on the base manifold – the result is given in Eq. (4.44). Since $\dot{Z}\cdot\bar{Z} = 0$ along this curve, it follows that $\omega = 0$ along it, so indeed it is a horizontal lift. Another example that we have encountered already: in Eq. (4.58) we wrote the Schrödinger equation, or equivalently the flow line of some isometry, as

$$\mathrm{i}\,\mathrm{d}Z^\alpha = H^\alpha{}_\beta Z^\beta \mathrm{d}t\ . \tag{4.92}$$

Evidently

$$\omega = \frac{1}{2}(Z^\alpha \bar{H}_\alpha{}^\beta \bar{Z}_\beta - \bar{Z}_\alpha H^\alpha{}_\beta Z^\beta)\ \mathrm{d}t = 0 \tag{4.93}$$

along the resulting curve in the bundle, so that this is the horizontal lift of a curve defined in the base manifold by the projective Schrödinger equation (4.59).

Now consider an arbitrary curve $C(\sigma)$ in $\mathbb{C}\mathbf{P}^n$, and an arbitrary lift of it to $\mathbb{C}^N$. Let the curve run from σ_1 to σ_2. Define its *geometric phase* as

$$\phi_{\mathrm{g}} = \arg\big(Z(\sigma_2)\cdot\bar{Z}(\sigma_1)\big) - \int_C \omega\ . \tag{4.94}$$

From now on we assume that the length of the curve is less than $\pi/2$ so that the argument that defines the *total phase* – the first term on the right-hand side – of the curve is well defined. Suppose that we change the lift of the curve by means of the transformation

$$Z^\alpha \to \mathrm{e}^{\mathrm{i}\lambda}Z^\alpha \qquad \Rightarrow \qquad \omega \to \omega + \mathrm{d}\lambda\ , \tag{4.95}$$

where λ is some function of σ. Although both the connection and the total phase change under this transformation, the geometric phase does not. Indeed it is easy to see that

$$\phi_{\mathrm{g}} \to \phi_{\mathrm{g}} + \lambda(\sigma_2) - \lambda(\sigma_1) - \int_{\sigma_1}^{\sigma_2}\mathrm{d}\lambda = \phi_{\mathrm{g}}\ . \tag{4.96}$$

The conclusion is that the geometric phase does not depend on the particular lift that we use. Hence it is genuinely a function of the original curve in

$\mathbb{C}\mathbf{P}^n$ itself. The total phase on the other hand is not – although it equals the geometric phase for a horizontal lift of the curve.

An interesting observation, with consequences, is that if we compute the total phase along the horizontal lift (4.44) of a geodesic in $\mathbb{C}\mathbf{P}^n$ we find that it vanishes. This means that the geometrical phase is zero for any lift of a geodesic. A geodesic is therefore a *null phase curve*. The converse is not true – we will find further examples of null phase curves in Chapter 6. To see what the consequences are, consider a *geodesic triangle* in $\mathbb{C}\mathbf{P}^n$, that is three points P, Q and R connected with geodesic arcs not longer than $\pi/2$. In flat space the lengths of the sides determine the triangle uniquely up to isometries, but in curved spaces this need not be so. As it happens a geodesic triangle in $\mathbb{C}\mathbf{P}^n$ is determined up to isometries by its side lengths and its *symplectic area*, that is the integral of the symplectic form Ω over any area bounded by the three geodesic arcs (Brehm, 1990). To such a triangle we can associate the *Bargmann invariant*[6]

$$\Delta_3(P,Q,R) = \frac{P\cdot\bar{Q}Q\cdot\bar{R}R\cdot\bar{P}}{P\cdot\bar{P}Q\cdot\bar{Q}R\cdot\bar{R}} = \cos D_{PQ}\cos D_{QR}\cos D_{RP}\mathrm{e}^{-\mathrm{i}\Phi} \ . \tag{4.97}$$

Here D_{PQ} is the Fubini–Study distance between the points whose homogeneous coordinates are P and Q, and so on. But what is the phase Φ? Since each side of the triangle is a geodesic arc the geometric phase of each side is zero, and by Eq. (4.94) the total phase of the side is equal to the integral along the arc of ω. Adding the contribution of all the sides (and normalizing the vectors) we get

$$\arg P\cdot\bar{Q}Q\cdot\bar{R}R\cdot\bar{P} = -\arg Q\cdot\bar{P} - \arg R\cdot\bar{Q} - \arg P\cdot\bar{R} = -\oint_{\partial\Delta}\omega \ . \tag{4.98}$$

It follows from Stokes' theorem that the phase Φ is the symplectic area of the triangle,

$$\Phi = \int_{\Delta}\Omega \ . \tag{4.99}$$

We can go on to define Bargmann invariants for four, five and more points in the same cyclic manner and – by triangulation – we find that their phases are given by the symplectic area of the geodesic polygon spanned by the points.

The geometric phase also goes under the name of the *Berry phase*; the case that Berry studied was that of an eigenstate of a Hamiltonian H that is carried around a loop by adiabatic cycling of H.[7]

---

[6] It is invariant under phase changes of the homogenous coordinates and attracted Bargmann's attention (Bargmann, 1964) because, unlike the Fubini–Study distance, it is a complex valued function defined on $\mathbb{C}\mathbf{P}^n$. Blaschke and Terheggen (1939) considered this early on. That its argument is the area of a triangle was proved by both physicists (Mukunda and Simon, 1993) and mathematicians (Hangan and Masala, 1994).

[7] The original paper by Berry (1984) is reprinted in a book edited by Shapere and Wilczek (1989). See Anandan and Aharonov (1990) and Mukunda and Simon (1993) for the point of view that we take here, and Chruściński and JamioŁkowski (2004) for much more.

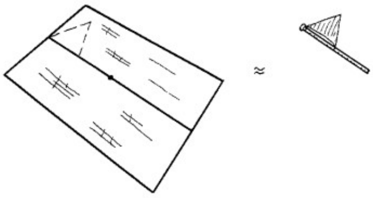

Figure 4.14. A flag may consist of a one-dimensional subspace of a two-dimensional subspace of a three-dimensional space – it is clear why it is called that!

4.9 Grassmannians and flag manifolds

Projective space is only the first of its kind. Starting from an N-dimensional vector space V, real or complex, we can consider nested sequences of subspaces V_i of dimension d_i, such that $V_1 \subset V_2 \subset \cdots \subset V_r$. This is called a *flag* of subspaces (as explained in Figure 4.14). The space of all flags of a given kind is known as a *flag manifold* and denoted by $\mathbf{F}^{(N)}_{d_1 \dots d_r}$; projective space is the easy case where a flag consists of a single one-dimensional subspace only. The next simplest case is that where the flags consist of a single M-dimensional subspace; such a flag manifold is known as the *Grassmannian* $\mathbf{F}^{(N)}_{M} = \mathbf{Gr}^{\mathbb{C}}_{M,N}$. The notation also tells us which field ($\mathbb{R}$ or $\mathbb{C}$) we are using; if there is no label then the complex numbers are implied.

To see how this works let us consider the case of $\mathbf{Gr}_{2,4}$, which is the space of 2-planes in a four-dimensional vector space. We fix a 2-plane in $\mathbb{C}^4$ by fixing two linearly independent vectors spanning that plane, and collect them into a rank two $N \times 2$ matrix

$$\begin{bmatrix} Z_{0,0} & Z_{0,1} \\ Z_{1,0} & Z_{1,1} \\ Z_{2,0} & Z_{2,1} \\ Z_{3,0} & Z_{3,1} \end{bmatrix} \sim \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ z_{2,0} & z_{2,1} \\ z_{3,0} & z_{3,1} \end{bmatrix} . \tag{4.100}$$

The entries in the matrix on the left are homogeneous coordinates on the Grassmannian. Then we exercised our right to perform linear combinations and rescalings of the columns to get the matrix in a standard form. The remaining four complex numbers serve as affine coordinates on the four complex dimensional Grassmannian. Note that if the upper two rows were linearly dependent this form could not have been reached, but since the matrix as a whole has rank two we can introduce a similar coordinate system by singling out another pair of rows. (Indeed it is not hard to see that the Grassmannian is a complex manifold that can be completely covered by six coordinate patches of this kind.) From a geometrical point of view it is sometimes advantageous to think of the Grassmannian of 2-planes as the space of projective lines in a projective space of dimension $N - 1$; it is an interesting exercise to convince oneself directly that the space of lines in 3-space is four-dimensional. On the other hand the use of an $N \times M$ matrix as homogeneous coordinates for $\mathbf{Gr}_{M,N}$ has advantages too and leads to an immediate proof that it is a complex manifold of $M(N-M)$ complex dimensions.[8]

When we get to more involved examples of flag manifolds any kind of explicit description of the space will get involved, too. For this reason it is a good idea to fall back on a description as coset spaces. Let us begin with $\mathbf{F}_1^{(4)} = \mathbb{C}\mathbf{P}^3$. The group $GL(4, \mathbb{C})$ acts transitively on the underlying vector space. Pick any point, say $p = (1, 0, 0, 0)$ and find its isotropy group – that subgroup of the transitive group that leaves the given point invariant. Here the isotropy group consists of all matrices h of the form

$$h = \begin{bmatrix} \bullet & \bullet & \bullet & \bullet \\ 0 & \bullet & \bullet & \bullet \\ 0 & \bullet & \bullet & \bullet \\ 0 & \bullet & \bullet & \bullet \end{bmatrix} , \tag{4.101}$$

where $\bullet$ is any complex number. This defines a subgroup of $GL(4, \mathbb{C})$, and we can now define $\mathbb{C}\mathbf{P}^3$ as a coset space following the recipe in Section 3.8. We can use $SL(4, \mathbb{C})$ as our starting point instead; the resulting coset will be the same once the form of h is restricted so that it has unit determinant. Call the resulting isotropy group $P_1^{(4)}$. Indeed we can restrict ourselves to $U(N)$ since the unitary subgroup of $GL(4, \mathbb{C})$ also acts transitively; when h is restricted to belong to $U(N)$ it becomes a block diagonal matrix representing $U(1) \times U(3)$. The argument clearly generalizes to any dimension, so that we have proved that

$$\mathbf{F}_1^{(N)} \equiv \mathbb{C}\mathbf{P}^{N-1} = \frac{SL(N, \mathbb{C})}{P_1^{(N)}} = \frac{U(N)}{U(1) \times U(N-1)} \ . \tag{4.102}$$

For real projective space we just have to replace $SL(\mathbb{C})$ with $SL(\mathbb{R})$ and the unitary groups by orthogonal groups.

The same argument repeated for the Grassmannian $\mathbf{Gr}_{2,4}$ reveals that the isotropy group can be written as the set $P_2^{(4)}$ of special linear matrices of the form

$$h = \begin{bmatrix} \bullet & \bullet & \bullet & \bullet \\ \bullet & \bullet & \bullet & \bullet \\ 0 & 0 & \bullet & \bullet \\ 0 & 0 & \bullet & \bullet \end{bmatrix} , \tag{4.103}$$

or as block diagonal unitary matrices belonging to $U(2) \times U(2)$ if only unitary transformations are considered. For the flag manifold $\mathbf{F}_{1,2,3}^{(N)}$ the isotropy group is a *Borel subgroup* B of $SL(4, \mathbb{C})$; by definition the *standard Borel subgroup* is the group of upper triangular matrices and a general Borel subgroup is given by conjugation of the standard one. If the group is $U(N)$ the Borel subgroup is the subgroup $U(1) \times U(1) \times U(1) \times U(1)$, given by diagonal matrices in the standard case. The isotropy groups considered above are examples of *parabolic*

---

[8] The affine coordinates are particularly useful if one wants to discuss the natural (Fubini–Study like) metric properties of the Grassmannians. See Wong (1967) for this.

subgroups P of the group G, represented by 'block upper triangular' matrices such that $B \subset P \subset G$. Thus we can write, in complete generality,

$$\mathbf{F}^{(N)}_{d_1 d_2 \dots d_r} = \frac{SL(N, \mathbb{C})}{P^{(N)}_{d_1 d_2 \dots d_r}} = \frac{U(N)}{[U(k_1) \times U(k_2) \dots U(k_{r+1})]} \ , \tag{4.104}$$

where $k_1 = d_1$ and $k_{i+1} = d_{i+1} - d_i$ (and $d_{r+1} = N$). Given that the real dimension of $U(N)$ is N^2 the real dimension of an arbitrary flag manifold is

$$\dim(\mathbf{F}^{(N)}_{d_1 d_2 \dots d_r}) = N^2 - \sum_{i=1}^{r+1} k_i^2 \ . \tag{4.105}$$

Equivalently it is simply twice the number of zeroes in the complex matrices representing the parabolic subgroup $P^{(N)}_{d_1 d_2 \dots d_r}$. For real flag manifolds, replace the unitary groups with orthogonal groups.

The two descriptions of flag manifolds given in Eq. (4.104) are useful in different ways. To see why we quote two facts: the quotient of two complex groups is a complex manifold, and the quotient of two compact groups is a compact manifold. Then the conclusion is that all flag manifolds are compact complex manifolds. Indeed they are also Kähler manifolds. This has to do with another way of arriving at them, based on *adjoint orbits* in a Lie algebra. This aspect of flag manifolds will be discussed at length in Chapter 8 but let us reveal the point already here. The Lie algebra of the unitary group is the set of Hermitian matrices, and such matrices can always be diagonalized by unitary transformations. The set of Hermitian matrices with a given spectrum $(\lambda_1, \lambda_2, \dots, \lambda_N)$ can therefore be written as

$$H_{\lambda_1 \lambda_2 \dots \lambda_N} = U H_{\text{diag}} U^{-1} \ . \tag{4.106}$$

This is an adjoint orbit and a little bit of thinking reveals that it is also a flag manifold $\mathbf{F}^{(N)}$; which particular one depends on whether there are degeneracies in the spectrum. For the special case when $\lambda_1 = 1$ and all the others are zero we came across this fact when we embedded $\mathbb{C}\mathbf{P}^n$ in the flat vector space of Hermitian matrices; see Eq. (4.61). The theme will be further pursued in section 8.5.[9]

A variation on the theme deserves mention too. A *Stiefel manifold* is by definition the space of sets of M orthonormal vectors in an N-dimensional vector space. It is not hard to see that these are the complex (real) homogeneous spaces

$$\mathcal{S}t^{(\mathbb{C})}_{M,N} = \frac{U(N)}{U(N-M)} \quad \text{and} \quad \mathcal{S}t^{(\mathbb{R})}_{M,N} = \frac{O(N)}{O(N-M)}. \tag{4.107}$$

This is not quite the same as a Grassmannian since the definition of the latter is insensitive to the choice of basis in the M-dimensional subspaces that are the points of the Grassmannian. As special cases we get $\mathcal{S}t^{(\mathbb{C})}_{1,N} = \mathbf{S}^{2N-1}$ and $\mathcal{S}t^{(\mathbb{R})}_{1,N} = \mathbf{S}^{N-1}$; see Section 3.8.

---

[9] For further information on flag manifolds, in a form accessible to physicists, consult Picken (1990). The adjoint orbits should really be coadjoint, but the distinction is irrelevant here.

Problems

◇ **Problem 4.1** Consider $n+2$ ordered points on the plane, not all of which coincide. Consider two such sets equivalent if they can be transformed into each other by translations, rotations and scalings. Show that the topology of the resulting set is that of $\mathbb{C}\mathbf{P}^n$. What does $\mathbb{C}\mathbf{P}^n$ have to do with archaeology?

◇ **Problem 4.2** If you manage to glue together a Möbius strip and a hemisphere you get $\mathbb{R}\mathbf{P}^2$. What will you obtain if you glue two Möbius strips together?

◇ **Problem 4.3** Carry through the argument needed to prove that a complex projective line cannot be shrunk to a point within $\mathbb{C}\mathbf{P}^n$, using formulae, and using the octant picture.

3.3 Sinus, Kosinus, Tangens

Die Winkelfunktionen Sinus, Kosinus und Tangens spielen in der Mathematik eine tragende Rolle. Sie sind die Basis aller Berechnungen, die auf Winkelmessung beruhen.

Betrachten wir den Einheitskreis: Ein Punkt P darauf habe in einem kartesischen Koordinatensystem die Koordinaten (x, y). Der zugehörige *Polarwinkel* sei φ (Abb. 3.22). Dann wird definiert:

$$x = \cos\varphi, \quad y = \sin\varphi, \quad \tan\varphi = \frac{y}{x} = \frac{\sin\varphi}{\cos\varphi} \tag{3.6}$$

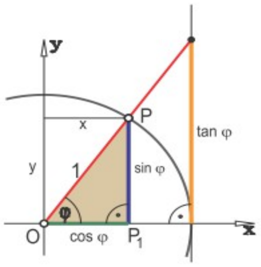

Abb. 3.22 Sinus, Kosinus, Tangens

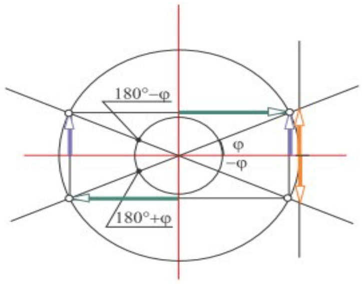

Abb. 3.23 $\sin(\pm\varphi)$, $\sin(180° \pm \varphi)$

Es folgt nach Pythagoras die wichtige Beziehung

$$\sin^2\varphi + \cos^2\varphi = 1 \tag{3.7}$$

Die Proportion $\tan\varphi : 1 = \sin\varphi : \cos\varphi$ zeigt, dass sich in Abb. 3.22 auch der Tangens auf der zur y-Achse parallelen (vertikalen) rechten Kreistangente $x = 1$ ablesen lässt.

Seltener wird der *Kotangens* verwendet (weil am Taschenrechner nicht verfügbar). Es handelt sich dabei um den Kehrwert des Tangens:

$$\cot\varphi = \frac{1}{\tan\varphi} = \frac{\cos\varphi}{\sin\varphi}$$

Aus Abb. 3.23 lassen sich folgende Beziehungen erkennen:

$$\begin{aligned} \sin(180° - \varphi) &= \sin\varphi & \qquad \sin(-\varphi) &= -\sin\varphi \\ \cos(180° - \varphi) &= -\cos\varphi & \qquad \cos(-\varphi) &= \cos\varphi \\ \tan(180° - \varphi) &= -\tan\varphi & \qquad \tan(-\varphi) &= -\tan\varphi \end{aligned} \tag{3.8}$$

Wir betrachten nun das rechtwinklige Dreieck OP_1P in Abb. 3.22. Es wird gebildet von:

- der dem Winkel φ anliegenden Kathete („Ankathete“) A mit der Länge x,

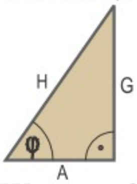
- von der φ gegenüberliegenden Kathete („Gegenkathete“) G mit der Länge y und

- der Hypothenuse H mit der Länge 1.

Es gilt:

$$\cos\varphi = \frac{A}{H}, \quad \sin\varphi = \frac{G}{H}, \quad \tan\varphi = \frac{G}{A} \tag{3.9}$$

Das gilt in jedem rechtwinkligen Dreieck mit Schenkelwinkel φ (ähnliche Dreiecke!).



Damit gilt im *rechtwinkligen Dreieck*

$$A = H\cos\varphi, \quad G = H\sin\varphi \tag{3.10}$$

Weiters gilt $\alpha = 90^\circ - \beta$. Durch Vertauschen der Bezeichnungsweisen erhält man die wichtige Beziehung

$$\cos\alpha = \sin(90^\circ - \alpha) \quad \text{bzw.} \quad \sin\alpha = \cos(90^\circ - \alpha) \tag{3.11}$$

Insbesondere gilt wegen $\cos 45^\circ = \sin 45^\circ$ und $\cos^2 45^\circ + \sin^2 45^\circ = 1$

$$\cos 45^\circ = \sin 45^\circ = \frac{1}{\sqrt{2}}. \tag{3.12}$$

Aus dem halben gleichseitigen Dreieck erkennt man sofort

$$\cos 60^\circ = \sin 30^\circ = \frac{1}{2}$$

und damit wegen $\cos^2 60^\circ + \sin^2 60^\circ = 1$

$$\sin 60^\circ = \cos 30^\circ = \frac{\sqrt{3}}{2}$$

Insgesamt haben wir jetzt die folgenden Hauptwerte, die man sich mit der Zeit einprägen sollte:

x	0°	30°	45°	60°	90°
$\cos x$	1	$\sqrt{3}/2$	$\sqrt{2}/2$	$1/2$	0
$\sin x$	0	$1/2$	$\sqrt{2}/2$	$\sqrt{3}/2$	1
$\tan x$	0	$1/\sqrt{3}$	1	$\sqrt{3}$	∞

(3.13)

∘ Als „Eselsbrücke“ kann man sich die Tabelle für den Sinus leicht merken (die Tabelle für den Kosinus ist dann „rückläufig“):

x	0°	30°	45°	60°	90°
$\sin x$	$\sqrt{0}/2$	$\sqrt{1}/2$	$\sqrt{2}/2$	$\sqrt{3}/2$	$\sqrt{4}/2$

Die folgenden *Additionstheoreme* brauchen wir uns nicht auswendig zu merken, wir benötigen sie aber bei den Drehungen in Abschnitt 6.1:

$$\begin{aligned}\sin(\alpha+\beta) &= \sin\alpha\cos\beta+\cos\alpha\sin\beta, \\ \cos(\alpha+\beta) &= \cos\alpha\cos\beta-\sin\alpha\sin\beta\end{aligned} \qquad (3.14)$$

Abb. 3.24 Beweise für die trigonometrischen Additionstheoreme

∘ *Beweis*:
Seien $P_\alpha(\cos\alpha/\sin\alpha)$ und $P_\beta(\cos\beta/\sin\beta)$ jene Punkte am Einheitskreis, die zu den Winkeln α und β gehören. Wir verdrehen nun P_β um α und erhalten so $P_{\alpha+\beta}(\cos(\alpha+\beta)/\sin(\alpha+\beta))$. Seine Koordinaten sind aber gemäß Abb. 3.24 links auch

$$P_{\alpha+\beta}(\cos\alpha\cos\beta-\sin\alpha\sin\beta/\sin\alpha\cos\beta+\cos\alpha\sin\beta).$$

■

Anwendung: Man zeige mit den Additionstheoremen

$$\cos 2x = 1-2\sin^2 x \text{ und damit } \sin\frac{x}{2} = \pm\sqrt{\frac{1}{2}\,(1-\cos x)} \qquad (3.15)$$

∘ *Beweis*:

$$\cos 2x = \cos(x+x) = \cos^2 x - \sin^2 x = (1-\sin^2 x) - \sin^2 x = 1-2\sin^2 x$$

$$\Rightarrow \sin x = \sqrt{\frac{1}{2}\,(1-\cos 2x)} \Rightarrow \sin\frac{\alpha}{2} = \sqrt{\frac{1}{2}\,(1-\cos\alpha)}$$

(Auf die Bezeichnungsweise kommt es nicht an.) ■

■

Anwendung: Wie wurden früher Tabellen für die Winkelfunktionen erstellt?

Die Frage ist eher vom historischen Standpunkt aus interessant. Ohne diese

Tabellen konnte man bis vor wenigen Jahrzehnten keine genauen Berechnungen machen! Schon die alten Griechen haben Tabellen für die Winkelfunktionen angelegt, die Araber haben diese übernommen und verfeinert. Auch die Wikinger sollen die geografische Breite auf See mit Tangens-Tabellen ermittelt haben. Wie der Taschenrechner bzw. Computer heute die Werte berechnet, besprechen wir bei der Differentialrechnung im Abschnitt über Reihenentwicklung (Anwendung S. 389).

Lösung:
Aus den Hauptwerten (3.13) lassen sich nach den Additionstheoremen (3.14) die Zwischenwerte

$$\sin 15^\circ = \cos 75^\circ = \sin(60^\circ - 45^\circ) \quad \text{und} \quad \sin 75^\circ = \cos 15^\circ = \sin(90^\circ - 15^\circ)$$

berechnen. Durch Übergang zum halben Winkel (3.15) bekommt man neue Werte, die ihrerseits mittels der Additionstheoreme zu neuen Werten führen, usw. Es war zwar viel Arbeit, aber man konnte beliebig viele Zwischenwerte auf diese Art ermitteln. Wenn man es „noch genauer wissen wollte", *interpolierte* man zwei Nachbarwerte linear (in sehr kleinen Intervallen kann man die Funktionen getrost durch eine Gerade ersetzen).
Die Tangenswerte ergeben sich als Quotient aus Sinus und Kosinus. ■

Gelegentlich braucht man die sog. *zweiten Additionstheoreme*

$$\begin{aligned}\sin\alpha + \sin\beta &= 2\sin\frac{\alpha+\beta}{2}\cos\frac{\alpha-\beta}{2}\\ \cos\alpha + \cos\beta &= 2\cos\frac{\alpha+\beta}{2}\cos\frac{\alpha-\beta}{2}\end{aligned} \tag{3.16}$$

∘ *Beweis*:
Wir betrachten Abb. 3.24 rechts: Die Punkte O, P, R und Q sollen eine Raute mit Seitenlänge 1 bilden. R hat zunächst die Koordinaten $R(\cos\alpha + \cos\beta / \sin\alpha + \sin\beta)$. Die halbe Diagonale OM hat die Länge $\cos\frac{\alpha-\beta}{2}$. Damit lassen sich die Koordinaten von R auch angeben durch

$$R(2\cos\frac{\alpha-\beta}{2}\cos\frac{\alpha+\beta}{2} / 2\cos\frac{\alpha-\beta}{2}\sin\frac{\alpha+\beta}{2})$$

■

Anwendung: Drehstrom oder Dreiphasenstrom (Abb. 3.25)
Bei der Erzeugung von Drehstrom rotiert ein magnetischer Läufer innerhalb dreier Induktionsspulen und induziert dabei drei phasenverschobene Wechselströme. Diese können einzeln oder gemeinsam verwendet werden. Man berechne die Summe aller Spannungen $y = \sin x + \sin(x + \frac{2\pi}{3}) + \sin(x + \frac{4\pi}{3})$ sowie die Spannungsdifferenz $y = \sin x - \sin(x + \frac{2\pi}{3})$ zwischen zwei aufeinander folgenden Phasen (vgl. dazu Anwendung S. 179).

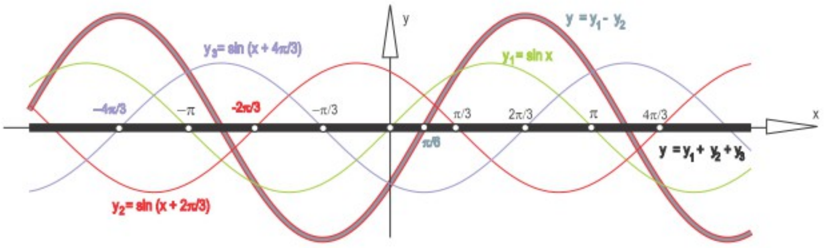

Abb. 3.25 Wellen können einander verstärken oder auslöschen

Lösung:
Wir zeigen: Die Summe zweier phasenverschobener Sinuslinien (Verschiebung x_0, gleiche Amplitude und Frequenz) ist wieder eine Sinuslinie gleicher Frequenz, aber unterschiedlicher Amplitude:
Nach den zweiten Additionstheoremen gilt nämlich

$$\sin x + \sin(x + x_0) = 2\,\sin\tfrac{x+(x+x_0)}{2}\,\cos\tfrac{x-(x+x_0)}{2} = 2\cos\tfrac{-x_0}{2}\,\sin(x+\tfrac{x_0}{2}).$$

Für $x_0 = \frac{2\pi}{3}$ ($\Rightarrow 2\cos\frac{-\pi}{3} = 1$) ergibt sich die Beziehung

$$\sin x + \sin(x + \tfrac{2\pi}{3}) = \sin(x + \tfrac{\pi}{3}).$$

Wegen $\sin x = -\sin(x+\pi) \Rightarrow \sin(x+\frac{\pi}{3}) = -\sin(x+\frac{4\pi}{3})$ ist diese Summe entgegengesetzt gleich der dritten Funktion, und die Gesamtsumme verschwindet:

$$\sin x + \sin(x + \frac{2\pi}{3}) + \sin(x + \frac{4\pi}{3}) = 0 \tag{3.17}$$

Die Spannungsdifferenz zwischen zwei Nachbarphasen ergibt sich durch

$$\sin x - \sin(x + x_0) = \sin x + \sin(-x - x_0) = \\ = 2\,\sin\tfrac{x-(x+x_0)}{2}\,\cos\tfrac{x+(x+x_0)}{2} = 2\sin\tfrac{-x_0}{2}\,\cos(x+\tfrac{x_0}{2}).$$

Für $x_0 = \frac{2\pi}{3}$ haben wir eine Verstärkung der Amplitude mit dem Faktor $2\sin -\frac{\pi}{3} = -\sqrt{3}$. Die Differenzspannung wird beschrieben durch

$$y = -\sqrt{3}\,\cos(x + \frac{\pi}{3}) = -\sqrt{3}\,\sin(\frac{\pi}{2} - (x + \frac{\pi}{3})) = \sqrt{3}\,\sin(x - \frac{\pi}{6})$$

Bei Einzelspannungen von 230 Volt ergibt sich damit eine maximale Spannungsdifferenz von etwa 400 Volt. ■

Anwendung: Schiefe Ebene (Abb. 3.26)
Um ein Fass von 100 kg Masse nicht auf eine Rampe heben zu müssen, rollt man es auf einem Brett, das $\alpha = 30°$ geneigt ist, hinauf. Welche Kraft $F = |\vec{F}|$ ist nötig (Reibung vernachlässigt), um die treibende Komponente $T = |\vec{T}|$ des Gewichts G zu kompensieren?

Lösung:

$$T = F = G\,\sin\alpha$$

$$G = m\,g = 100\text{kg} \cdot 9{,}81\text{m/s}^2 = 981\,\text{N}$$

$$\Rightarrow F = 981\text{N} \cdot \frac{1}{2} = 490{,}5\,\text{N}$$

■

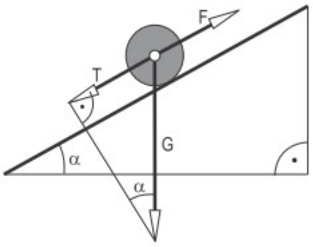

Abb. 3.26 Schiefe Ebene in Theorie...

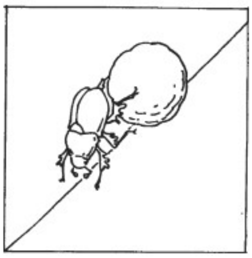

Abb. 3.27 ...und Praxis

Anwendung: Pyramidenrampen

Die alten Ägypter haben sicherlich schiefe Ebenen („Rampen") benutzt, um die schweren Steinblöcke zu heben (auf Schlitten zu ziehen). In Anwendung S. 71 haben wir gesehen, dass weitaus der meiste Teil der Quader in den unteren Schichten verbaut wurde. Für diese niedrigen Schichten bot sich durchaus eine – mit der Höhe des Pyramidenstumpfs wachsende – Rampe an. Rampenmodelle für größere Höhen scheitern allerdings an der praktischen Durchführbarkeit solcher Modelle. Offensichtlich haben die damaligen Baumeister mit wesentlich ausgefeilteren Methoden gearbeitet („Kippschlitten" u. Ä.).

Der Steinbruch der Cheops-Pyramide lag etwa 400 m südlich der Pyramide. Wie hoch konnte man auf dieser Wegstrecke die Kalksteinblöcke bei 8% Rampenneigung anheben? Wie lange hätte eine solche Rampe sein müssen, um auch den allerletzten Baustein der Pyramide, das „Pyramidion", auf die Spitze der Cheops-Pyramide zu transportieren?

Lösung:

Die Steigung der Rampe (Neigungswinkel α) ist $\tan\alpha = 8 : 100$. Bei 400 m Basisstrecke bedeutet dies einen Hub von $400 \cdot \frac{8}{100}\,\mathrm{m} = 32\,\mathrm{m}$. Immerhin ist das gut ein Fünftel der Bauhöhe, und etwa die Hälfte aller Blöcke ist bis in diese Höhe verbaut. Um auch das Pyramidion über die Rampe zu transportieren, müsste diese allerdings über eine fünf mal so lange Basisstrecke verfügen (2 000 m). Allein die Dämme der Rampe hätten dann ein Vielfaches des Volumens der gesamten Pyramide erfordert! ■

Anwendung: Keilkräfte (Abb. 3.28)

Ein symmetrischer Keil mit dem Spitzwinkel α wird mit der Kraft F in die Unterlage gedrückt. Wie groß sind die Normalkräfte F_1 bzw. F_2 gegen die Wände?

Lösung:

$$F_1 = F_2 = \frac{\frac{F}{2}}{\sin\varphi} = \frac{F}{2\sin\frac{\alpha}{2}}$$

F_1 wird somit umso größer, je kleiner $\sin\varphi$ wird, also je kleiner α ist. ■

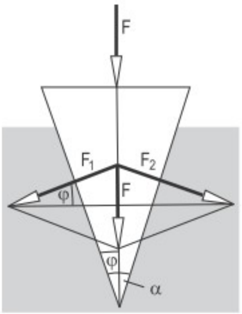

Abb. 3.28 Keilkräfte in Theorie…

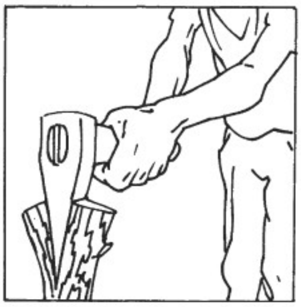

Abb. 3.29 … und Praxis

Anwendung: Keilriemen (Abb. 3.30)
Gegeben seien die Radien R und r sowie der Zentralabstand d. Wie lang ist der Riemen?

Lösung:
So einfach das Beispiel scheint, benötigen wir doch einen kleinen Trick, den man „sehen" muss: Durch Parallelverschieben des gemeinsamen Tangentenstücks der beiden Kreise ergibt sich ein rechtwinkliges Dreieck, in dem dann der Pythagoras anwendbar ist: $t = \sqrt{d^2 - (R-r)^2}$. Weiters ist dort $\sin\varphi = (R-r)/d \;\Rightarrow \varphi$ (im Bogenmaß!). Damit ergibt sich die Riemenlänge mit

$$L = 2\left[R\left(\frac{\pi}{2} + \varphi\right) + t + r\left(\frac{\pi}{2} - \varphi\right)\right]$$

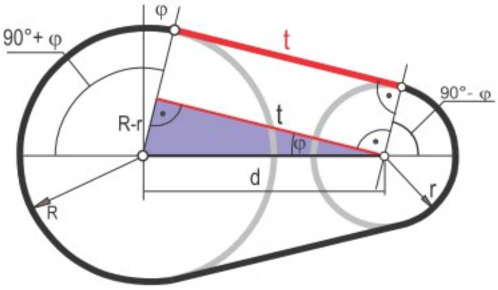

Abb. 3.30 Keilriemen

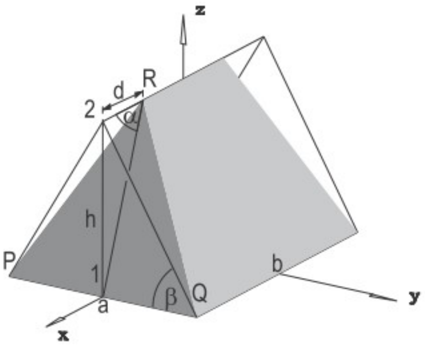

Abb. 3.31 Walmdach

Anwendung: Walmdach (Abb. 3.31)
Man berechne das Volumen des skizzierten Walmdachraumes bei gegebenen Traufenlängen a, b und gegebenen Dachneigungswinkeln α, β.

Lösung:
Im Dreieck $Q12$ gilt

$$h = \frac{a}{2}\tan\beta,$$

Damit ist die Fläche A des Dreiecks $PQ2$ bestimmt:

$$A = \frac{ah}{2}.$$

Das Volumen ergibt sich aus der Differenz des Volumens des dreiseitigen Prismas mit Querschnittsfläche A und Länge b und des doppelten Volumens des Tetraeders $PQ2R$, dessen Dreieck $PQ2$ ebenfalls die Fläche A hat, und dessen dazu normale Kante $R2$ die Länge d hat. d ergibt sich aus dem rechtwinkligen Dreieck $12R$ mit

$$d = h/\tan\alpha$$

$$\Rightarrow V = A\,b - 2\,\frac{A\,d}{3} = A(b - \frac{2d}{3})$$ ■

Anwendung: Kurvenlage eines Motorrads (Abb. 3.32)
Wenn ein Motorrad (Gewicht $G = m\,g$) mit der Geschwindigkeit v eine Kurve (Radius r) durchfährt, muss es sich um den Winkel α neigen, um nicht durch die Fliehkraft ($F = mv^2/r$) umzukippen.

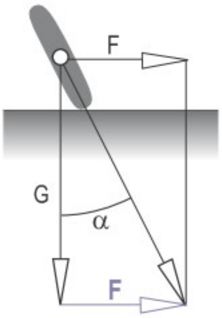

Abb. 3.32 Kurvenlage in Theorie...

Abb. 3.33 ...und Praxis

Lösung:
Es ist

$$\tan\alpha = \frac{F}{G} = \frac{v^2}{gr}$$

(unabhängig von der Masse, Abb. 3.34). Außerdem muss die Reibungskraft größer als F sein.

Zahlenbeispiel:

1) Aus einem Foto (Abb. 3.33 links) sind der Neigungswinkel α und der Kurvenradius r bekannt. Wie schnell war das Moped auf dem Gartenweg unterwegs?
$\alpha = 15°,\ r = 10\,\text{m} \Rightarrow v = \sqrt{g\,r\,\tan\alpha} \approx 5\,\text{m/s} \approx 18\,\text{km/h}$
2) Wie groß muss der Winkel sein, wenn v und r gegeben sind?
$r = 70\,\text{m},\ v = 72\,\text{km/h} = 20\,\text{m/s} \Rightarrow \tan\alpha \approx 0{,}58 \Rightarrow \alpha \approx 30°$

3) Der abgebildete Extrem-Carver (Abb. 3.35) fährt eine Kurve mit einem Radius von $r = 5$ m mit einer Geschwindigkeit von $v = 12$ m/s. Daraus ergibt sich $\tan\alpha = 2{,}88$, was bedeutet, dass das Brett unter einem Winkel von 71° geneigt sein muss, damit der Carver sein Gleichgewicht halten kann. Dabei wirkt mehr als das Dreifache der Erdanziehungskraft auf den Sportler. Das Berühren des Schnees wie auf dem Foto ist eine physikalische Notwendigkeit bei einer Standard-Hangneigung von 20°. Der Athlet ist gezwungen, sich buchstäblich über den Schnee zu ziehen, wenn er es um die Kurve schaffen will. ■

Abb. 3.34 Der Neigungswinkel hängt von der Geschwindigkeit, nicht aber von der Masse ab!

Abb. 3.35 Extremes Snowboarding

Anwendung: Verebnung eines Drehkegels (Abb. 3.36)
Ein Drehkegel (Radius r, Höhe h) geht bei Abwicklung („Verebnung“) in einen Kreissektor mit dem Radius s und dem Zentriwinkel ω über. Man berechne ω in Abhängigkeit vom halben Öffnungswinkel α des Kegels.

Lösung:
Gemäß Abb. 3.36 müssen die Bogenlängen am Basiskreis des Drehkegels und jene am Kreissektor übereinstimmen, also gelten:

$$2\pi\, r = s\,\omega \Rightarrow \omega = 2\pi\,\frac{r}{s}$$

Mit $\dfrac{r}{s} = \sin\alpha$ ergibt sich die Formel

$$\omega = 2\pi\,\sin\alpha \quad \text{bzw.} \quad \omega^\circ = 360^\circ\,\sin\alpha \tag{3.18}$$

Die zweite Variante der Formel entsteht dabei aus der ersten durch Multiplikation mit $\frac{180}{\pi}$. ■

Anwendung: Schubkurbelgetriebe (Otto-Motor) (Abb. 3.37 links)
Der Kolben treibt über den Kolbenbolzen B und die Schubstange AB den Kurbelzapfen A an und bewirkt die Drehung der Kurbelwelle L. Man be-

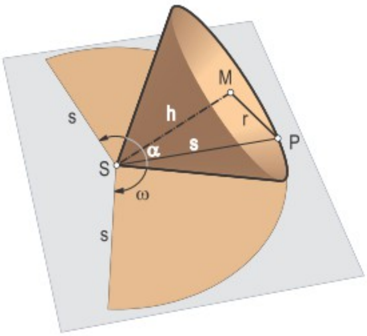

Abb. 3.36 Verebnung des Drehkegels

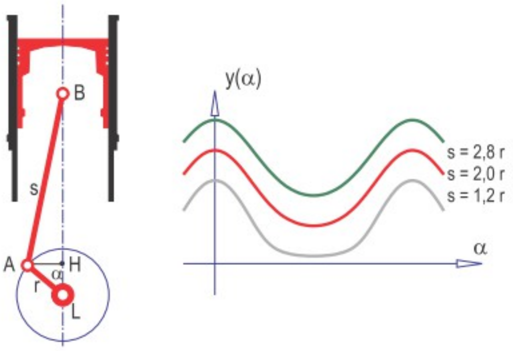

Abb. 3.37 *Otto*-Motor, Zeit-Weg-Diagramme

rechne den Abstand $\overline{LB}$ in Abhängigkeit vom Drehwinkel α – diese Distanz ist der Schlüssel zur gesamten kinematischen Untersuchung des Getriebes (Geschwindigkeits- und Beschleunigungsverhältnisse).

Lösung:

Die Strecke $y = \overline{LB}$ ist natürlich vom Drehwinkel α abhängig, und dieser ist wiederum proportional zur Zeit t. Man erhält also mit der Gleichung $y = y\big(\alpha(t)\big) = y(t)$ ein Weg-Zeit-Diagramm von B.

$$\overline{LB} = \overline{LH} + \overline{HB}$$

$$\overline{LH} = r\,\cos\alpha,\ \overline{AH} = r\,\sin\alpha,\ \overline{HB} = \sqrt{s^2 - \overline{AH}^2}$$

$$y = \overline{LB} = r\,\cos\alpha + \sqrt{s^2 - r^2\sin^2\alpha}$$

Abb. 3.37 rechts zeigt solche Diagramme $y = y(\alpha)$ für verschiedene Proportionen $r : s$. Für $s >> r$ (sprich: s viel größer als r) gilt

$$\sqrt{s^2 - r^2\sin^2\alpha} = s\sqrt{1 - \left(\frac{r}{s}\right)^2\sin^2\alpha} \approx s$$

und das Weg-Zeit-Diagramm nähert sich der gewöhnlichen Sinuslinie (die Graphen von $y = \sin x$ und $y = \cos x$ unterscheiden sich nur durch Parallelverschiebung längs der x-Achse um $\frac{\pi}{2}$. In beiden Fällen spricht man daher von einer Sinuslinie)

$$y = r\,\cos\alpha + s.$$

Das Demo-programm `otto_engine.exe` auf der Webseite zum Buch (`www.uni-ak.ac.at/math`) wurde unter Verwendung von $y(\alpha)$ erstellt. Für den Maschinenbauer ist zusätzlich noch ein Geschwindigkeitsdiagramm wichtig. Dieses erhält man, wie wir im Kapitel *Differentialrechnung* sehen werden, durch „Ableiten" der Funktion (Anwendung S. 281). ■

Relativ häufig brauchen wir folgende Formel:

$$\sin 2\alpha = 2 \sin\alpha \cos\alpha \tag{3.19}$$

∘ *Beweis*:
Wir betrachten das rechtwinklige Dreieck ABC in Abb. 3.38 (mit $\overline{AC} = 1$). Es hat die Fläche

$$A_1 = \frac{1}{2} \sin\alpha \cos\alpha$$

Wir spiegeln es an AB und erhalten ein doppelt so großes (gleichschenkeliges) Dreieck ACC^* (Fläche $A_2 = \sin\alpha\cos\alpha$). Die Höhe CH in diesem Dreieck ist $\sin 2\alpha$. Damit lässt sich die Fläche A_2 auch wie folgt berechnen:

$$A_2 = \frac{1 \cdot \sin 2\alpha}{2} = \sin\alpha\cos\alpha = 2\,A_1$$

■

Anwendung: Fläche des regelmäßigen n-Ecks (Abb. 3.39)
Man berechne die Fläche eines regelmäßigen n-Ecks mit Umkreisradius r.

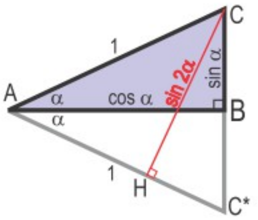

Abb. 3.38 $\sin 2\alpha = 2\sin\alpha\cos\alpha$

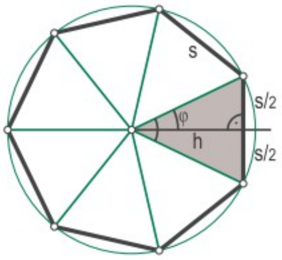

Abb. 3.39 Fläche des reg. n-Ecks

Lösung:
Es gilt

$$\frac{s}{2} = r\,\sin\varphi,\ \ h = r\,\cos\varphi \quad \text{mit} \quad \varphi = \frac{360^\circ}{2n}.$$

Daraus berechnet sich die Fläche

$$A = n \cdot \frac{s}{2} \cdot h = n\,r^2\,\sin\varphi\cos\varphi = n\,r^2 \frac{\sin 2\varphi}{2} \ \Rightarrow$$

$$A = \frac{n\,r^2}{2} \sin\frac{360^\circ}{n} \tag{3.20}$$

∘ Lassen wir n „gross“ werden. Dann „konvergiert“ die Fläche des Vielecks gegen die Kreisfläche $\pi\,r^2$. Schon *Archimedes* hat vor mehr als 2 000 Jahren auf ähnliche Weise – nämlich mit dem *Umfang* des regelmäßigen n-Ecks – die Zahl π recht gut angenähert.
Verwenden wir die „Grenzwertschreibweise“, dann gilt zunächst

$$A_\circ = r^2 \lim_{n\to\infty} \frac{n}{2} \sin\frac{360^\circ}{n} = r^2\,\pi.$$

Durch Übergang zum Bogenmaß ($360° = 2\pi$) erhalten wir nach Kürzen durch r^2 und Division durch π

$$\lim_{n\to\infty} \frac{n}{2\pi} \sin \frac{2\pi}{n} = 1.$$

Schreiben wir statt $\frac{2\pi}{n}$ noch x (sodass x gegen 0 konvergiert, wenn n gegen unendlich strebt), dann erhalten wir eine wichtige Beziehung, die wir in der Differentialrechnung brauchen:

$$\lim_{x\to 0} \frac{1}{x} \cdot \sin x = \lim_{x\to 0} \frac{\sin x}{x} = 1 \tag{3.21}$$

In Worten ausgedrückt:

Für sehr kleine Winkel stimmen Bogenmaß und Sinus überein.

■

Anwendung: Schiefer Wurf nach oben und maximale Wurfweite

Man errechnet die Höhe h nach t Sekunden mittels Modifizierung von Formel (1.17) in Anwendung S. 32:

$$h = G(t) - B(t) = (v_0 \sin\alpha\,)t - \frac{g}{2}t^2 \tag{3.22}$$

v_0 und g sind wieder Anfangsgeschwindigkeit und Erdbeschleunigung. α bezeichnet den Anfangswinkel zur Horizontalen. Der Luftwiderstand wird vernachlässigt.

Man berechne die Wurfweite bei gegebenem v_0 und α. Für welches α erzielt man die größte Wurfweite?

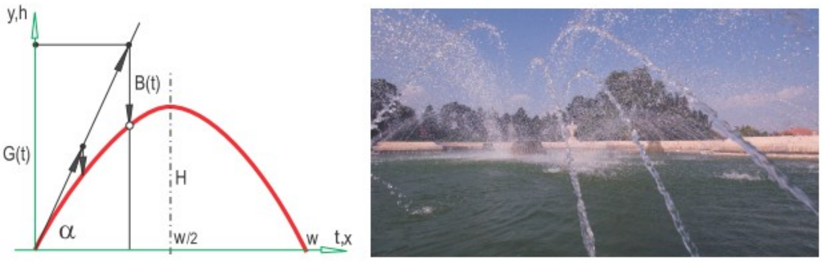

Abb. 3.40 Schiefer Wurf nach oben

Lösung:

Durch Lösen der quadratischen Gleichung (3.22) erhält man

$$t_{1,2} = \frac{1}{g}\left(v_0 \sin\alpha \pm \sqrt{v_0^2 \sin^2\alpha - 2gh}\right)$$

Der höchste Punkt wird für $D = v_0^2 \sin^2\alpha - 2gh = 0$, also

$$\text{zum Zeitpunkt } t_0 = \frac{v_0 \sin\alpha}{g} \text{ in der Höhe } H = \frac{v_0^2 \sin^2\alpha}{2g}$$

erreicht. Die Gesamtzeit bis zum Aufprall in der Ebene $h = 0$ ist dann $2t_0$. Für die horizontale Komponente (die x-Koordinate des Wurfobjekts) gilt $x(t) = t\,v_0 \cos\alpha$. Aus der Gesamtzeit ergibt sich die Wurfweite:

$$w = 2t_0 v_0 \cos\alpha = \frac{2\sin\alpha\cos\alpha\, v_0^2}{g} = \frac{1}{g} v_0^2 \sin 2\alpha$$

Abb. 3.41 *Galileos* Experiment

Abb. 3.42 Hoher Weitsprung oder weiter Hochsprung?

Die theoretisch maximale Wurfweite ergibt sich für maximales $\sin 2\alpha$. Der Sinus nimmt bei 90° seinen Maximalwert 1 an. Aus $\sin 2\alpha = 1$ folgt $2\alpha = 90°$ und daher ist für $\alpha = 45°$ die Wurfweite maximal. In Anwendung S. 386 wird die maximale Wurfweite am schrägen Hang besprochen.

∘ In der Praxis muss noch – spätestens seit *Galileos* Experiment mit den Kugeln aus Eisen und Holz vom Turm zu Pisa (Abb. 3.41) – der Luftwiderstand einkalkuliert werden. Die Wurfparabel wird dann eine Parabel 3. Ordnung. Beim Weitwerfen eines Schlagballs, beim Kugelstoßen, beim Speerwurf, aber auch beim Weitsprung (Abb. 3.42), ist für einen Anfangswinkel von $\alpha = 45°$ meist aus physiologischen Gründen nicht die größte Anfangsgeschwindigkeit v_0 erreichbar. Diese ist aber noch wichtiger als der Anfangswinkel: Die Wurfweite (Sprungweite) wächst ja *quadratisch* mit v_0. Deshalb sind die besten Sprinter oft auch die besten Weitspringer (Carl Lewis). ■

Gleichungen vom Typ $P \sin x + Q \cos x + R = 0$

Dieser Gleichungstyp kommt in der Praxis recht häufig vor (Anwendung S. 144, Anwendung S. 340) und führt auf eine quadratische Gleichung:
Wir formen zunächst um und erhalten

$$P \sin x = -Q \cos x - R \Rightarrow P^2 \sin^2 x = (Q \cos x + R)^2$$

$$\Rightarrow P^2 (1 - \cos^2 x) = Q^2 \cos^2 x + R^2 + 2QR \cos x$$

Setzen wir zur Abkürzung $u = \cos x$, dann haben wir die quadratische Gleichung

$$(P^2 + Q^2)\, u^2 + 2QR\, u + R^2 - P^2 = 0$$

mit den beiden (unter Umständen auch zusammenfallenden bzw. nicht reellen) Lösungen für $u = \cos x$

$$\begin{aligned} u_{1,2} &= \frac{-2QR \pm 2\sqrt{Q^2R^2 + (P^2+Q^2)(P^2-R^2)}}{2(P^2+Q^2)} = \\ &= \frac{-QR \pm \sqrt{P^4 + P^2Q^2 - P^2R^2}}{P^2+Q^2} = \frac{-QR \pm P\sqrt{P^2+Q^2-R^2}}{P^2+Q^2} \end{aligned}$$

Anwendung: Schnitt zweier konfokaler Kegelschnitte

In Kapitel 6 brauchen wir des Öfteren die Lösung der Gleichung (z.B. in Anwendung S. 340, Anwendung S. 340)

$$\frac{r_1}{1+\varepsilon_1\,\cos x} = \frac{r_2}{1+\varepsilon_2\,\cos(x+\delta)}$$

Sie tritt beim Schnitt zweier Kegelschnitte mit einem gemeinsamen Brennpunkt auf. Der konstante Wert δ ist der „Verdrehungswinkel" der beiden Kegelschnitte. Man führe die Gleichung mittels der Additionstheoreme auf die Form $P\,\sin x + Q\,\cos x + R = 0$, deren Lösung ja bekannt ist.

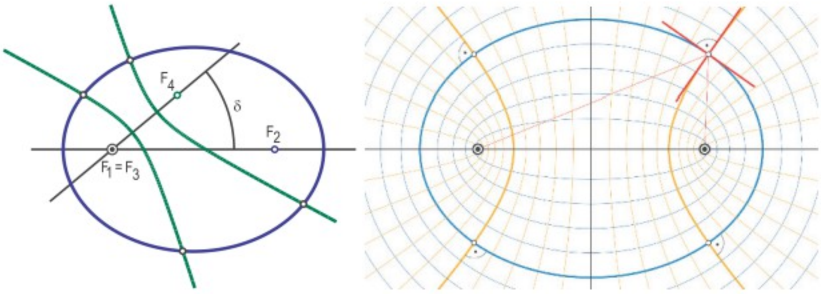

Abb. 3.43 Schnitt von Kegelschnitten mit einem bzw. zwei gemeinsamen Brennpunkten (rechts)

Lösung:
Durch Ausmultiplizieren erhalten wir zunächst

$$r_2(1+\varepsilon_1\,\cos x) = r_1(1+\varepsilon_2\,\cos(x+\delta)).$$

Setzen wir $\cos(x+\delta) = \cos x\,\cos\delta - \sin x \sin\delta = c\,\cos x - s\,\sin x$, dann haben wir

$$r_2 + r_2\,\varepsilon_1\,\cos x = r_1 + r_1\,\varepsilon_2\,(c\,\cos x - s\,\sin x)$$

und damit

$$\underbrace{(r_2\,\varepsilon_1 - r_1\,\varepsilon_2\,c)}_{P}\,\cos x + \underbrace{r_1\,\varepsilon_2\,s}_{Q}\,\sin x + \underbrace{r_2 - r_1}_{R} = 0$$

∘ Sind beide Brennpunkte identisch (Abb. 3.43 rechts), schneiden einander die Kurven (ohne Beweis) stets rechtwinklig. Man spricht in diesem Zusammenhang von orthogonalen Kegelschnittsbüscheln (vgl. Anwendung S. 544). ■

3.4 Das schiefwinklige Dreieck

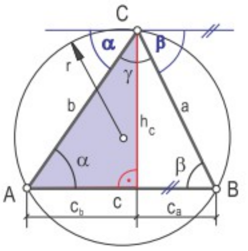

Abb. 3.44 Winkelsumme im Dreieck

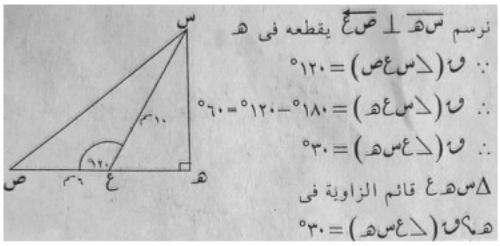

نرسم سه ⊥ صع يقطعه فى ه
∵ ق(∠سعص) = ١٢٠°
∴ ق(∠سعه) = ١٨٠° − ١٢٠° = ٦٠°
∴ ق(∠عسه) = ٣٠°
Δسهع قائم الزاوية فى
ه ∴ ق(∠عسه) = ٣٠°

Abb. 3.45 Aus einem arabischen Lehrbuch …

Zur eindeutigen Festlegung eines schiefwinkligen Dreiecks benötigen wir genau *drei Angabeelemente.*
Ausnahme: Die Angabe der drei Winkel α, β und γ genügt nicht, weil ja zwischen den drei Winkeln folgender Zusammenhang besteht: *Die Winkelsumme im Dreieck beträgt* 180°.

$$\boxed{\alpha + \beta + \gamma = 180^\circ} \tag{3.23}$$

∘ *Beweis*:
Wir zeichnen in C die Parallele zu AB (Abb. 3.44). Dort treten α und β als Parallelenwinkel noch einmal auf. ■
Aus dieser Beziehung folgt übrigens $\sin\gamma = \sin\big(180^\circ - (\alpha+\beta)\big)$ und somit

$$\sin\gamma = \sin(\alpha + \beta) \tag{3.24}$$

∘ Die sog. elliptische Geometrie beschäftigt sich mit Räumen, in denen man keine Parallele zu einer Geraden ziehen kann. Dort beträgt die Winkelsumme im Dreieck nicht 180°, sondern ist größer und nicht für jedes Dreieck gleich. Dies ist in der sphärischen Geometrie von Bedeutung (sphärische Dreiecke, siehe dazu Abb. 4.71), spielt aber auch in der modernen Physik eine wichtige Rolle (Schlagwort „gekrümmter Raum“).
Seien nun die Seiten und Winkel des Dreiecks bekannt. Wir berechnen die Hilfsgrößen h_c, c_a und c_b:

$$h_c = a\sin\beta,\ \ c_a = a\cos\beta,\ \ c_b = c - c_a = c - a\cos\beta. \tag{3.25}$$

Nun gilt nach Pythagoras

$$c_b^2 + h_c^2 = b^2 \Rightarrow (c - a\cos\beta)^2 + (a\sin\beta)^2 = b^2$$
$$\Rightarrow\ c^2 + a^2\underbrace{(\cos^2\beta + \sin^2\beta)}_{1} - 2ac\cos\beta = b^2,$$

was zum

Kosinussatz führt, der eine Verallgemeinerung des Pythagoreischen Lehrsatzes darstellt (die beiden unteren Formeln entstehen durch „zyklisches Vertauschen“ der Bezeichnungen):

$$\begin{aligned} b^2 &= c^2 + a^2 - 2ca\cos\beta \\ c^2 &= a^2 + b^2 - 2ab\cos\gamma \\ a^2 &= b^2 + c^2 - 2bc\cos\alpha \end{aligned} \tag{3.26}$$

Um sich von Bezeichnungsweisen zu lösen, merkt man sich den Satz am besten in Worten:

Das Quadrat über einer Seite ist gleich der Summe der Quadrate der beiden anderen Seiten, vermindert um das doppelte Produkt der anderen Seitenlängen mal dem Kosinus des eingeschlossenen Winkels.

Bei Angabe der Dreieckseiten lassen sich damit die Winkel berechnen, z.B.

$$\cos\alpha = \frac{b^2 + c^2 - a^2}{2bc}$$

Anwendung: Kräfte im Gleichgewicht (Abb. 3.46)
Drei komplanare Kräfte (also Kräfte, die in einer Ebene wirken)

$$F_1 = 60\text{N}, F_2 = 45\text{N}, F_3 = 30\text{N}$$

greifen in einem Punkt an und halten einander das Gleichgewicht. Berechnen wir die Winkel, die sie paarweise miteinander einschließen!
Lösung:

$$a = 60,\ b = 45,\ c = 30 \Rightarrow \text{Kosinussatz} \Rightarrow$$

$$\alpha = 104{,}5^\circ,\ \beta = 46{,}6^\circ \Rightarrow$$

$$\varphi = \alpha + \beta = 151{,}1^\circ,\ \psi = 180^\circ - \alpha = 75{,}5^\circ,\ \sigma = 180^\circ - \beta = 133{,}4^\circ. \qquad ■$$

Sind zwei Seiten und der von ihnen eingeschlossene Winkel gegeben, wendet man ebenfalls den Kosinussatz an.

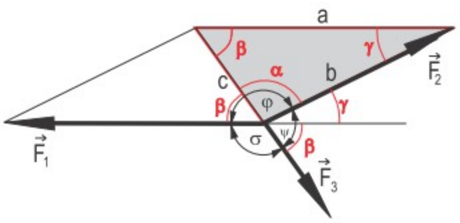

Abb. 3.46 Kräfte im Gleichgewicht

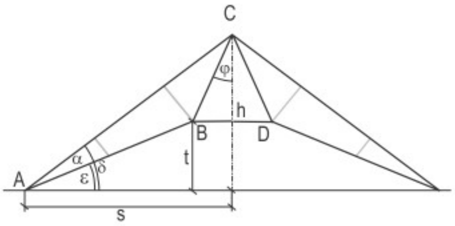

Abb. 3.47 Belgischer Dachbinder

Anwendung: Belgischer Dachbinder (Abb. 3.47)
Gegeben sind Dachneigungswinkel δ, Untergurtneigungswinkel ε, Gesamtbreite $2s$, Untergurtlänge $\overline{AB}$. Gesucht sind die anderen Balkenlängen.

Lösung:
Ermittelt man die Sparrenlänge $\overline{AC} = \dfrac{s}{\cos\delta}$, so sind vom Dreieck ABC zwei Seiten AB, AC und der eingeschlossene Winkel $\alpha = \delta - \varepsilon$ bekannt. Die Seite $\overline{BC}$ liefert der Kosinussatz:

$$\overline{BC} = \sqrt{\overline{AB}^2 + \overline{AC}^2 - 2\overline{AB}\,\overline{AC}\cos\alpha}$$

$$\overline{BD} = 2(s - \overline{AB}\,\cos\varepsilon)$$

■

Anwendung: Schnitt zweier Kugeln (Abb. 3.48)
Der Schnitt zweier Kugeln Σ_1, Σ_2 (Mittelpunkte M_1, M_2, Radien r_1, r_2, „Zentralabstand“ $\overline{M_1M_2} = d$) ist ein Kreis k mit Mitte M und Radius r in einer Normalebene zur Achse M_1M_2. Man berechne r und $e = \overline{MM_1}$. Für welches d ist $r = 0$ bzw. $r^2 < 0$ ($\Rightarrow$ r nicht reell)?

Lösung:
In Abb. 3.48 erkennen wir ein schiefwinkliges Dreieck M_1M_2S mit den bekannten Seitenlängen r_1, r_2 und d. Für dieses gilt:

$$r_2^2 = r_1^2 + d^2 - 2r_1d\,\cos\alpha \Rightarrow \cos\alpha = \frac{r_1^2 + d^2 - r_2^2}{2r_1d}$$

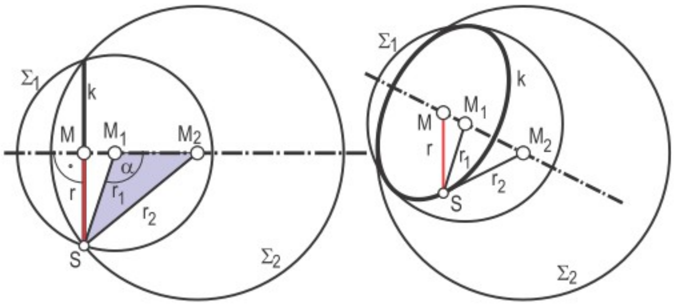

Abb. 3.48 Schnittkreis zweier Kugeln (spezielle und allgemeine Ansicht)

Es muss gelten:

$$\cos\alpha \leq 1 \Rightarrow \frac{r_1^2 + d^2 - r_2^2}{2r_1d} \leq 1$$

$$\Rightarrow r_1^2 + d^2 - r_2^2 \leq 2r_1d \Rightarrow r_1^2 - 2r_1d + d^2 \leq r_2^2 \Rightarrow (r_1 - d)^2 \leq r_2^2$$

Für $(r_1 - d)^2 > r_2^2$ wird der Schnittkreis nicht reell sein. Für

$$r_1 - d = \pm r_2 \Rightarrow r_1 - r_2 = d \text{ oder } r_1 + r_2 = d$$

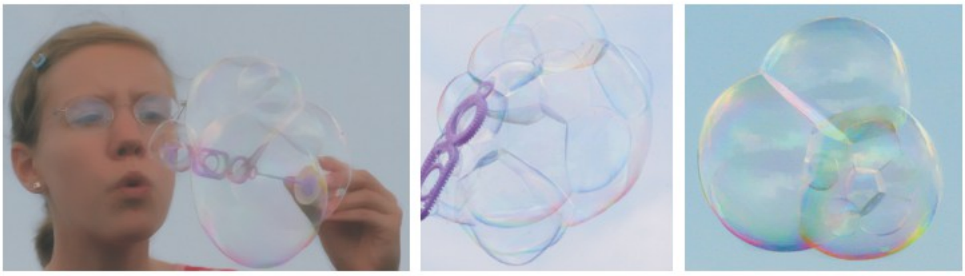

Abb. 3.49 Entstehung von Seifenblasen aus mehreren Kugeln

berühren sich die Kugeln in einem Punkt („Nullkreis"). Im Fall eines reellen Schnittkreises ergeben sich nun der Radius r und der Abstand e des Mittelpunkts M von M_1:

$$r = r_1 \sin\alpha \quad \text{und} \quad e = r_1 \cos\alpha$$

∘ Die Ebene, in welcher der Schnittkreis k liegt, heißt *Potenzebene*. Der Schnitt zweier Kugeln ist immer ein Kreis – reell oder imaginär. Mit Verweis auf Anwendung S. 544 sei erwähnt: Alle Kugeln haben zusätzlich den sog. *absoluten Kreis* gemeinsam, der imaginär ist und noch dazu „im Unendlichen" liegt. ■

Fläche des Dreiecks:

Zunächst gilt für die Fläche A des Dreiecks (mit den Bezeichnungen von Abb. 3.44)

$$A = \frac{c\,h_c}{2} = \frac{c\,b\,\sin\alpha}{2}$$

Weil die Beschriftung vertauscht werden kann, gilt ebenso

$$\boxed{A = \frac{a\,c\,\sin\beta}{2} = \frac{b\,a\,\sin\gamma}{2} = \frac{c\,b\,\sin\alpha}{2}} \tag{3.27}$$

Aus (3.27) folgt unmittelbar der

Sinussatz:

$$\boxed{\frac{a}{\sin\alpha} = \frac{b}{\sin\beta} = \frac{c}{\sin\gamma}} \tag{3.28}$$

In Worten:

Der Quotient aus Seitenlänge und Sinus des gegenüberliegenden Winkels ist konstant. Oder: Das Verhältnis zweier Seiten ist gleich dem Verhältnis der Sinus-Werte der gegenüberliegenden Winkel.

Damit lassen sich folgende Aufgaben lösen:

Tycho and Mathematics

Geometry was an essential tool to convert Tycho's measurements into celestial positions. Living in the computer age as I do, I have to admit that I never gave this a second thought until I realized that he worked before logarithms were invented. Multiplication and division were therefore much more severe and labour-intensive problems than they were once logarithms became available.

The key art was spherical trigonometry, which is a shorthand name for the analysis of triangles on the surfaces of spheres. Of course, the sphere the early scientists thought of was a faraway sphere on whose inside surface were the "fixed" stars.

The parameters governing such a triangle are built up in Figs. 1.5, 1.6, 1.7, and 1.8.

Thus, our triangle on the surface of a sphere can be uniquely defined entirely in terms of angles, provided that its sides all lie on great circles.

Now let me define some planar triangles to help me analyse the spherical triangle (Fig. 1.9). I do this by drawing lines tangential to the two great circles that meet at A.

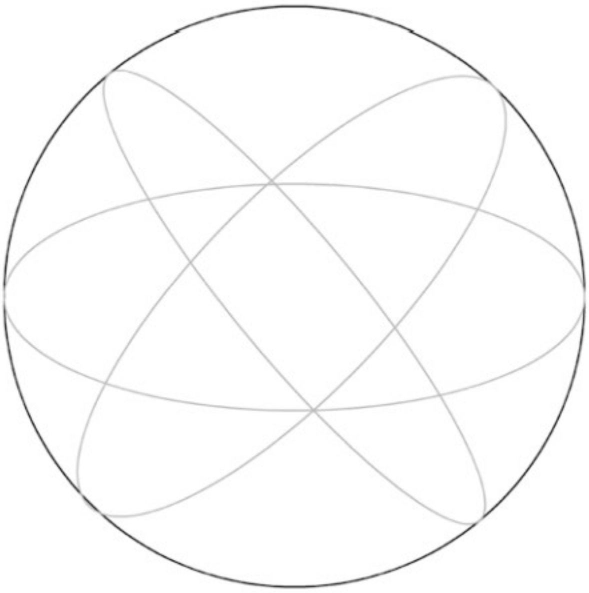

Fig. 1.5 Imagine a sphere onto whose surface three great circles are drawn. A great circle is a circle with the same radius as the sphere, whose centre is the centre of the sphere. (Image: Author)

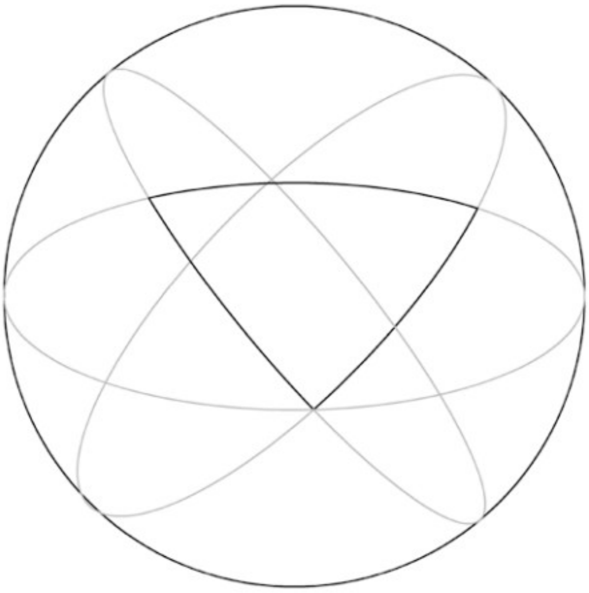

Fig. 1.6 These three great circles form the sides of a triangle on the sphere. They actually host another triangle on the other side of the sphere, but we will not consider that for now. (Image: Author)

Then by the cosine rule, these two equations are true.

$$\begin{aligned} \mathrm{DE}^2 &= \mathrm{AD}^2 + \mathrm{AE}^2 - 2(\mathrm{AD})(\mathrm{AE})\cos A; \\ \mathrm{DE}^2 &= \mathrm{OD}^2 + \mathrm{OE}^2 - 2(\mathrm{OD})(\mathrm{OE})\cos a. \end{aligned} \tag{1.2}$$

Because we chose tangents, the angles ∠OAD and ∠OAE are right angles. Thus,

$$\begin{aligned} \mathrm{OD}^2 &= \mathrm{OA}^2 + \mathrm{AD}^2; \\ \mathrm{OE}^2 &= \mathrm{OA}^2 + \mathrm{AE}^2. \end{aligned} \tag{1.3}$$

Substitute the equations of Eq. (1.3) into Eq. (1.2):

$$\begin{aligned} \mathrm{DE}^2 &= \mathrm{AD}^2 + \mathrm{AE}^2 - 2(\mathrm{AD})(\mathrm{AE})\cos A; \\ \mathrm{DE}^2 &= \mathrm{OA}^2 + \mathrm{AD}^2 + \mathrm{OA}^2 + \mathrm{AE}^2 - 2(\mathrm{OD})(\mathrm{OE})\cos \boldsymbol{a}. \end{aligned} \tag{1.4}$$

Now subtract the upper from the lower of Eq. (1.4).

$$0 = 2\left(\mathrm{OA}^2\right) + 2(\mathrm{AD})(\mathrm{AE})\cos A - 2(\mathrm{OD})(\mathrm{OE})\cos a. \tag{1.5}$$

Rearranging Eq. (1.5) gives

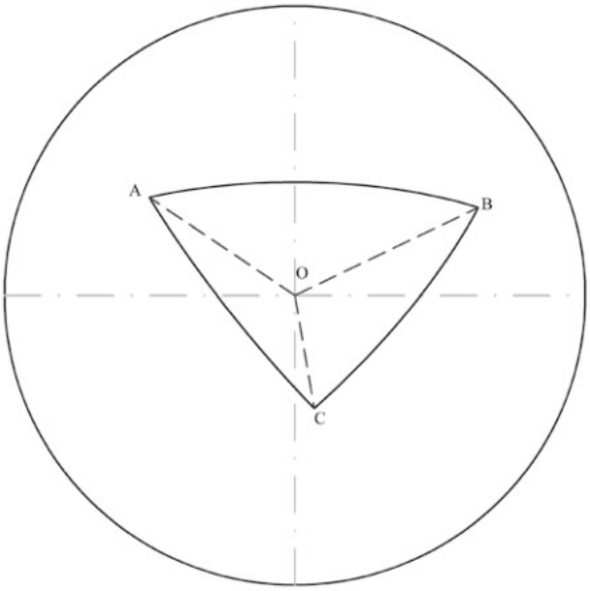

Fig. 1.7 Let this triangle have vertices A, B and C, all in upper case. Let the centre of the sphere be at O. (Image: Author)

$$\begin{aligned}\cos a &= \frac{\mathrm{OA}}{\mathrm{OE}}\frac{\mathrm{OA}}{\mathrm{OD}}+\frac{\mathrm{AE}}{\mathrm{OE}}\frac{\mathrm{AD}}{\mathrm{OD}}\cos A \\ \text{so } \cos a &= \cos b\cos c+\sin b\sin c\cos A\end{aligned} \tag{1.6}$$

using the definitions of sine as opposite/hypotenuse and cosine as adjacent/hypotenuse. Rearranging Eq. (1.6) gives

$$\cos A=\frac{\cos a-\cos b\cos c}{\sin b\sin c}\ . \tag{1.7}$$

In the pre-logarithmic age, the very useful Eq. (1.7) would have been messy to manipulate. It involves two multiplications and a division.

It is therefore worth some effort to see if we can turn the multiplications into additions or subtractions.

We will only deal with the cases where angles are right angles or less because Tycho's measurements did not use angles >90°. By following the logic in Fig. 1.10, it can be seen that

$$\sin\left(g+h\right)=\sin g\,cos\,h\ +\ \cos g\,sin\,h \tag{1.8}$$

and

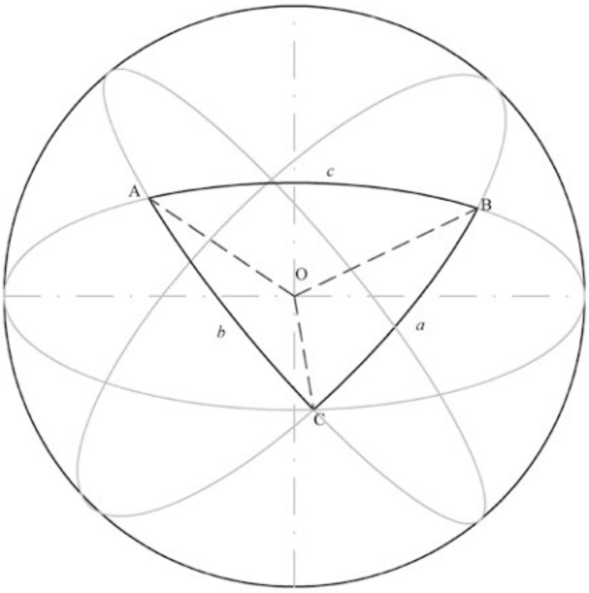

Fig. 1.8 Let the side opposite A has length *a*, let that opposite B has length *b* and let that opposite C has length *c*. A better way to analyse the triangle is to regard *a*, *b* and *c* as angles. *a* is the angle BOC; *b* is the angle COA and *c* is the angle BOA. (Image: Author)

$$\cos(g+h)=\cos g\cos h\ -\ \sin g\sin h \tag{1.9}$$

Proofs of these formulae for all angles, whether greater than 90° or not, are given in Appendix 3.

Eq. (1.8) can be used like this:

$$\sin g\sin\ h=\frac{1}{2}\left[\cos(f-g)-\cos(f+g)\right], \tag{1.10}$$

and Eq. (1.9) can be used like this:

$$\cos g\cos\ h=\frac{1}{2}\left[\cos(f-g)+\cos(f+g)\right], \tag{1.11}$$

These relations can be used in Eq. (1.7) to eliminate the multiplications but not the division:

$$\cos A=\frac{2\cos a-\left[\cos(b-c)+\cos(b+c)\right]}{\cos(b-c)-\cos(b+c)}. \tag{1.12}$$

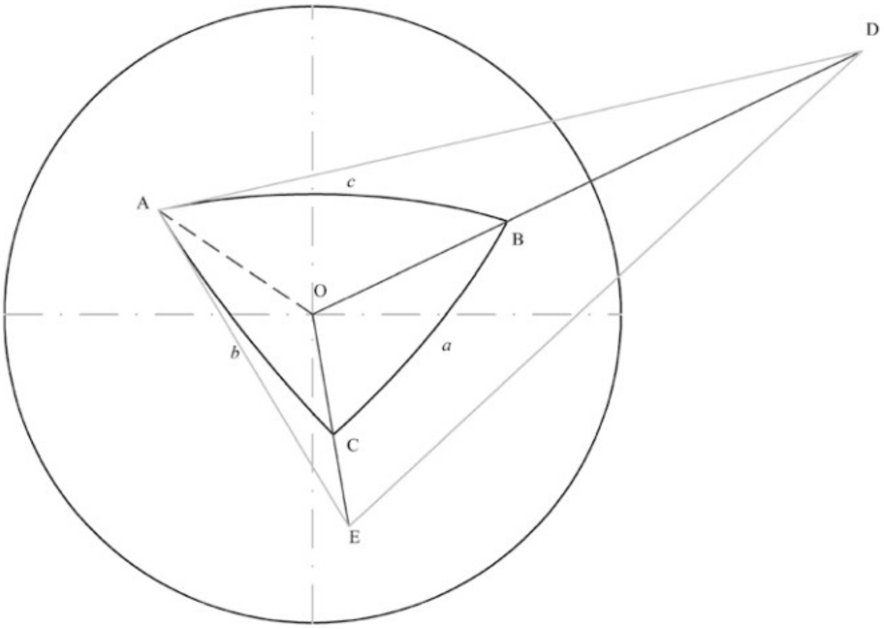

Fig. 1.9 Two lines are drawn tangent to the two great circles that cross at A. The lines OB and OC are projected until they meet these tangent lines at D and E, respectively. (Image: Author)

This elimination of multiplication was well worth the bother when you could not use logarithms. Indeed, the process was given a name: *prosthaphaeresis*. This compound word was built from the Greek words *prosthesis* and *aphaeresis* (subtract).

In those days, Eqs. (1.2)–(1.12) were not written out as formulae. They were written in words [24].

Tycho claimed priority for this technique. For this he has been in hot water with historians ever since. It's the perfect storm in a teacup. There does not appear to be enough evidence to settle the matter decisively [24], but it seems likely that Tycho was introduced to the formula by an assistant, Johannes Wittich [25]. Thoren [25] reports that Wittich brought the method to Tycho's observatory, having developed it beforehand. Tycho, who was nothing if not competitive, seems to have viewed prosthaphaeresis as something of a trade secret. He was not best pleased when he found out that, after leaving his employment, Wittich published the technique [24]. Such a driven man as Tycho venting his anger may well have been an impressive sight.

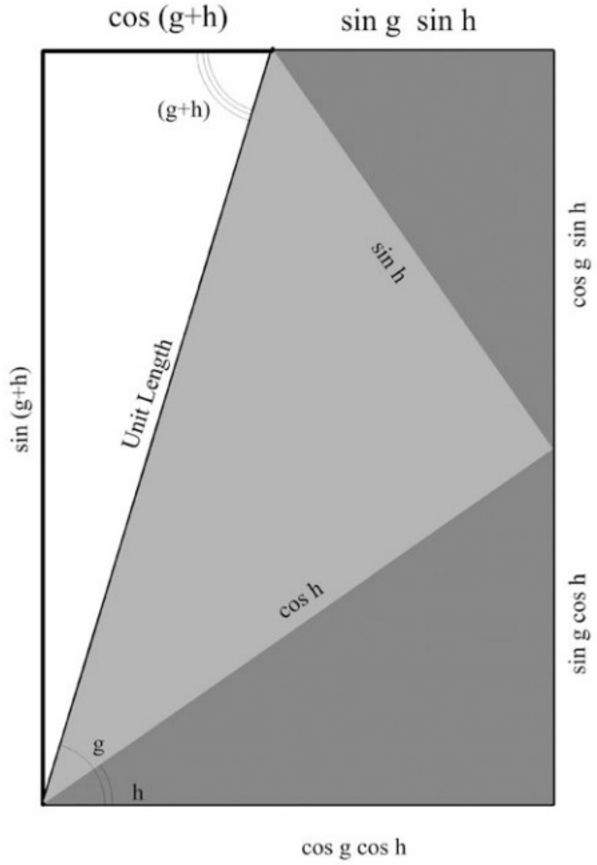

Fig. 1.10 Diagram showing how to manipulate sines and cosines of sums of angles

Tycho's Instruments

Tycho was no lone genius. In fact, you could even make a case for saying that his operation at his observatory in Uraniborg, Hveen, the Danish island now part of Sweden and known as Ven, was the first example of "big science". By the standards of today's big science, where the biggest projects employ thousands, Tycho's operation was small, yet his grant from the King of Denmark was 1% of the total royal expenditure. That was not to be sneezed at.

His first big challenge was to observe a supernova in 1572. He was careful to measure the position of the supernova relative to those of the other stars in Cassiopeia, within which constellation it had appeared. He looked

+,-.+ + +/ ! + % @ ! !

this disparity of emphasis that we are impelled to seek the reasons for it. There are several.

We mentioned earlier that in the classical period industry, commerce, and finance were conducted by slaves. Hence the educated people, who might have produced new ideas and new methods for handling numbers, did not concern themselves with such problems. Why worry about the use of numbers in measurement if one doesn't measure, or in trading if one dislikes trade? Nor do philosophers need the numerical dimensions of even one rectangle to speculate about the properties of all rectangles.

Like most philosophers the Greeks were star-gazers. They studied the heavens to penetrate the mysteries of the universe. But the use of astronomy in navigation and calendar reckoning hardly concerned the Greeks of the classical period. For their purposes, shapes and forms were more relevant than measurements and calculations, and so geometry was favored. Of these forms, the circle and sphere, suggested of course by superficial observation of the sun, moon, and planets, received the major share of attention. Hence their astronomical interests, too, led the classical Greeks to favor geometry.

The twentieth century seeks reality by breaking matter down—witness our atomic theories. The Greeks preferred to build matter up. For Aristotle and other Greek philosophers the form of an object is the reality to be found in it. Matter as such is primitive and shapeless; it is significant only when it has shape. It is no wonder, then, that geometry, the study of forms, was the special concern of the Greeks.

Finally, it was the solution of a vital mathematical problem that drove the Greek mathematicians into the camp of the geometers. We have already spoken of the fact that the Babylonian civilization, as well as earlier ones, used integers and fractions. The Babylonians were familiar also with a third type of number which arose through the application of a theorem on right triangles.

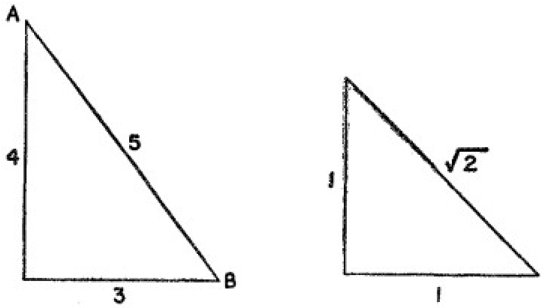
First, let us examine the theorem. If a right triangle has arms of lengths 3 and 4, the hypotenuse, or side opposite the right angle (*AB* in fig. 2) has length 5. Now the square of 5, namely 25, is the sum of the squares of 3 and 4, i.e., $5^2 = 3^2 + 4^2$. This relationship among the sides of a right triangle, that is, that the square of the length of the hypotenuse is equal to the sum of the squares of the lengths of the other two sides, is commonly known as the Pythagorean theorem.

To the Babylonians and Egyptians the fact, if not a proof, of this relationship was known.

Suppose now that the arms of a right triangle both have length 1 (fig. 3). What would be the length of the hypotenuse? Let us call the hypotenuse x. Then according to the Pythagorean theorem its length must be such that

$$x^2 = 1^2 + 1^2 = 2.$$

Hence x, the length of the hypotenuse, must be a number whose square is 2. We indicate the number whose square is 2 by $\sqrt{2}$ and call it the square root of 2. But what number equals $\sqrt{2}$? That is, what number multiplied by itself gives 2?



Figures 2 and 3. Two right triangles

The answer, as the Pythagorean school of mathematicians discovered to its great dismay, is that there is no whole number or fraction whose square is 2. $\sqrt{2}$ is a new kind of number, and they called it *irrational* because it could not be expressed exactly as a ratio of whole numbers, as 4/3 or 3/2. By contrast, whole numbers and fractions are called *rational* numbers. These terms are in use today.

The irrational number is a much neglected topic in the history of thought and a troublesome member of our number system. We have just seen that such numbers must be used in order to represent lengths and they are, moreover, explicitly and implicitly involved in almost all of mathematics. Yet how can we add, subtract, multiply, or divide such numbers? For example, how can we add 2 and $\sqrt{2}$? How do we divide $\sqrt{7}$ by $\sqrt{2}$?

The Babylonians had a makeshift, though practical, solution of these difficulties. They approximated the value of $\sqrt{2}$. For example, since the square of 14/10 or 1.4 is 1.96, and since 1.96 is nearly equal to 2, 1.4 must be nearly equal to $\sqrt{2}$. An even better approximation to $\sqrt{2}$ is 1.41 because the square of 1.41 is 1.988.

The Babylonian approximation to $\sqrt{2}$ does not permit exact reasoning with irrational numbers, for no matter how many decimal places we are willing to use we cannot write a rational number whose square is *exactly* 2. Yet, if mathematics is to merit its claim to being an exact study, it must evolve a method of working with $\sqrt{2}$ itself and not an approximation of it. To the Greek mind, this difficulty was as genuine and as prepossessing as the problem of food to a castaway on a coral reef.

Not content to use the less scrupulous method of the Babylonians, the Greeks undertook to face the logical difficulty squarely. In order to think about irrational numbers with exactness they conceived the idea of working with all numbers geometrically. They started out this way. A length was chosen to represent the number 1. Other numbers were then represented in terms of this length. To represent $\sqrt{2}$, for example, they used a length equal to the hypotenuse of a right triangle whose sides were one unit in length. The sum of 1 and $\sqrt{2}$ was a length formed by adjoining a unit segment to the length representing $\sqrt{2}$. In this geometrical form the sum of a whole number and an irrational one is no more difficult to conceive than the sum of one and one.

Similarly the product of two numbers, 3 and 5 for example, was expressed geometrically as the area of the rectangle with dimensions 3 and 5. In the case of 3 and 5 the use of area as a way of thinking about the product may be no great advantage. But one can also think of the product of 3 and $\sqrt{2}$ as an area. To think about this second rectangle is no more difficult than to think of the first one; yet it provides an exact way of working with the product of an integer and an irrational number or, for that matter, two irrational numbers.

The Greeks not only operated with numbers in the geometric manner but went so far as to solve equations involving unknowns by series of geometrical constructions. The answers to these constructions were line segments whose lengths were the unknown values. The thoroughness of their conversion to geometry may be judged from the fact that the product of four numbers was unthinkable in classical Greece because there was no geometric figure to represent it in the manner that area and volume represented the product of two and three numbers respectively. Incidentally, we still speak of a number such as 25 as the *square* of 5 and of 27 as the *cube* of 3 in conformity with Greek thought.

The preference of the Greeks for geometry was so marked that during his travel in Laputa, Gulliver was again forced to comment:

> The knowledge I had in mathematics gave me great assistance in acquiring their phraseology, which depended much upon that science and music; and in the latter I was not unskilled. Their ideas are perpetually conversant in lines and figures. If they would, for example, praise the beauty of a woman, or any other animal, they describe it by rhombs, circles, parallelograms, ellipses, and other geometrical terms, or by words of art drawn from music, needless here to repeat. I observed in the King's kitchen all sorts of mathematical and musical instruments, after the figures of which they cut up the joints that were served to his Majesty's table.

Because the Greeks converted arithmetical ideas into geometrical ones and because they devoted themselves to the study of geometry, that subject dominated mathematics until the nineteenth century, when the difficulties in treating irrational numbers on an exact, purely arithmetical basis were finally resolved. In view of the clumsiness and complexity of arithmetical operations geometrically performed, this conversion was, from a practical standpoint, a highly unfortunate one. The Greeks not only failed to develop the number system and algebra which industry, commerce, finance, and science must have, but they also hindered the progress of later generations by influencing them to adopt the more awkward geometrical approach. Europeans became so habituated to Greek forms and fashions that Western civilization had to wait for the Arabs to bring a number system from far-off India.

Unfortunate as this Greek perversion of the number system and of algebra may appear to us with our understanding of progress, it still should not invoke on Greek heads the condemnation that has sometimes been heaped there. The one backward step the Greeks took was in itself thoroughly reasonable; moreover, the damage done is heavily outweighed by the incomparable good of their other accomplishments.

When most people describe the Greek contributions to modern civilization, they talk in terms of art, philosophy, and literature. No doubt the Greeks deserve the highest praise for what they bequeathed to us in these fields. Greek philosophy is as alive and significant today as it was then. Greek architecture and sculpture, especially the latter, are more beautiful to the average educated person of the twentieth century than the creations of his own age. Greek plays still appear on Broadway. Nevertheless, the contribution of the Greeks that did most to determine the character of present-day civilization was their mathematics. By altering the nature of the subject in the manner we have related, they were able to proffer their supreme gift. This we proceed to examine.

and fixing some smaller neighbourhood $W \subsetneq V$ of a. Recall that $D \subseteq S$. Define a map $\psi\colon D \to S$, as follows.

$$\psi(x) = \begin{cases} x & \text{if } x \in f^{-1}(W) \\ f^{-1} \circ h \circ f(x) & \text{if } x \in D \smallsetminus A. \end{cases}$$

The function above is well defined and continuous, since f is injective away from A and B and $f^{-1} \circ h \circ f(x) = x$ on $f^{-1}(W) \smallsetminus A$.

We also check that $B \subseteq \operatorname{Int} D$ is the only inverse set of ψ. This follows, since h maps $f(D)$ into V and f is injective away from A and B. To finish, we need to show that $\psi(\operatorname{Int} D)$ is open in S. We check by hand that $\psi(\operatorname{Int} D) = f^{-1} \circ h \circ f(\operatorname{Int} D)$. We know from before that $f(\operatorname{Int} D)$ is open in T. Then $f^{-1} \circ h \circ f(\operatorname{Int} D)$ is open, since h is a homeomorphism and f is continuous. Now apply Lemma 3.28 to the map $\psi\colon D \to S$ to conclude that B is cellular. A similar proof shows that A is cellular. □

3.4 Brown's Proof of the Schoenflies Theorem

After our lengthy interlude in the previous section, we return to the Schoenflies theorem, which we restate below in an equivalent form.

Theorem 3.29 (Schoenflies theorem [Bro60]) *Let $i\colon S^{d-1} \hookrightarrow S^d$ be a continuous embedding admitting a bicollar. Then the closure of each component of $S^d \smallsetminus i(S^{d-1})$ is homeomorphic to D^d.*

Proof By the bicollar hypothesis, there exists $J\colon S^{d-1} \times [-1,1] \to S^d$ such that $J|_{S^{d-1}\times\{0\}}$ equals i. From elementary homology computations, as in the proof of Theorem 3.5, it follows that the complement of the image of J in S^d has exactly two connected components. Denote their closures by A and B, where A meets $J(S^{d-1} \times \{1\})$.

Observe that the quotient space $S^d/\{A, B\}$ is homeomorphic to S^d due to the existence of the bicollar. In other words, $S^d/\{A, B\}$ can be identified with the (unreduced) suspension of S^{d-1}, which is homeomorphic to S^d, as indicated in Figure 3.8. Thus we have the composition

$$f\colon S^d \xrightarrow{\pi} S^d/\{A, B\} \xrightarrow{\cong} S^d,$$

where $\cong$ denotes homeomorphism and π denotes the quotient map. This map $f\colon S^d \to S^d$ has exactly two inverse sets, namely A and B, and is surjective. By Proposition 3.27, each of A and B is cellular.

Let D denote the closed northern hemisphere of S^d, thought of as a subset of the codomain S^d. By definition, D is a copy of the d-dimensional ball. Let $U := A \cup (J(S^{d-1} \times (0,1]))$; that is, U is the component of $S^d \smallsetminus i(S^{d-1})$ containing A. Then we have the restriction $f|_{\overline{U}}\colon \overline{U} \to D$, whose unique inverse set is A, which is cellular in S^d and thus in $\overline{U}$ by Proposition 3.16.

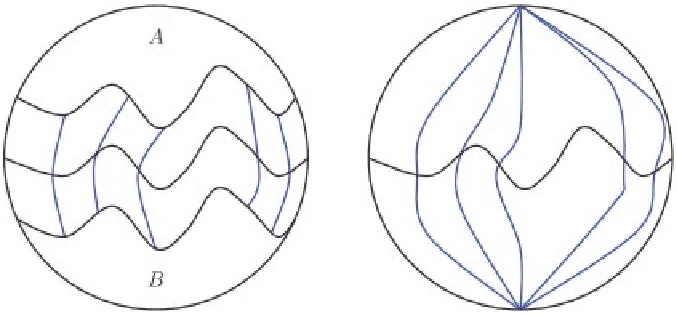

Figure 3.8 Brown's proof of the Schoenflies theorem. Going from left to right, the regions labelled A and B are collapsed to a point each, stretching out a neighbourhood of the equator in the process.

Our goal is to apply Proposition 3.22 to $\overline{U}$. To do so, we first need to show that $\overline{U}$ is a manifold (with boundary). The only possible failure could be near the boundary. As a subspace of S^d, $\overline{U}$ is already Hausdorff and second countable, so we only need to show that it is locally Euclidean. Let $E := J(S^{d-1} \times [0, \frac{1}{2}])$. Note that $\overline{U} = U \cup E$. Moreover, f restricts to a continuous bijection from E to some collar of ∂D. This collar of D is closed by the closed map lemma (Lemma 3.23). Therefore $f|_E$ is a homeomorphism, so $\overline{U}$ is a manifold, as needed.

Then we have the following diagram:

$$\begin{tikzcd}
\overline{U} \arrow[r, "f"] \arrow[d, "\pi"'] & D \\
\overline{U}/A. \arrow[ur, "\overline{f}"'] &
\end{tikzcd}$$

The map f is constant on the fibres of the quotient map $\pi\colon \overline{U} \to \overline{U}/A$ and thus descends to the map $\overline{f}$, which is a homeomorphism by the closed map lemma (Lemma 3.23). Next, since A is cellular, the map π is approximable by homeomorphisms by Proposition 3.22. Let $\widetilde{\pi}\colon \overline{U} \to \overline{U}/A$ be any such approximating homeomorphism. Then $\overline{f} \circ \widetilde{\pi}\colon \overline{U} \to D$ is a homeomorphism. It follows that $\overline{U}$ is homeomorphic to the d-dimensional ball $D \cong D^d$, as claimed. $\square$

$\widetilde{A}_2$, the core $\widetilde{q}$ of $\widetilde{Q}$ gives a path from a point in $\widetilde{A}_1$ to a point in $\widetilde{A}_2$, which must intersect at least one of D and D'. This contradicts that $\widetilde{Q}$ is disjoint from D and D'. Therefore, $\widetilde{Q}$ has substantial intersection with at least one of $\widetilde{B}_1$ and $\widetilde{B}_2$.

We see that if A does not have substantial intersection with P, then both of $\widetilde{A}_1$, $\widetilde{A}_2$, and at least one of $\widetilde{B}_1$ and $\widetilde{B}_2$, have substantial intersection with $\widetilde{Q}$. Pushing these intersections downstairs, we conclude that A and B both have substantial intersection with Q, completing the proof of Proposition 6.4. ☐

Now we are ready to show that the decomposition $\mathcal{B}_2$ does not shrink.

Proof of Theorem 6.1 Recall that we write T for the initial solid torus in the defining sequence for $\mathcal{B}_2$, and we call the two nested solid tori in the defining pattern P and Q, as shown in Figure 6.1. Let A and B be embedded meridional discs in T, union thin annuli of width $\delta > 0$ in $S^3 \smallsetminus \operatorname{Int} T$. Suppose that A and B are distance $\kappa > 0$ apart. Choose

$$\varepsilon < \min\{\kappa, \delta/2\}.$$

Write $\pi\colon S^3 \to S^3/\mathcal{B}_2$ for the quotient map. We want to choose a metric on $S^3/\mathcal{B}_2$, which we may do, since $\mathcal{B}_2$ is upper semi-continuous (Corollary 4.13). Hausdorff [Hau30] showed that for a metrizable space E with a subspace F, and prescribed metric on F, one may find a metric on E that extends the given metric on F. Apply this to $S^3/\mathcal{B}_2$, to obtain a metric that agrees with the standard metric on $\overline{S^3 \smallsetminus T}$. In other words, for all $x, y \in \overline{S^3 \smallsetminus T}$, we have $d_{S^3}(x,y) = d_{S^3/\mathcal{B}_2}(\pi(x), \pi(y))$. We have used that $\pi|_{\overline{S^3 \smallsetminus T}}$ is a homeomorphism.

Now let $h\colon S^3 \to S^3$ be a homeomorphism such that $d_{S^3/\mathcal{B}_2}(\pi(x), \pi(h(x))) < \varepsilon$ for every $x \in S^3$; that is, h satisfies (i) of Definition 4.16. Then, by the construction of the metric $d_{S^3/\mathcal{B}_2}$, for $x \in T$ and $y \in S^3 \smallsetminus T$, the distance $d_{S^3/\mathcal{B}_2}(x,y) \geq d_{S^3/\mathcal{B}_2}(\partial T, y)$. It follows that for every $x \in S^3$ whose distance from T is at least ε, both $x, h(x) \in \overline{S^3 \smallsetminus T}$ and so $d_{S^3}(h(x), x) < \varepsilon$.

For $\nu > 0$, let $N_\nu(T)$ denote a ν-neighbourhood of T, namely all the points of distance at most ν from T.

Claim *$h^{-1}(\partial A) \subseteq N_{3\delta/2}(T) \smallsetminus T$ and $h^{-1}(\partial B) \subseteq N_{3\delta/2}(T) \smallsetminus T$. Moreover, both curves have linking number one with the core of T.*

The first sentence is immediate from the properties of h and the choice of ε and δ. The homeomorphism h moves points of ∂A less than ε. The linking number between ∂A (respectively, $h^{-1}(\partial A)$) and the core of T can be computed as the degree of the Gauss map $S^1 \times S^1 \to S^2$ given by sending (x,y), with $x \in \partial A$ (respectively, $h^{-1}(\partial A)$) and y in the core of T, considered as vectors in $\mathbb{R}^3$, to $(x-y)/\|x-y\|$. But a perturbation of the Gauss map, small relative to the diameter of S^2, does not change its degree. This proves the claim.

We next prove that some decomposition element intersects both of the discs $A_0 := h^{-1}(A)$ and $B_0 := h^{-1}(B)$. By the claim, and linking number considerations, both A_0 and B_0 have substantial intersections with T. In more detail, ∂A_0 and the core of T have linking number one, so form a nontrivial link. The argument of Lemma 6.5, with the linking number used instead of the triple linking number, shows that A_0 and B_0 has a substantial intersection with T, and similarly for B. By Lemma 6.3, applied after making a small isotopy of ∂T so that A_0 and ∂T intersect transversely (we can make such an isotopy without affecting the decomposition elements), A_0 contains a meridian of T and therefore contains a smaller disc A_0' with boundary a meridian of T. Similarly, B_0 contains a smaller disc B_0' with boundary a meridian of T. By Proposition 6.4, at least one of P and Q has substantial intersection with both A_0' and B_0', and therefore with A_0 and B_0. Without loss of generality, let it be P.

By Lemma 6.3, A_0 and B_0 both contain discs A_1 and B_1 in S^3 bounded by meridians for P. Let $P_1, Q_1 \subseteq P$ be the solid tori of the next stage of the defining sequence for $\mathcal{B}_2$. Apply Proposition 6.4 again to see that at least one of P_1 and Q_1 has substantial intersection with both of A_1 and B_1, and so has substantial intersection with both A_0 and B_0. Again, we assume without loss of generality that P_1 has these substantial intersections.

Iterate this procedure to obtain a sequence $P \supsetneq P_1 \supsetneq P_2 \supsetneq \cdots$ in the defining sequence with substantial (and in particular nonempty) intersection with A_0 and B_0. Thus the decomposition element $\Delta = P \cap P_1 \cap P_2 \cap \cdots$ intersects both $A_0 = h^{-1}(A)$ and $B_0 = h^{-1}(B)$. This implies that $h(\Delta)$ intersects both A and B. Therefore, $\operatorname{diam}_{S^3} h(\Delta)$ is at least as large as the minimal distance from a point in A to a point in B; that is, $\operatorname{diam} h(\Delta) > \kappa > \varepsilon$.

Now $h\colon S^3 \to S^3$ was chosen to be some homeomorphism satisfying (i) of Definition 4.16. We have shown that there exists an ε such that for any such h, (ii) of Definition 4.16, that $\operatorname{diam}_{S^3} h(\Delta) < \varepsilon$ for every decomposition element $\Delta \in \mathcal{B}_2$, is not satisfied. Therefore, $\mathcal{B}_2$ does not shrink. This completes the proof of Theorem 6.1. $\square$

(c) The map f restricts to a homeomorphism $f|_{f^{-1}(E)}\colon f^{-1}(E) \to E$.

Then f can be approximated by homeomorphisms that agree with f on $f^{-1}(E)$.

The fact that f restricts to a homeomorphism from $S^3 = \partial D^4$ to itself implies that f has degree one and is thus surjective.

Observe that the inverse sets of f form an upper semi-continuous decomposition $\mathcal{D}$ of D^4 by Lemma 9.3, since every inverse set is closed in the compact space D^4. Let $\pi\colon D^4 \to D^4/\mathcal{D}$ be the quotient map. We obtain a well defined continuous function $\overline{f}\colon D^4/\mathcal{D} \to D^4$, since f is constant on the fibres of π. The function $\overline{f}$ is a continuous bijection from a compact space to a Hausdorff space and is thus a homeomorphism by the closed map lemma (Lemma 3.23). The ball to ball theorem establishes that f is approximable by homeomorphisms $f_n\colon D^4 \to D^4$. By composing with $\overline{f}^{-1}$, we see that the quotient map π is approximable by the homeomorphisms $\overline{f}^{-1} \circ f_n\colon D^4 \to D^4/\mathcal{D}$. This used that $\overline{f}^{-1}$ is uniformly continuous by the Heine–Cantor theorem (Theorem 3.25). The following diagram shows the maps. The diagram commutes when the top arrow denotes the function f.

$$\begin{tikzcd}
D^4 \arrow[r, "f", "f_n"'] \arrow[d, "\pi"'] & D^4 \\
D^4/\mathcal{D} \arrow[ur, "\overline{f}"'] &
\end{tikzcd}$$

We also remark that the restriction to dimension four is completely irrelevant and the proof we give will work in all dimensions. However, a result of Siebenmann [Sie73] shows that functions between manifolds of dimension five or higher, with far fewer restrictions than in Theorem 10.1, are approximable by homeomorphisms. This was known prior to the ball to ball theorem, which would have been an easy special case in high dimensions. Thus the 4-dimensional case is what requires a special argument.

10.1 The Main Idea of the Proof

Before going into the details, we outline the main idea of the proof. First, in an attempt to reduce confusion, we re-label the source and the target copies of D^4 as X and Y and consider the function $f\colon X \to Y$.

The proof will directly use the definition of a function being approximable by homeomorphisms (Definition 3.19). That is, given $\varepsilon > 0$, we will find a homeomorphism $h\colon X \to Y$ such that $d(h, f) < \varepsilon$. Note that f fails to be a homeomorphism exactly at the inverse sets, and at first sight the ones with largest diameter are the most offensive. With the goal of constructing a homeomorphism h as above, we wish to control the inverse sets with diameter greater than some fixed ε. By the hypothesis that the collection of inverse sets is null, we have only finitely many such inverse sets to worry about.

Consider the Cantor function (Figure 10.1) which has a large horizontal spot in the middle, demonstrating its non-injectivity. We present a strategy to approximate the Cantor function by homeomorphisms. Finding such an approximation for the Cantor function is

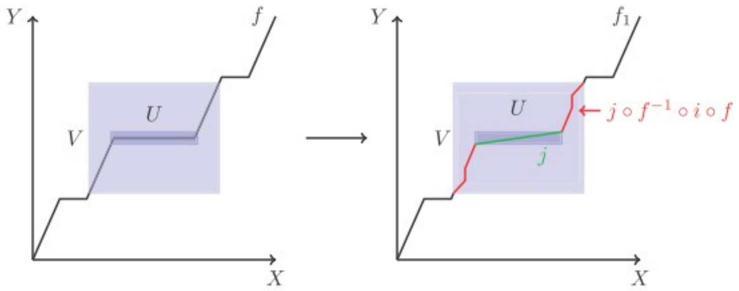

Figure 10.1 A modification of the Cantor function. On the right, we see that certain vertical segments (red) are created.

in general not hard, but the complicated strategy we are about to give has the advantage of working in the 4-dimensional context. We work with the graph of the Cantor function as in Figure 10.1 and find small neighbourhoods $U \subseteq V$ of the region in the graph corresponding to the largest inverse set, namely the horizontal spot in the middle. We then modify the function. It remains the same outside of V. Within U, we tilt it slightly in order to eliminate the inverse set. However, the price we pay is the creation of certain vertical cliffs in the region $V \smallsetminus U$. In other words, the result of the modification no longer has the large inverse set but is also no longer a function. It is instead a *relation*, meaning that it is a multi-valued function. We will define relations carefully soon. On the other hand, the vertical regions are located in small neighbourhoods and we may hope to be able to control them.

The strategy of the proof is then as follows. We perform the modification above to all the large inverse sets we wish to control. This replaces large horizontal steps with smaller vertical steps. Then we utilize the symmetry of the situation and consider the graph for the inverse function (really, relation). This has a number of vertical steps, upon which we can apply the same modification as above, before using the symmetry again. This process creates some new horizontal steps, but these have small diameter. By performing this iteration over and over again, we eventually reduce all the horizontal regions of our graph to small diameter, as desired.

In preparation for the proof, we give the precise formulae for the first step. Assume that some inverse set of f maps to $0 \in Y$, and suppose this is the inverse set we presently wish to control. Take two concentric, closed, round balls $U \subsetneq V \subseteq Y$ with distinct radii around $0 \in Y$, where U has very small radius. Define a stretching homeomorphism $i\colon V \to Y$ that is the identity on U and sends $V \smallsetminus U$ onto $Y \smallsetminus U$. In particular, $i|_{\partial V}\colon \partial V \to \partial Y$ is a homeomorphism. We could define such a function i as a radial expansion for now, but in later steps we will need more flexibility.

Note that the composition $i^{-1} \circ f\colon X \to V$ restricted to ∂X is a homeomorphism onto ∂V. Therefore, $(i^{-1} \circ f)|_{\partial X}$ can be extended to a homeomorphism $j\colon X \to V$ by the Alexander trick.

Finally, we define a relation $f_1 \colon X \to Y$ as follows.

$$f_1 = \begin{cases} f & \text{on } X \smallsetminus f^{-1}(V) \\ j \circ (f^{-1} \circ i \circ f) & \text{on } f^{-1}(V \smallsetminus U) \\ j & \text{on } f^{-1}(U), \end{cases} \tag{10.1}$$

using that $f(f^{-1}(V \smallsetminus U)) \subseteq V$. We check that the definitions match on the overlaps $\partial f^{-1}(V)$ and $\partial f^{-1}(U)$. Recall that, since f is continuous, $\partial f^{-1}(V) \subseteq f^{-1}(\partial V)$ and $\partial f^{-1}(U) \subseteq f^{-1}(\partial U)$. First, $i = \mathrm{Id}$ on U, so

$$j \circ f^{-1} \circ i \circ f = j \circ f^{-1} \circ f = j$$

on $f^{-1}(\partial U)$. Next, $j = i^{-1} \circ f$ on ∂X. Therefore,

$$j \circ f^{-1} \circ i \circ f = i^{-1} \circ f \circ f^{-1} \circ i \circ f = f$$

on $f^{-1}(\partial V)$. Observe that f_1 no longer has a singular point at 0, since $f_1^{-1}(0) = j^{-1}(0)$ and j is a homeomorphism. However, f_1 need not be a function, as we now explain. Consider a point $y \in V \smallsetminus U \subseteq Y$ such that $i(y)$ lies in the singular image of f. Recall that f is surjective. Then, given $x \in f^{-1}(V \smallsetminus U)$ with $y = f(x)$, the set $f^{-1}(i(f(x)))$ has cardinality strictly greater than one. This cardinality is preserved under the homeomorphism j. In other words, the relation f_1 maps x to the set $\{j \circ f^{-1} \circ i \circ f(x)\}$, which has more than one element, and as a result, f_1 is not a function. Helpfully, this failure only occurs for points mapping to V, and we could choose V to be arbitrarily small, as long as it is bigger than U. Thus the places where f_1 fails to be a function can be controlled.

This describes the principal idea behind the proof of the ball to ball theorem. In the next two sections, we address some necessary preliminaries.

10.2 Relations

Given sets X and Y, a subset of $X \times Y$ is said to be a *relation* from X to Y. For the rest of this section, we restrict ourselves to relations where, for every $x \in X$, there is some $y \in Y$ with $(x, y) \in R$. These are denoted by $R \colon X \to Y$, expressing the fact that the *domain* of R is all of X. We think of a relation $R \colon X \to Y$ as a multi-valued function which assigns to every $x \in X$ the subset $R\{x\} := \{y \in Y \mid (x, y) \in R\}$. Of course, any function from X to Y is a relation from X to Y. More precisely, we define the *graph* of a function $f \colon X \to Y$ as the set $\{(x, y) \mid x \in X, y \in Y, y = f(x)\} \subseteq X \times Y$. A function corresponds uniquely to its graph and thus corresponds to a relation. We will frequently refer to the graph of a function as simply the function for convenience. A relation $R \colon X \to Y$ is (the graph of) a function if and only if $R\{x\}$ is a singleton set for all $x \in X$, in which case we write $R(x)$ for the image of $x \in X$; that is, $R\{x\} = \{R(x)\}$ for all $x \in X$.

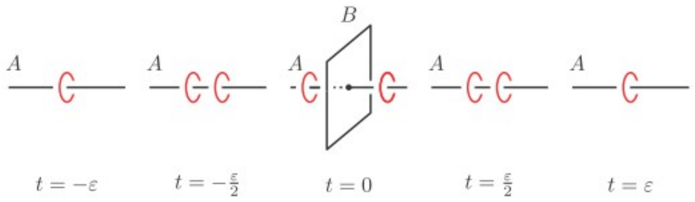

Figure 15.1 A Clifford torus at a double point of the surfaces A and B. As usual, the fourth coordinate is interpreted as time, t. The double point is seen at the $t = 0$ time slice. The red circles depicted trace out the Clifford torus as we move backwards and forwards in time. Note that each S^1 factor of the torus corresponds to a meridian of either A or B, and as such bounds a meridional disc that intersects the respective surface transversely at a single point. Compare with Figure 1.5.

Given a group G and $g \in G$, let $\langle\langle g \rangle\rangle$ denote the normal subgroup of G generated by g. We have that

$$\begin{aligned}\pi_1(M \smallsetminus (A' \cup B)) &\cong \pi_1(M \smallsetminus (A' \cup B \cup D))/\langle\langle \mu_D \rangle\rangle \\ &\cong \pi_1(M \smallsetminus (A' \cup B \cup D))/\langle\langle \gamma_T \rangle\rangle \\ &\cong \pi_1(M \smallsetminus (A \cup B))/\langle\langle [\mu_A, \mu_B] \rangle\rangle,\end{aligned}$$

as asserted.

15.2 Elementary Geometric Techniques

The following operations will be described on (immersed) surfaces. Where necessary, these operations can be extended to framed surfaces, and therefore to stages of capped or uncapped gropes or towers. However, we will not comment on this every time, unless there is extra particular care that needs to be taken.

15.2.1 Tubing

Tubing was described in [FQ90, Sections 1.8 and 1.9]. Suppose we have an immersed connected surface, A. Let Σ and Σ' be two other immersed surfaces intersecting A transversely at points p and p', respectively, with $p \neq p'$. Let γ be a smooth, embedded arc in A joining p and p'. Consider a tubular neighbourhood of γ intersecting A and B in small discs about p and p'. Cut out these discs from $A \cup B$ and glue on the rest of the boundary of the neighbourhood of γ to $\Sigma \cup \Sigma'$. In other words, we are gluing in a meridional annulus for γ. This process is called *tubing* Σ *into* Σ' (*along* $\gamma \subseteq A$) or vice versa. (In [FQ90], the resulting surface is called the *sum* of Σ and Σ'.) We shall at times also refer to this process as tubing p into the surface Σ'. If Σ and Σ' are distinct framed immersed surfaces, then the result of tubing is itself immersed and inherits a framing coming from the framing of the annulus, of Σ, and of Σ'. If Σ and Σ' are the same immersed framed surface, we need additionally that the intersection points p and p' have opposite signs, otherwise we would obtain a

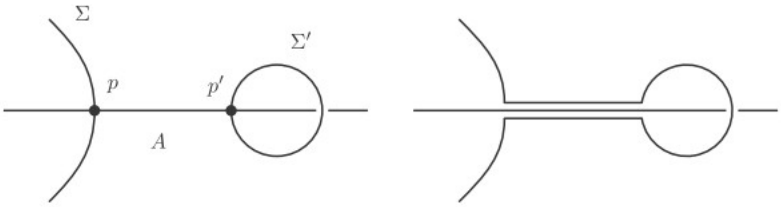

Figure 15.2 Tubing into a transverse sphere.

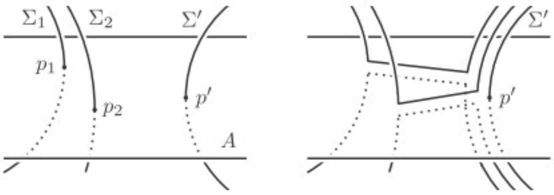

Figure 15.3 Tubing multiple points of intersection.

nonorientable surface. Note that the notion of 'opposite signs' is still meaningful even if the ambient space M is nonorientable, by using the arc γ to transport a local orientation at p to one at p'.

We will often tube surfaces into geometrically transverse spheres; that is, Σ' will be a framed sphere such that p' is its unique point of intersection with A. This situation is depicted in Figure 15.2. Note that this operation then decreases the number of points of intersection between A and Σ by one.

In most cases, we will tube into a parallel push-off of Σ' instead of Σ' itself. This will allow us to tube multiple times, as follows. Suppose that Σ' is a framed surface geometrically transverse to A; that is, A and Σ' intersect exactly once, at the point p'. Now suppose we have surfaces Σ_i intersecting A at the points p_i, for $i = 1, \ldots, k$. Then take k parallel push-offs of Σ', using distinct nonvanishing sections of the normal bundle (of the form $\Sigma' \times \{p\}$ in the given framing). These intersect A at k distinct points. Find pairwise disjoint, embedded arcs on A joining these points to the $\{p_i\}$ and use these to tube each Σ_i into a distinct parallel push-off of Σ'. This eliminates the intersection points $p_1, \ldots, p_k$, and also leaves the original Σ' unchanged for further tubing or other constructions. This process is described in Figure 15.3.

Note that if some surface B intersects Σ', then now Σ_i intersects B for each i. In particular, if Σ' has double points, then the tubing creates new points in $\Sigma_i \pitchfork \Sigma_j$, for all i, j, as well as in $\Sigma_i \pitchfork \Sigma'$.

15.2.2 Boundary Twisting

Boundary twisting was introduced in [FQ90, Section 1.3]. Suppose we have two immersed surfaces A and B in a 4-manifold M such that part of the boundary of B is embedded in A, as shown in Figure 15.4(a), and this part of ∂B lies in the interior of M. For us, this situation usually arises when B is a Whitney disc pairing intersection points of A with itself

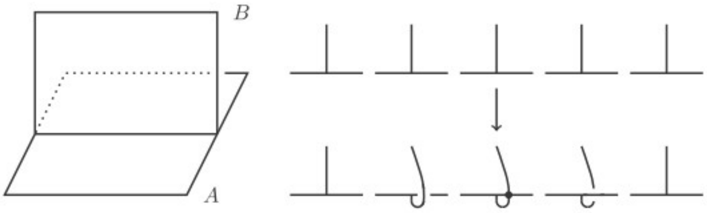

Figure 15.4 Boundary twisting. Left: Before boundary twisting. Right: Cross sections for the picture on the left, before and after boundary twisting. Each cross section shows a 3-dimensional time slice.

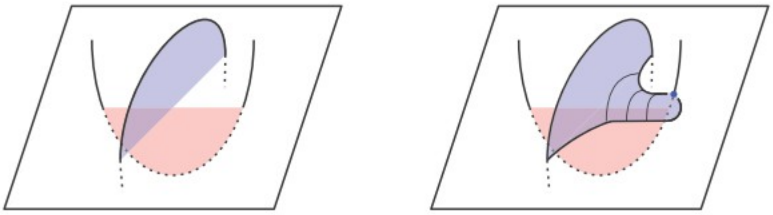

(a) (b)

Figure 15.5 Boundary push off to ensure Whitney circles are disjoint. We perform a regular homotopy of one Whitney circle until it becomes disjoint from the other, introducing a new intersection point for the corresponding Whitney disc.

or some other surface. Another commonly occurring situation is that of a cap of a grope or tower attached to a lower stage. The operation of *boundary twisting* B about A consists of changing a collar of B near a point in its boundary on A, as depicted in Figure 15.4(b). Note that this creates a new point of intersection between A and B and changes the framing of B by a full twist.

15.2.3 Making Whitney Circles Disjoint

We saw in Chapter 11 that, given two immersed surfaces A and B, if $\lambda(A, B) = 0$, the intersection points between A and B can be paired up with Whitney discs (Proposition 11.10). *A priori*, the corresponding Whitney circles may intersect one another. Performing the Whitney trick with intersecting Whitney circles leads to new intersections, which we would like to avoid. We ensure that Whitney circles are disjoint by pushing one Whitney circle along the other, as shown in Figure 15.5. This is a regular homotopy, and as we see in the figure, leads to new intersections between a Whitney disc and either A or B.

To achieve this in general for surfaces A and B, enumerate the Whitney arcs, and then work on the arcs in order. For the ith arc, push other arcs with index greater than i off the ith arc, starting with one of the arcs closest to the endpoint, until the ith arc is disjoint from all

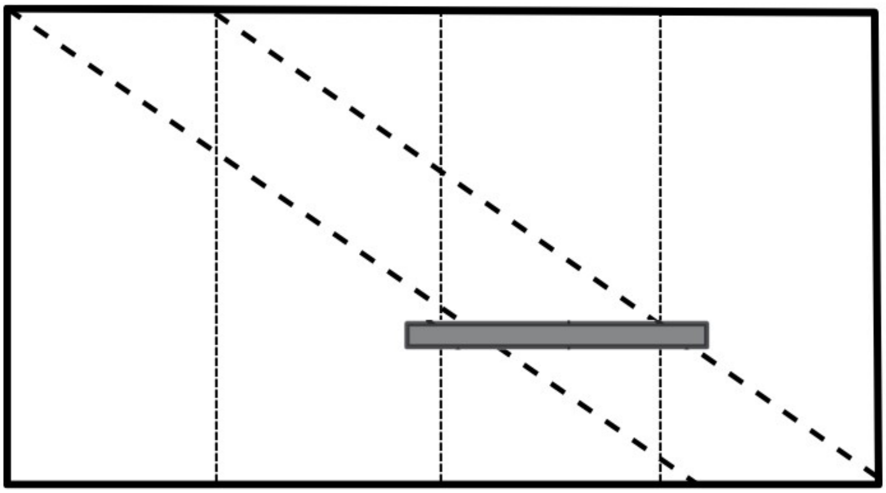

FIGURE 3. Blocking rays through a rectangle

We set $X_1 = \bigcup_{j=1}^{k_1} X_1(j)$ and proceed by induction. Assuming that X_i has been defined, find a collection of rectangles in each rectangle of X_i that block the bottom from the top, each of the new rectangles having diameter less than $1/(i+1)$. The union of these smaller rectangles is X_{i+1}.

The intersection $\bigcap_{i=0}^{\infty} X_i$ is an opaque Cantor set in the sense that every segment from the bottom of X_0 to the top must intersect the Cantor set.

6.3.2. A Fat Cantor Set. The total length of the segments removed from $[0, 1]$ in forming the middle-thirds Cantor set is

$$\frac{1}{3} + \left(\frac{1}{3}\right) \cdot \left(\frac{2}{3}\right) + \left(\frac{1}{3}\right) \cdot \left(\frac{2}{3} \cdot \frac{2}{3}\right) + \cdots = 1.$$

We conclude that the middle-thirds Cantor set has length $1 - 1 = 0$.

But the only critical condition required in the construction of the general Cantor set is that the pieces remaining at each stage have diameters approaching 0 in the limit. In order to satisfy that requirement, it suffices, for example, to make sure that each remaining piece have diameter less than one-half the diameter of the preceding pieces. Thus we may remove a total length as little as we please. As a result, there are Cantor sets in $[0, 1]$ with length as close to 1 as we choose.

6.3.3. A Wild Cantor Set. A Cantor set X in 3-space $\mathbb{R}^3$ is *tame* if there is a homeomorphism of $\mathbb{R}^3$ to itself that takes X to the middle-thirds Cantor set Y viewed as a subset of the x-axis. Otherwise X is called *wild*.

Although each Cantor set is 0-dimensional, there are Cantor sets in 3-space that are so complicated and tangled that one could form a necklace out of them that could be placed around the neck and would not fall off. The standard example X is, in fact, called *Antoine's Necklace*. The Cantor set X must be wild because it does not share the following property with the middle-thirds Cantor set Y.

EXERCISE 6.20. View the standard middle-thirds Cantor set Y as a subset of the x-axis in 3-space $\mathbb{R}^3$. Let $f : \mathbb{S}^1 \to \mathbb{R}^3 \setminus Y$. Then the map f can be extended to a map $F : \mathbb{B}^2 \to \mathbb{R}^3 \setminus Y$.

Here is a description of Antoine's necklace; see Figure 4:

We take as X_0 a solid torus (a solid doughnut). Inside of it, forming X_1, is a finite collection of smaller disjoint solid tori linked together in a chain that circles the interior of X_0. The set X_2 is formed by a collection of even smaller chains, one such chain circling the interior of each of the links making up X_1, and so forth. The necklace X is the set of points that lie in each of the smaller and smaller sets X_0, X_1, X_2, ...

Here is a property that distinguishes X from Y topologically:

Consider the circle C that goes through the hole in the doughnut X_0. Then C does not bound even a singular disk in $\mathbb{R}^3 \setminus X$. (Proving this fact is nontrivial.)

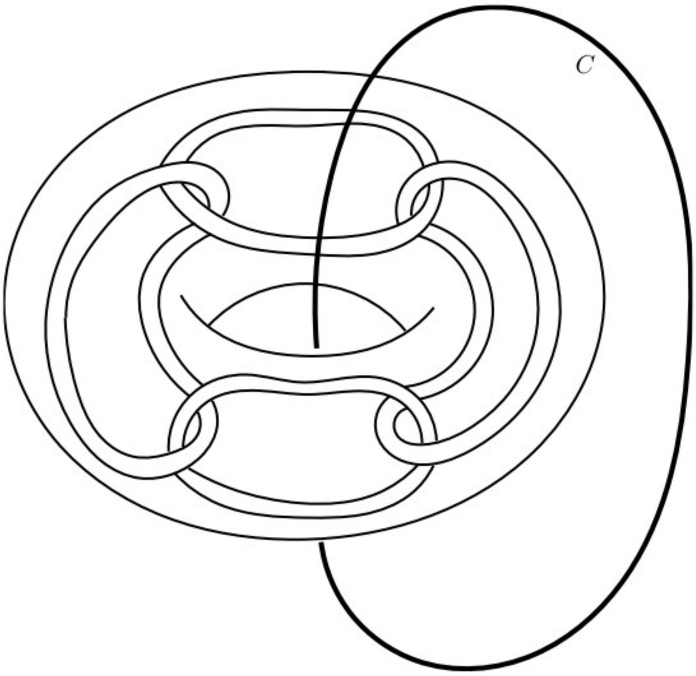

FIGURE 4. Antoine's Necklace

6.3.4. Hausdorff Dimension and a Fractal Cantor Set. Felix Hausdorff suggested another measure of dimension based on measure rather than topology. The middle-thirds Cantor set which we introduced in Definition 6.16 has, according to Hausdorff, dimension equal to $\log 2/\log 3 \approx .63092975...$ as opposed to covering dimension 0. Mandelbrot has defined a *fractal* as a set whose Hausdorff dimension is not equal to its Lebesgue covering dimension [86, 87, 88]. Since the covering dimension of the middle-thirds Cantor set is equal to 0, that set is, according to Mandelbrot's definition, a fractal.

Hausdorff observed that the volume of an n-dimensional cube is proportional to the nth power of its diameter and suggested that, for an arbitrary set X, the nth power of the diameter be taken as an approximation to the *n-dimensional volume* of X, regardless of the fine-scale shape of the object X. To refine the approximation, take an open (or closed) cover U of X by small sets and define the approximate n-dimensional volume $H^n(X, U)$ to be the sum of the nth powers $|u|^n$ of the diameters $|u|$ of the elements $u \in U$. Hausdorff noted that, in this manner it is possible to assign every subset of a separable metric space an n-dimensional volume for every n. Here are the details:

In order to make the n-dimensional volume of X well-defined, the covers of X by small open sets should be as efficient as possible. To that end, fix a positive number δ, consider all possible countable open covers U of X by sets of diameter $< \delta$, and define the δ-approximate n-dimensional volume $H^n_\delta(X)$ of X to be the infimum of the approximations $H^n(X, U)$. Finally, define the n-dimensional volume $H^n(X)$ of X by the formula

$$H^n(X) = \lim_{\delta \to 0} H^n_\delta(X).$$

There is nothing in this definition that requires that n be a nonnegative integer. Thus Hausdorff noted that one could assign an r-dimensional volume $H^r(X)$ to X for every nonnegative number r by adding rth powers of diameters.

Hausdorff proved as a consequence of the following theorem that, given the set X, there is a unique nonnegative number d such that $H^r(X) = \infty$ for $r < d$ and $H^r(X) = 0$ for $r > d$. He called this number d the *dimension* of X. We call it the *Hausdorff dimension* of X.

THEOREM 6.21. *Suppose that r and s are nonnegative real numbers such that $r < s$ and that $H^r(X) < \infty$. Then $H^s(X) = 0$.*

PROOF. Pick a positive number P such that $H^r(X) < P$. Then, for each $\eta > 0$, there is a countable open cover U_η of X by sets of diameter $< \eta$ such that $H^r(X, U_\eta) < P$. Thus, for each $\delta > 0$ and for each $\eta < \delta$,

$$H^s_\delta(X) \le H^s(X, U_\eta) = \sum\{|u|^s : u \in U_\eta\}$$

$$\le \eta^{s-r} \sum\{|u|^r : u \in U_\eta\} = \eta^{s-r} H^r(X, U_\eta) < \eta^{s-r} P.$$

Hence, for each $\delta > 0$, $H^s_\delta(X) \le \eta^{s-r} P$. It follows that $H^s_\delta(X) = 0$ and hence that $H^s(X) = 0$. □

Hausdorff gave interesting examples of sets whose (Hausdorff) dimension is not an integer. Here is one of his examples.

THEOREM 6.22. *The Hausdorff dimension of the middle-thirds Cantor set C is $r = \log 2/\log 3$. Furthermore, $H^r(C) = 1$.*

PROOF. We first show why it is natural to conjecture that $r = \log 2/\log 3$ is the Hausdorff dimension of C:

It is hard to imagine covers of C that are more efficient than the defining covers C_n, where $C = \bigcap_{n=1}^\infty C_n$ and C_n is the disjoint union of 2^n intervals of length $(1/3^n)$. The 2^n intervals of C_n define a closed cover U_n of C that, for the arbitrary dimension s, gives the following approximation to $H^s(C)$:

$$J^s(C, U_n) = \sum\{|u|^s \,:\, u \in U_n\} = \left(\frac{2}{3^s}\right)^n = e^{n(\log 2 - s\log 3)},$$

where we have used the identity $a^b = e^{b\log a}$.

If $\log 2 - s\log 3 = 0$, which implies $s = \log 2/\log 3$, we have $H^s(C, U_n) = e^{n\cdot 0} = 1$, which is neither ∞ nor 0. For $s < \log 2/\log 3$, $H^s(C, U_n) \to \infty$. For $x > \log 2/\log 3$, $H^s(C, U_n) \to 0$. We conclude that $s = (\log 2/\log 3 = r)$ is the most probable dimension of C In view of the previous theorem, it remains only to show that $H^r(C) = 1$.

The estimates that we have already made show that $H^r(C) \leq 1$. It remains to prove that $H^r(C) \geq 1$.

To that end, we suppose to the contrary that $H^r(C) < 1$. We fix a positive number δ, and consider an open cover U of C by sets of diameter $< \delta$ such that $H^r(C, U) < 1$. Since C is compact, we may assume that the cover U is finite. Without increasing the sum, we may assume that each element of U is an open interval. Expanding each element of U a tiny bit if necessary, we may assume that the end points of the interval lie in the complement of C. We replace these open intervals by their corresponding closed intervals, and proceed to modify this cover by closed intervals as follows.

If $I = [a, b]$ is one of the intervals, we may shorten I until its endpoints a and b actually lie in C. Let E denote the largest gap in C between the endpoints of I. This gap divides I into three subintervals P', E, and P'', with $a \in P'$ and $b \in P''$.

We need three facts:

(1) $3^r = 2$. (Take the logarithm of both sides.)

(2) $(3/2)(|P'| + |P''|) \leq |P'| + |E| + |P''|$. (This follows from the fact that $|P'|, |P''| \leq |E|$. In order to see that $|P'|, |P''| \leq |E|$, consider the last $n \geq 0$ such that the endpoints a and b of the interval I lie in the same interval J of C_n. Then E is the middle third of J, P' is a subinterval of the first third of J, and P'' is a subinterval of the last third of J.)

(3) $((|P'| + |P''|)/2)^r \geq (|P'|^r + |P''|^r)/2$. (This follows since $r < 1$ so that the function x^r is concave. See Figure 5)

From (1), (2), and (3) we deduce

$$|I|^r = (|P'| + |E| + |P''|)^r \geq (\frac{3}{2}(|P'| + |P''|))^r$$
$$= 2((|P'| + |P''|)/2)^r \geq 2(|P'|^r + |P''|^r)/2 = |P'|^r + |P''|^r.$$

Thus we may replace I by P' and P''.

A finite number of such operations can be used to reduce the covering to one by intervals of the same C_n. But at that stage, the approximate area is ≥ 1 by the calculation of the first half of the proof, contradicting our (false) assumption that the approximate area was < 1, a contradiction, as we wished to show. Hence $H^r(C, U) \geq 1$.

Thus $H^r(C) = 1$; and the proof is complete. □

6.3.5. The Cantor Function. There is a natural map from the Cantor set onto the unit interval. See an approximation to the graph of this function in Figure 7. This mapping is at the basis of the Cantor function: a continuous function that has slope 0 almost everywhere, yet increases in such a way that it maps the unit interval $[0, 1]$ *onto* itself.

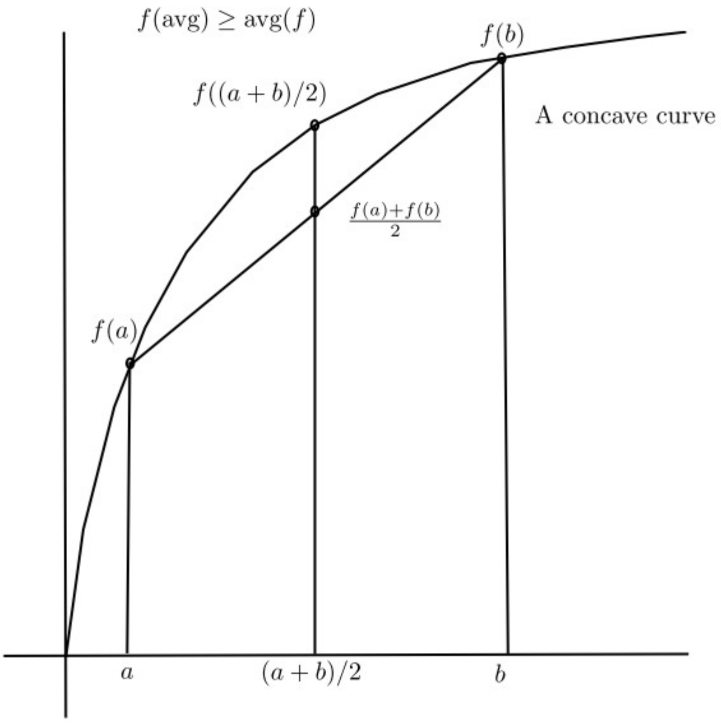

FIGURE 5. A concave curve

The idea of the construction is to create a monotone decomposition of the interval. Recall the definition of monotone decomposition in Section 5.2, Definition 5.8, and both Corollary 5.7 and Theorem 5.9 from that section. We describe the construction in generality:

We partition $[0,1]$ into a collection X of points and closed subintervals. See Figure 6. In the case of the Cantor set, the closed subintervals are the closures of the open intervals removed in defining the Cantor set. The elements of X are then equivalence classes of an equivalence relation on $[0,1]$. We assume that there are at least two, hence uncountably many, equivalence classes, most of which contain only a single point of $[0,1]$. At most countably many of the equivalence classes are closed intervals, since each contains an open set and there can be no more than countably many disjoint open sets.

FIGURE 6. Monotone decomposition of an interval

We recall the *identification space* or *decomposition space* whose points are the elements of X. That is, each element of X, even if it consists of more than one point of $[0,1]$, is abstractly considered to be one point of X. We assigned a topology to X in the usual manner as follows. We considered the function $p : [0,1] \to X$

which assigned to each point $x \in [0,1]$ the equivalence class $p(x) = [x] \in X$ which contains x. We declared a subset $U \subset X$ to be an open subset of X iff the union $U^* = p^{-1}(U)$ of the elements of U formed an open subset of $[0,1]$. Note that, by this definition, the map $p : [0,1] \to X$ is continuous. We proved the following earlier.

THEOREM 6.23. *The decomposition space X is an arc.*

DEFINITION 6.24. Let I denote the set of closed intervals $[x_\alpha, y_\alpha]$ in $[0,1]$ that are closures of the open intervals deleted from $[0,1]$ in defining the middle-third Cantor set C. Let X denote the partition of $[0,1]$ into the elements of I and the singleton sets containing the points not included in any of the intervals of I. We assign X the identification-space topology. Let $p : [0,1] \to X$ denote the continuous function that assigns each point $x \in [0,1]$ the element $p(x) = [x] \in X$ which contains x. Note that X is an arc by the previous theorem. Hence we may identify X with $[0,1]$ and p with a map from $[0,1]$ to itself which fixes 0 and 1.

THEOREM 6.25. *Let I, $X = [0,1]$, and $p : [0,1] \to X = [0,1]$ be as in the previous definition. Then we may assume that $p(I)$ is the set of rational numbers in the open interval $(0,1)$.*

PROOF. The set $p(I)$ is a countable dense subset of $(0,1) \subset [0,1] = X$. Every countable dense subset of $(0,1)$ is embedded in $[0,1]$ in exactly the same way. □

COROLLARY 6.26. *The set of points of the middle-thirds Cantor set C that are not endpoints of any of the open intervals removed in forming C is homeomorphic to the set of irrational points between 0 and 1.*

THEOREM 6.27. *There is a (weakly) monotone continuous function $f : [0,1] \to [0,1]$, with $f(0) = 0$ and $f(1) = 1$ that has derivative 0 almost everywhere.*

PROOF. Map the first middle third to 1/2. Map the next larger intervals to 1/4 and 3/4. Map the four next intervals to 1/8, 3/8, 5/8, and 7/8, etc. Extend continuously to the remaining points of $[0,1]$. Since the sum of the lengths of the intervals defining the Cantor set is

$$\frac{1}{3} \cdot \left(1 + (2/3) + (2/3)^2 + \cdots + (2/3)^n + \cdots\right) = \frac{1}{3} \cdot \frac{1}{1-(2/3)} = 1,$$

the graph is horizontal on a set of measure 1 yet rises from 0 to 1.

□

6.4. Cantor Sets in the Plane Are Tame

We saw that there are Cantor sets in 3-dimensional space which are so entangled that they can act like a necklace and not fall off when placed around the neck. Are there Cantor sets in the plane with similar entanglement? We show in this section that there are no such Cantor sets in the plane. Not only are Cantor sets in the plane homeomorphic by definition to the standard middle-thirds Cantor set, but the homeomorphisms can be realized as the restrictions of homeomorphisms from the plane to itself. That is, every embedding of the Cantor set in the plane is equivalent to the standard embedding. We call all standard embeddings of an object *tame embeddings*.

CHAPTER 3

Gravity As Curvature

We now turn to the description of curvature.

3.1. Einstein Identified Gravity with the Curvature of Space-Time

Albert Einstein identified gravity with the curvature of space-time: A massive object distorts, or curves, space-time; and other objects respond gravitationally by following (locally) shortest paths in that curved space, paths that deserve to be called straight. Misner, Thorne, and Wheeler, in their book "Gravitation" [97], compare the path followed by an object acting under the influence of gravity to a straight cut in the surface of an apple where this cut, near the stem of the apple, dips toward the stem as if that stem were a source of gravitational force.

Two problems must be solved in application of Einstein's ideas: (1) We usually recognize the curvature of an object by observing how it curves in some larger space (= extrinsic curvature). Since we live *within* space-time, how can we recognize and describe its curvature from within space-time itself (= intrinsic curvature)? (2) How do we recognize and describe the paths in a curved object that are locally shortest, hence deserve to be called *straight* (= geodesic)?

Gauss showed us how these problems can be solved for 2-dimensional surfaces. Riemann generalized Gaussian curvature to higher dimensions by considering the Gaussian curvature of each 2-dimensional slice in higher dimensional space.

In this introduction to curvature, we will restrict ourselves, as Gauss did, to 2-dimensional surfaces that reside in 3-dimensional Euclidean space. But we will not follow Gauss's path. For both questions, we will first approximate the surface by a polyhedral surface where it is easy to answer both questions: How flat is a polyhedral surface? How straight is an edge path in a polyhedral surface? The corresponding concepts in smooth surfaces will then follow by a limiting process.

CHAPTER 4

Curvature by Polyhedral Approximation

4.1. Approximating Smooth Surfaces by Polyhedra

Gauss described a smooth surface in $\mathbb{R}^3$ locally as the image of a map $S : \mathbb{R}^2 \to \mathbb{R}^3 : (x, y) \mapsto (x, y, z)$, where z is a many-times differentiable function of x and y. It is an easy matter to triangulate such a surface.

Key Idea 4.1. *Every smooth surface S in $\mathbb{R}^3$ can be closely approximated locally by polyhedral surfaces S''.*

We restrict our attention to piecewise smooth disks in the surface S.

Definition 4.2. A disk D in a smooth surface S is called *piecewise smooth* if there are finitely many points $p_0, p_1, \ldots, p_n = p_0$ in the boundary ∂D of D that divide ∂D into arcs $p_0p_1, p_1p_2, \ldots, p_{n-1}p_n$ each of which is smooth and such that there is a well-defined angle of turning in ∂D at each of the points $p_1, p_2, \ldots, p_n$.

Theorem 4.3. *If $D \subset \mathbb{R}^2$ is a disk that is mapped homeomorphically by $S : \mathbb{R}^2 \to \mathbb{R}^3$ to a piecewise smooth disk $S(D) \subset S$, then $S(D)$ can be closely approximated by polyhedral disks $D' \subset \mathbb{R}^3$.*

Proof. Choose points $q_0, q_1, \ldots, q_m = q_0$ in cyclic order on ∂D that divide ∂D into tiny arcs. Since D is piecewise smooth, the points q_i will be the vertices of a polygonal simple closed curve J in $\mathbb{R}^2$ that closely approximates ∂D. The curve J bounds a disk $D' \subset \mathbb{R}^2$ that approximates D. The disk D' can be triangulated with very small triangles T_j. If A, B, and C are the vertices of T_j, then S maps them to vertices $A' = S(A)$, $B' = S(B)$, and $C' = S(C)$. The vertices A', B', and C' are the vertices of a triangle $T'_j \subset \mathbb{R}^3$. The triangles T'_j are the triangles of a polyhedral disk D' that closely approximates $S(D)$. ☐

4.2. The Curvature of a Polyhedral Disk

In this chapter we define the curvature of a polyhedral disk in $\mathbb{R}^3$. We shall see that curvature is the average obstruction to flattening that disk into the plane locally without distorting lengths or areas.

4.3. How Flat Is a Disk?

We consider a polyhedral disk D, not assumed to be flat, triangulated by finitely many Euclidean triangles. Combinatorially, we can picture the disk as lying in the flat plane as in Figure 1, but to do this we may have to change angles and side lengths of the individual triangles.

If we fix our intention on one of the interior vertices v of our disk, then the triangles containing that vertex form a polyhedral cone with that vertex as tip of the cone. This polyhedral cone is called the *star* of the vertex v in D and is denoted

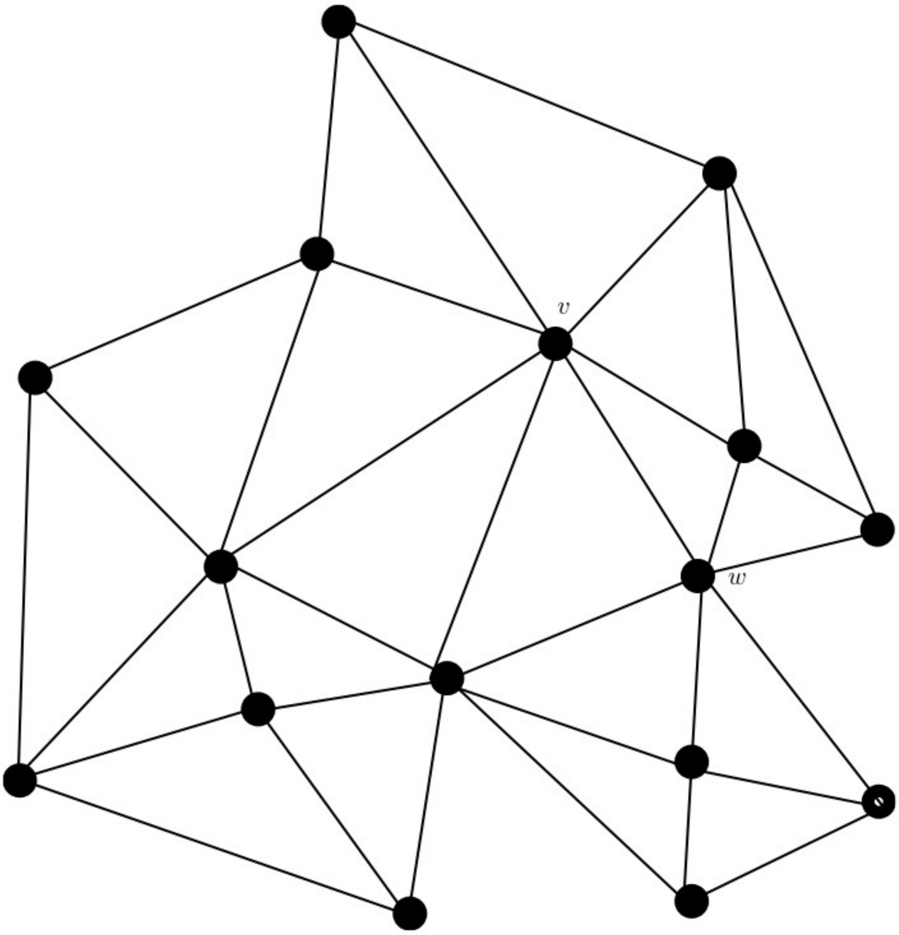

FIGURE 1. A triangulated disk in the flat plane

by star(v, D). This star can be drawn in the plane as a disk if we allow ourselves to distort lengths and angles (left side of Figure 2). If we cut star(v, D) along one of the edges emanating from v, then we can embed the triangles of the result in the plane, one by one, without distorting lengths or angles (right side of the Figure 2).

The cut star, as laid out in the plane, will close up naturally to form a planar disk if an only if the sum $i(v)$ of the angles at v is exactly 2π ($= 360$ degrees). We may take the difference $2\pi - i(v)$ as a measure of the degree to which the star of v in D fails to be flat. The angle $i(v)$ can potentially take on any value in the range $(0, \infty)$ so that $2\pi - i(v)$ can lie anywhere in the range $(-\infty, 2\pi)$. If the angle $i(v)$ is larger than 2π, then the undistorted triangles will spiral around the vertex v any number of times.

DEFINITION 4.4. Let $I(D)$ denote the set of interior vertices of D, and let $|I(D)|$ denote the number of those vertices. Let $i(v)$ denote the angle sum at each

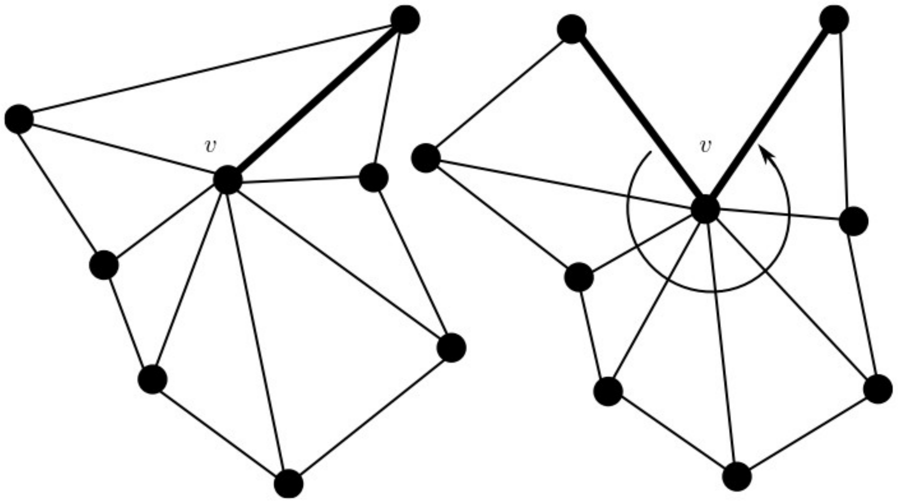

FIGURE 2. The star of an interior vertex

element $v \in I(D)$, and let $i(D) = \sum\{i(v) \mid v \in I(D)\}$. Then we may take the sum

$$\operatorname{def}(D) = \sum\{2\pi - i(v) \mid v \in I(D)\} = 2\pi \cdot |I(D)| - i(D)$$

as a global measure of the degree to which D fails to be flat. We call $\operatorname{def}(D)$ the *angle defect* of D.

4.4. How Straight Is a Disk Boundary?

We again consider a polyhedral disk D, not assumed to be flat, triangulated by finitely many Euclidean triangles. Combinatorially, we picture the disk as lying in the flat plane as before, but repeated in Figure 3. However, to do this we may have to change angles and side lengths of the individual triangles.

If we fix our attention on one of the boundary vertices w of our disk, then the triangles containing that vertex form a polyhedral cone with that vertex as tip of the cone. This polyhedral cone is called the *star* of the vertex w in D and is denoted by $\operatorname{star}(w, D)$. This star can be drawn in the plane as a disk with $\partial D \cap \operatorname{star}(w, D)$ straight if we allow ourselves to distort lengths and angles (left side of Figure 4). If we are careful to embed each triangle in the plane, one by one, without distorting lengths or angles (right side of Figure 4), the result will be a planar disk with $\partial D \cap \operatorname{star}(v, D)$ straight if and only if the sum $b(w)$ of the angles at w is exactly π ($= 180$ degrees).

We may take the difference $\pi - b(w)$ as a measure of the degree to which the boundary of D fails to be straight at w. The angle $b(w)$ can potentially take on any value in the range $(0, \infty)$ so that $\pi - b(w)$ can lie anywhere in the range $(-\infty, \pi)$. If the angle $b(w)$ is larger than 2π, then the undistorted triangles will spiral around the vertex w any number of times.

DEFINITION 4.5. Let $B(D)$ denote the set of boundary vertices of D, and let $|B(D)|$ denote the number of those vertices. Let $b(w)$ denote the angle sum at each element $w \in B(D)$, and let $b(D) = \sum\{b(w) \mid w \in B(D)\}$. Then we may take

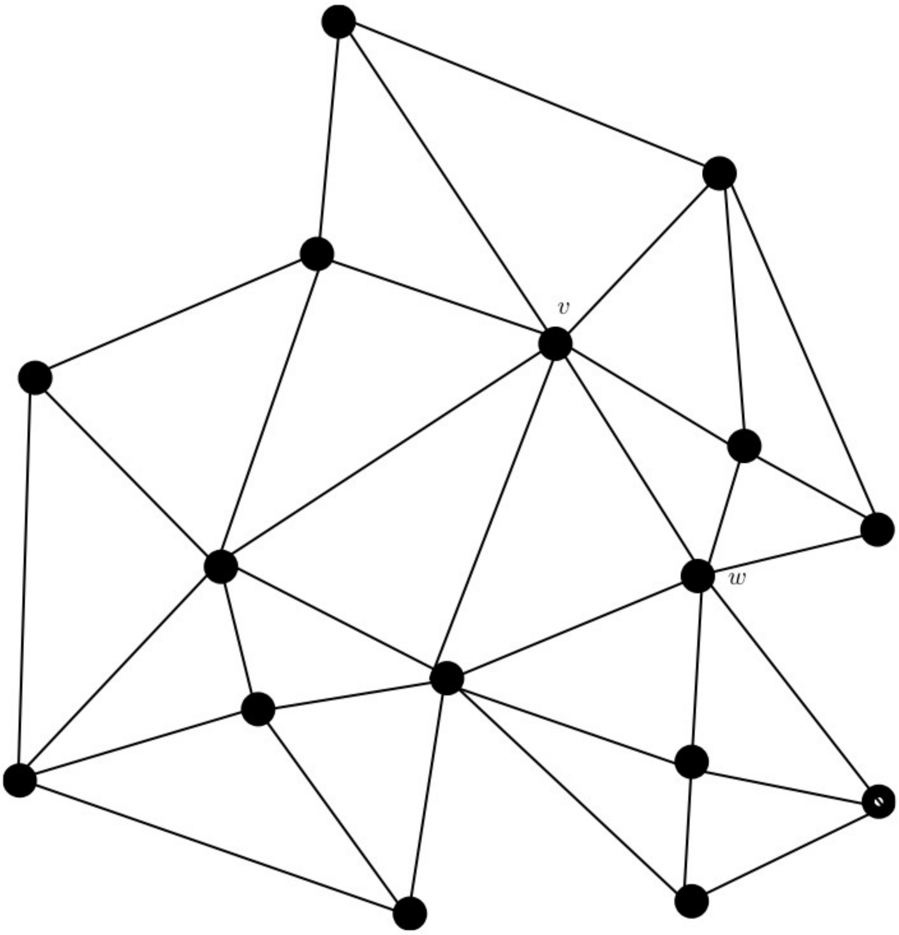

Figure 3. The triangulated disk again

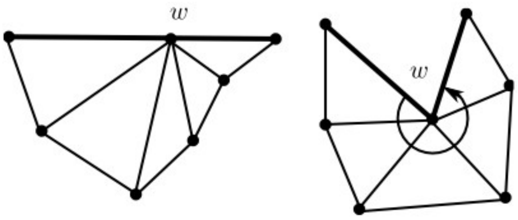

Figure 4. The star of a boundary vertex

the sum

$$\partial\mathrm{def}(D) = \sum\{\pi - b(w) \mid w \in B(D)\} = \pi \cdot |B(D)| - b(D)$$

as a global measure of the degree to which ∂D fails to be straight. (Of course, we do not expect a disk boundary to be straight.) We call $\partial\mathrm{def}(D)$ the *boundary defect* of D.

4.5. Duality Theorem: Angle Defect + Boundary Defect = 2π

As before, we assume that D is a polyhedral disk, not necessarily flat, triangulated by finitely many Euclidean triangles.

THEOREM 4.6 (Duality Theorem). *In a polyhedral disk D,*

$$\mathrm{def}(D) + \partial\mathrm{def}(D) = 2\pi.$$

REMARK. This easy but important theorem shows that angle defect and boundary defect are equally effective for measuring the degree to which a disk D fails to be flat. This duality between angle defect and boundary defect is very important. Angle defect gives a very intuitive picture of how difficult it is to flatten a surface into the plane, hence captures the notion of curvature. Boundary defect, on the other hand, captures the notion of how straight a path is and leads to beautiful derivative formulas by which we can study curvature.

A first consequence of this duality, as explained in a subsequent section, will be the famous theorem known as the Umlauf Theorem, Theorem 4.7, which, for simple closed polygonal curves in a planar surface, states that the boundary defect is always 2π since the angle defect of a planar surface is always 0. That is, as we travel along a planar simple closed curve, turning sometimes to the left and sometimes to the right, in the end we always turn precisely through a net angle of 2π.

A second consequence of the duality is a formula for the area of a disk in the 2-sphere $\mathbb{S}^2$ of radius 1. The area is precisely $2\pi - \partial\mathrm{def}$ (Theorem 4.9). This result will be an important ingredient in our proof of Gauss's *Theorema Egregium* (= *remarkable theorem*), Theorems 6.4 and 6.5, which shows that intrinsic and extrinsic views of curvature are equivalent. *End remark.*

PROOF OF THE DUALITY THEOREM, THEOREM 4.6. We review the notation of the preceding sections:

$I(D)$ is the set of interior vertices of D and $|I(D)|$ the number of such vertices.
$B(D)$ is the set of boundary vertices of D and $|B(D)|$ the number of such vertices.
$i(D)$ is the sum of all interior angles.
$b(D)$ is the sum of all boundary angles.
$\mathrm{def}(D) = |I(D)| \cdot 2\pi - i(D)$.
$\partial\mathrm{def}(D) = |B(D)| \cdot \pi - b(D)$.

We proceed by induction on the number T of triangles in D. See Figure 5.

If $T = 1$ so that D consists of a single triangle, D has no interior vertices, which implies that $\mathrm{def}(D) = 0$. On the other hand, $\partial\mathrm{def}(D) = 3 \cdot \pi - \pi = 2\pi$. Thus the theorem is true for $T = 1$.

We assume that $T > 1$ and that the theorem is true for all disks D with fewer than T triangles. If we take one triangle ABC with edge AC in the boundary of D, then at least one of the other edges, say AB is an interior edge of D. We consider two cases according to whether the vertex B is a boundary vertex or an interior vertex.

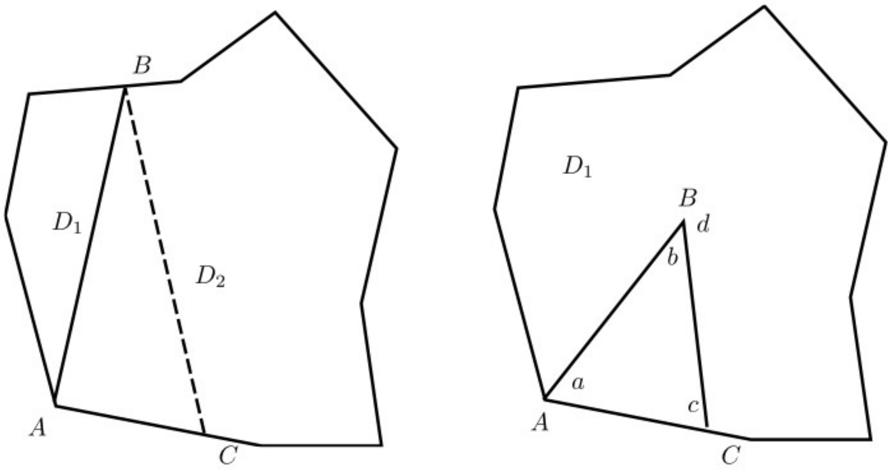

FIGURE 5. The two cases in the proof of the Duality Theorem

Case 1. Suppose that B is a boundary vertex of D. Then AB divides D into two subdisks D_1 and D_2 that share the edge AB. We calculate:

$$\begin{align*}
\operatorname{def}(D) + \partial\operatorname{def}(D) &= \Big(|I(D)| \cdot 2\pi - i(D)\Big) + \Big(|B(D)| \cdot \pi - b(D)\Big) \notag\\
&= \Big(|I(D_1)| + |I(D_2)|\Big) \cdot 2\pi - \Big(i(D_1) + i(D_2)\Big) \notag\\
&\quad + \Big(|B(D_1)| + |B(D_2)| - 2\Big) \cdot \pi - \Big(b(D_1) + b(D_2)\Big) \notag\\
&= \Big(\operatorname{def}(D_1) + \partial\operatorname{def}(D_1)\Big) + \Big(\operatorname{def}(D_2) + \partial\operatorname{def}(D_2)\Big) - 2\pi \notag\\
&= 2\pi + 2\pi - 2\pi \tag{4.1}\\
&= 2\pi. \notag
\end{align*}$$

Case 2. Suppose that B is an interior vertex of D. Then $AB \cup BC$ divides the triangle ABC with angles a, b, c at vertices A, B, C from a subdisk D_1 with angle d at B. We calculate:

$$\begin{align*}
\operatorname{def}(D) + \partial\operatorname{def}(D) &= \Big(|I(D)| \cdot 2\pi - i(D)\Big) + \Big(|B(D)| \cdot \pi - b(D)\Big) \notag\\
&= \Big(|I(D_1)| + 1\Big) \cdot 2\pi - \Big(i(D_1) + b + d\Big) \notag\\
&\quad + \Big(|B(D_1)| - 1\Big)\pi - \Big(b(D_1) + a + c - d\Big) \notag\\
&= \Big(\operatorname{def}(D_1) + \partial\operatorname{def}(D_1)\Big) + \big(2\pi - b - d - \pi - a - c + d\big) \notag\\
&= 2\pi + \Big(\pi - (a + b + c)\Big) \tag{4.2}\\
&= 2\pi. \notag
\end{align*}$$

□

4.6. The Curvature of a Polyhedral Disk

We have seen that both $\operatorname{def}(D)$ and $\partial\operatorname{def}(D)$ are reasonable measures of how difficult it is to flatten a polyhedral disk in the plane without distorting lengths and areas. Both of these measures are scale invariant. Hence we normalize by dividing by area. We define the *curvature* $K(D)$ of D to be the average

$$K(D) = \frac{\operatorname{def}(D)}{\operatorname{Area}(D)} = \frac{2\pi - \partial\operatorname{def}(D)}{\operatorname{Area}(D)}.$$

4.7. Applications of the Duality Between Angle Defect and Boundary Defect

In this section we use the duality between angle defect and boundary defect to trivially deduce a famous about the flat Euclidean plane which is known as the *Umlauf Theorem.* We then use the same duality to develop a formula for the area of a disk in the 2-sphere $\mathbb{S}^2$ of radius 1.

4.7.1. The Umlauf Theorem.

THEOREM 4.7 (Umlauf Theorem). *If D_0 is a polyhedral planar disk, then $\partial\operatorname{def}(D_0) = 2\pi$. That is, if one traverses the boundary of a planar disk, then the net angle, positive and negative, through which one turns is 2π. (In German, "laufen" means "to run" and "um" is a preposition meaning "around".)*

PROOF. Since D_0 is planar, it is obvious that the angle defect of D_0 is 0. Hence $2\pi = \operatorname{def}(D_0) + \partial\operatorname{def}(D_0) = \partial\operatorname{def}(D_0)$. □

4.7.2. The Area of a Disk in the 2-Sphere $\mathbb{S}^2$.

DEFINITION 4.8. A disk $D_0 \subset \mathbb{S}^2$ is said to be *spherically polyhedral* if its boundary is a finite union of segments lying in great circles of $\mathbb{S}^2$. The reason for calling its boundary polygonal is this: Given two points $x, y \in \mathbb{S}^2$, with $x \neq -y$, the shortest path between x and y on $\mathbb{S}^2$ is unique and lies on a great circle. That is, great circles deserve to be called *straight* on $\mathbb{S}^2$. We shall discuss this at some length later. A *spherical triangle* is a spherically polyhedral disk with three edges. A *spherical triangulation* of a spherically polyhedral disk is a union of spherical triangles, where each pair of triangles that intersect meet either in a vertex or a common edge.

REMARK. It is important to note that polyhedral and spherically polyhedral approximations to disks in $\mathbb{S}^2$ are closely related. Supposing that the vertices of a polyhedral approximation lie in $\mathbb{S}^2$, projection from the center of $\mathbb{S}^2$ will take the polyhedral approximation to a spherically polyhedral approximation. *End remark.*

THEOREM 4.9. *If $D_0 \subset \mathbb{S}^2$ is a disk that is spherically polyhedral, then* $\operatorname{Area}(D_0) = 2\pi - \partial\operatorname{def}(D_0)$.

PROOF. Since boundary defect measures the angles through which a path turns relative to a straight path, and since great circle segments on a sphere are straight, the boundary defect of a spherically polygonal path is simply the sum of the turning angles at the vertices between successive great-circle segments. Recall that the turning angle is the difference $\pi - b(w)$ between straight (π) and the angle sum ($b(w)$) in D_0 at boundary vertex w. We employ our previous notations:

$$\partial\mathrm{def}(D_0) = \sum_w \{\pi - b(w)\} = \pi \cdot |B(D_0)| - b(D_0),$$

where the sum is taken over the vertices w of the spherical polygonal boundary path, $b(w)$ is the angle sum of D_0 at w, $|B(D_0)|$ is the number of vertices w, and $b(D_0)$ is the sum of all the $b(w)$.

We assume that D_0 has a spherical triangulation. We proceed by induction on the number N of spherical triangles in this triangulation. The key case is that of a single triangle, where $N = 1$:

LEMMA 4.10 (The Triangle Lemma). *Suppose that* $\Delta = ABC \subset \mathbb{S}^2$ *is a triangle whose sides are great-circle segments on the* 2*-sphere* $\mathbb{S}^2$ *of radius* 1 *with angles* α*,* β*, and* γ *at the vertices* A*,* B*, and* C*, respectively. Then the area of* Δ *is given by the formula*

$$\mathrm{Area}(\Delta) = \alpha + \beta + \gamma - \pi.$$

The Triangle Lemma gives the desired result for $N = 1$ since, in that case, the turning angles at A, B, and C are, respectively, $\pi - \alpha$, $\pi - \beta$, and $\pi - \gamma$ and

$$2\pi - \partial\mathrm{def} = 2\pi - 3\pi + \alpha + \beta + \gamma = \alpha + \beta + \gamma - \pi.$$

We assume the Triangle Lemma for the moment and complete the induction on N as follows. If $N > 1$, then we assume the result inductively for fewer than N triangles. Exactly as in the proof of the Duality Theorem, we take one triangle ABC with edge AC in the boundary of D_0, where at least one of the other edges, say AB is an interior edge of D_0. We consider two cases acording to whether the vertex B is a boundary vertex or an interior vertex. See Figure 6.

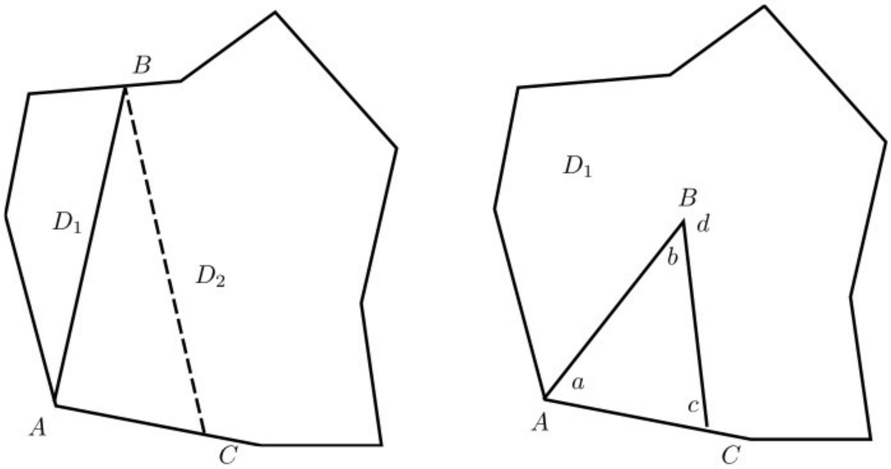

FIGURE 6. The two cases in the proof of the Triangle Lemma

Case 1. Suppose that B is a boundary vertex of D. Then AB divides D into two subdisks D_1 and D_2 that share the edge AB. We note that $|B(D_0)| =$

$|B(D_1)| + |B(D_2)| - 2$ and that $b(D_0) = b(D_1) + b(D_2)$. Hence, we calculate:

$$\begin{aligned} 2\pi - \big(\pi \cdot |B(D_0)| - b(D_0)\big) &= 2\pi - \pi B(D_1) - \pi B(D_2) + 2\pi + b(D_1) + b(D_2) \\ &= 2\pi - \big(\pi B(D_1) - b(D_1)\big) \\ &\quad + 2\pi - \big(\pi B(D_2) - b(D_2)\big) \\ &= \mathrm{Area}(D_1) + \mathrm{Area}(D_2) \\ &= \mathrm{Area}(D_0). \end{aligned}$$

Case 2. Suppose that B is an interior vertex of D_0. Then $AB \cup BC$ divides the triangle ABC with angles a, b, c at vertices A, B, C from a subdisk D_1 with angle d at B. We note that $|B(D_0)| = |B(D_1)| - 1$ and $b(D_0) = b(D_1) + a + c - d = b(D_1) + a + c + b - 2\pi$. (Note that $b + d = 2\pi$ since D_0 is smooth at B.) Hence, we calculate:

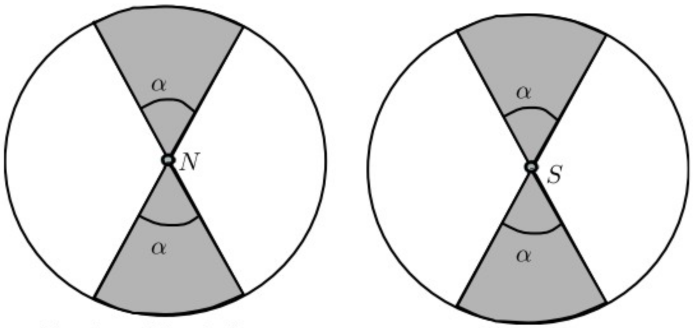
$$\begin{aligned} 2\pi - \big(\pi \cdot |B(D_0)| - b(D_0)\big) &= 2\pi - \pi|B(D_1)| + \pi + b(D_1) + a + b + c - 2\pi \\ &= 2\pi - (\pi \cdot |B(D_1)| - b(D_1)) + (a + b + c - \pi) \\ &= \mathrm{Area}(D_1) + \mathrm{Area}(ABC) \\ &= \mathrm{Area}(D_0). \end{aligned}$$

□

We turn now to the proof of the Triangle Lemma.

LEMMA 4.11. *If great circles I and J on $\mathbb{S}^2$ meet at angle α, then the union $I \cup J$ bounds two spherical digons on $\mathbb{S}^2$ of total area $(2\alpha/2\pi) \cdot 4\pi = 4\alpha$. (A spherical digon is a two-sided "polygon" bounded by portions of two great circles. See Figure 7.)*

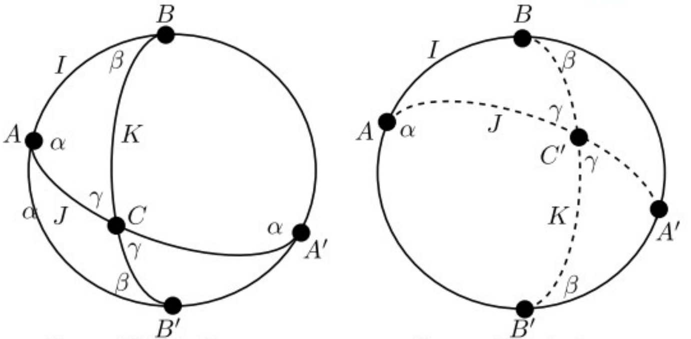
PROOF. We lose no generality in assuming that I and J are longitudes that meet at the north pole N and the south pole S. In Figure 7, we view the northern hemisphere and the southern hemisphere separately, side by side, with the two digons formed from the shaded regions. It is obvious geometrically that the two shaded digons compose the fraction $(2\alpha/2\pi)$ of the total area of the sphere $\mathbb{S}^2$. Since the sphere $\mathbb{S}^2$ has area 4π, the desired result follows. □



Northern Hemisphere Southern Hemisphere

FIGURE 7. The double lune between two great circles

Proof of the Triangle Lemma. The triangle Δ is bounded by portions of three great circles $I \supset AB$, $J \supset AC$, and $K \supset BC$. See Figure 8.



Upper Hemisphere Lower Hemisphere

Figure 8. Analyzing the spherical triangle

In the figure, we take I as bounding an upper hemisphere and a lower hemisphere, which we view side by side. We have labelled each of the resulting angles in the diagram that are given by α, β, and γ. Great circles I and J meet at A and its antipodal point $A' = -A$; I and K meet at B and its antipode $B' = -B$; J and K meet at C and its antipode $C' = -C$.

Let $D(\alpha)$ denote the union of the two digons with angles α bounded by $I \cup J$. Let $D(\beta)$ denote the union of those with angles β bounded by $I \cup K$. Let $D(\gamma)$ denote the union of those with angles γ bounded by $J \cup K$. Note that

$$\text{Area}(D(\alpha)) = 4\alpha; \quad \text{Area}(D(\beta)) = 4\beta; \quad \text{Area}(D(\gamma)) = 4\gamma$$

by the lemma. Then $D(\alpha)$, $D(\beta)$, and $D(\gamma)$ together cover each of the congruent triangles $\Delta = ABC$ and $\Delta' = A'B'C'$ three times and cover each of the complementary triangles exactly one time. Taking one of the copies of Δ and of Δ' and adding them to the complement, we see that $D(\alpha)$, $D(\beta)$, and $D(\gamma)$ cover the entire sphere $\mathbb{S}^2$ once, and each of Δ and Δ' twice. Thus

$$\text{Area}(D(\alpha)) + \text{Area}(D(\beta)) + \text{Area}(D(\gamma)) = \text{Area}(\mathbb{S}^2) + 2\text{Area}(\Delta) + 2\text{Area}(\Delta').$$

Consequently, since Δ and Δ' have the same area,

$$4\alpha + 4\beta + 4\gamma = 4\pi + 4\text{Area}(\Delta)$$

or

$$\text{Area}(\Delta) = \alpha + \beta + \gamma - \pi,$$

as claimed. □

4.8. The Curvature of a Smooth Disk

We define the angle defect of a smooth disk to be the limit of the angle defects of its polyhedral approximations. We define the boundary defect of a smooth disk to be the limit of the boundary defects of its polyhedral approximations.

We define the curvature $K(D_0)$ of a smooth disk D_0 as a limit of the curvatures of polyhedral approximations D:

$$K(D_0) = \lim_{D \to D_0} K(D),$$

where the limit is taken over polyhedral approximations D to D_0 and

$$K(D) = \frac{\operatorname{def}(D)}{\operatorname{Area}(D)} = \frac{2\pi - \partial\operatorname{def}(D)}{\operatorname{Area}(D)}.$$

We define curvature $K(S, p)$ of a smooth surface S at a point $p \in S$ by taking a second limit:

$$K(S, p) = \lim_{D_0 \to p} K(D_0).$$

REMARK. We have already developed enough information to see that these limits exist for the plane and the 2-sphere. That $K(D)$ exists for a smooth disk in a smooth surface will follow in a subsequent section when we develop an integral formula for boundary defect. Finally, that $K(S, p)$ exists will be a consequence of our proof of Gauss's famous *Theorema Egregium*, Theorems 6.4 and 6.5. *End remark.*

Using angle defect, with angle defect in the plane being 0, we have the immediate corollaries,

COROLLARY 4.12. *For every planar disk D_0 and every point p in the plane $\mathbb{R}^2$,*

$$K(D_0) = 0 \quad \textit{and} \quad K(\mathbb{R}^2, p) = 0.$$

COROLLARY 4.13. *The Umlauf Theorem is true not just for planar disks that are polyhedral but also for all planar disks.*

Using boundary defect and the area formula for spherical polyhedral disks D which gives $\operatorname{Area}(D) = 2\pi - \partial\operatorname{def}(D)$, we find

COROLLARY 4.14. *For every spherical disk D_0 and every point $p \in \mathbb{S}^2$,*

$$K(D_0) = 1 \quad \textit{and} \quad K(\mathbb{S}^2, p) = 1.$$

adapted to the decompositions (2.2.9) and (2.2.15) and calculate the image explicitly using (2.2.5).[17]

2.2.6 Prove that the mappings $\mathrm{pr}^{1,0} \circ \iota$ and $\mathrm{pr}^{0,1} \circ \iota$, defined by (2.2.13), are $\mathbb{C}$-linear and $\mathbb{C}$-anti-linear, respectively. Show that (2.2.14) holds.

2.2.7 Prove the second assertion in Corollary 2.2.15. *Hint.* Use point 2 of Proposition 2.2.14.

2.2.8 Prove that h defined by (2.2.27) is linear in the first and anti-linear in the second entry.

2.2.9 Prove formula (2.2.31).

2.2.10 Give an alternative proof of Proposition 2.2.24 by using (2.2.37) and (2.1.33).

2.2.11 Prove formula (2.2.47).

2.2.12 Prove formula (2.2.51). *Hint.* Prove that $\mathsf{g}((\nabla_X \mathsf{J})Y, Z) = \mathsf{g}(\nabla_X(\mathsf{J}Y), Z) + \mathsf{g}(\nabla_X Y, \mathsf{J}Z)$ and rewrite the terms on the right hand side according to (2.2.40). Use formula I/4.1.6. Alternatively, the proof can be found in [381], see Proposition 4.2 in Chap. IX.

2.2.13 Prove that for $H = \mathrm{Sp}(n, \mathbb{R})$, the cokernel of the mapping (2.2.2) is isomorphic to $\bigwedge^3(\mathbb{R}^{2n})^*$. Show that the corresponding intrinsic torsion coincides with the exterior derivative of the almost symplectic form, cf. Example 2.2.21.

2.3 Curvature and Holonomy

In this section, we continue the discussion of connections compatible with H-structures. Here, we consider exclusively torsion-free connections and ask which holonomy groups may occur for such a connection. This question has first been studied systematically by Berger, see [68, 69].

At this point, the reader may wish to recall the basic notions from the general holonomy theory as presented in Sect. 1.7. For a linear connection Γ in $L(M)$, let $P_{u_0}(\Gamma)$ be the holonomy bundle of Γ with base point $u_0 \in L(M)$. By Proposition 1.7.12, Γ is reducible to $P_{u_0}(\Gamma)$ and thus, for any $u \in P_{u_0}(\Gamma)$, the curvature Ω of Γ takes values in the Lie algebra $\mathfrak{h}_{u_0}(\Gamma)$ of the holonomy group $\mathscr{H}_{u_0}(\Gamma) \subset \mathrm{GL}(n, \mathbb{R})$. By the Ambrose-Singer Theorem 1.7.15, we have

$$\mathfrak{h}_{u_0}(\Gamma) = \mathrm{span}\left\{\Omega_u(X, Y) : u \in P_{u_0}(\Gamma)\,,\ \ X, Y \in \Gamma_u\right\}\,. \tag{2.3.1}$$

It is the condition of torsion-freeness which makes the above question nontrivial. If we drop this assumption, then any closed Lie subgroup $H \subset \mathrm{GL}(n, \mathbb{R})$ may occur as the holonomy group of a linear connection on some n-dimensional manifold M, see [283]. However, in general, such a connection will have a nontrivial torsion. By the Bianchi identity (2.1.17), vanishing of the torsion implies

---

[17] Cf. also Example 2.2.19.

$$\Omega \wedge \theta = 0\,, \tag{2.3.2}$$

and, by the Ambrose-Singer Theorem, this yields a nontrivial restriction on the holonomy. Now, let $P \subset L(M)$ be an H-structure on an n-dimensional manifold M, let ω be an H-compatible connection and let Ω be its curvature. For simplicity, let us denote $\mathbb{R}^n \equiv V$. By Remark 2.1.16, we may represent Ω equivalently by the curvature mapping

$$\mathscr{R} : P \to \bigwedge^2 V^* \otimes \mathfrak{h} \tag{2.3.3}$$

fulfilling the equivariance condition (2.1.25) with respect to the natural representation $\sigma : H \to \operatorname{Aut}\left(\bigwedge^2 V^* \otimes \mathfrak{h}\right)$ given by

$$\sigma_a((\xi \wedge \tau) \otimes A) := \left((a^{-1})^{\mathrm{T}}\xi \wedge (a^{-1})^{\mathrm{T}}\tau\right) \otimes \operatorname{Ad}(a)A\,. \tag{2.3.4}$$

Since the exterior products of the components θ^i of θ span the spaces of horizontal forms, (2.3.2) implies that $\mathscr{R}$ takes values in the kernel $\mathfrak{K}(\mathfrak{h})$ of the mapping

$$\delta : \bigwedge^2 V^* \otimes \mathfrak{h} \to \bigwedge^3 V^* \otimes V\,, \quad \delta = (a \otimes \mathrm{id}) \circ (\mathrm{id} \otimes \iota_{\mathfrak{h}})\,, \tag{2.3.5}$$

where a is the anti-symmetrization mapping, cf. (2.2.2). Clearly,

$$\mathfrak{K}(\mathfrak{h}) = \left\{F \in \bigwedge^2 V^* \otimes \mathfrak{h} : F(\mathbf{x}, \mathbf{y})\mathbf{z} + F(\mathbf{y}, \mathbf{z})\mathbf{x} + F(\mathbf{z}, \mathbf{x})\mathbf{y} = 0\,,\ \ \mathbf{x}, \mathbf{y}, \mathbf{z} \in V\right\}\,.$$

The space $\mathfrak{K}(\mathfrak{h})$ is called the space of curvature mappings.

Lemma 2.3.1 *The subspace*

$$\underline{\mathfrak{h}} := \operatorname{span}\left\{F(\mathbf{x}, \mathbf{y}) \in \mathfrak{h} : F \in \mathfrak{K}(\mathfrak{h})\,,\ \ \mathbf{x}, \mathbf{y} \in V\right\} \tag{2.3.6}$$

is an ideal of $\mathfrak{h}$.

Proof Let $F(\mathbf{x}, \mathbf{y}) \in \underline{\mathfrak{h}}$ and let $A \in \mathfrak{h} \subset \operatorname{End}(V)$. Then, we may write

$$[F(\mathbf{x}, \mathbf{y}), A] = \tilde{F}(\mathbf{x}, \mathbf{y}) - F(A\mathbf{x}, \mathbf{y}) - F(\mathbf{x}, A\mathbf{y})\,,$$

where

$$\tilde{F}(\mathbf{x}, \mathbf{y}) = [F(\mathbf{x}, \mathbf{y}), A] + F(A\mathbf{x}, \mathbf{y}) + F(\mathbf{x}, A\mathbf{y})\,.$$

One checks by direct inspection that $\tilde{F} \in \mathfrak{K}(\mathfrak{h})$. ∎

Note that $\tilde{F}$ corresponds exactly to the action of A on F obtained by differentiating the equivariance condition (2.1.25).[18] Thus, by the Ambrose-Singer Theorem, for the Lie algebra $\mathfrak{h}_{u_0}(\Gamma)$ of the holonomy group of a torsion-free connection Γ, we have

$$\underline{\mathfrak{h}_{u_0}(\Gamma)} = \mathfrak{h}_{u_0}(\Gamma)\,.$$

We conclude that a Lie subalgebra $\mathfrak{h} \subset \mathfrak{gl}(n, \mathbb{R})$ can occur as the Lie algebra of the holonomy group of a torsion-free connection only if it coincides with the ideal $\underline{\mathfrak{h}}$. This is commonly referred to as the first criterion of Berger. It yields a necessary condition for a Lie subalgebra to be the holonomy Lie algebra of a torsion-free connection.

Next, let us analyze the Bianchi identity (2.1.16) in terms of $\mathscr{R}$. The covariant derivative $D\mathscr{R} = \mathrm{d}\mathscr{R} + \sigma'(\omega)\mathscr{R}$ is a horizontal 1-form on P with values in $\mathfrak{K}(\mathfrak{h})$.

Definition 2.3.2 A torsion-free connection fulfilling $D\mathscr{R} = 0$ is called locally symmetric.

Decomposing $D\mathscr{R}$ with respect to the horizontal frame $\{\theta^i\}$, we obtain a function $D\mathscr{R} : P \to V^* \otimes \mathfrak{K}(\mathfrak{h})$. Using the fact that the commutators of horizontal standard vector fields corresponding to a torsion-free connection are vertical (Exercise 2.3.1), we calculate

$$\begin{aligned} D\Omega(B(\mathbf{x}), B(\mathbf{y}), B(\mathbf{z})) &= \mathrm{d}\Omega(B(\mathbf{x}), B(\mathbf{y}), B(\mathbf{z})) \\ &= B(\mathbf{x})\big(\Omega(B(\mathbf{y}), B(\mathbf{z})\big) - \Omega([B(\mathbf{x}), B(\mathbf{y})], B(\mathbf{z})) + \text{cycl.} \\ &= \mathrm{d}\mathscr{R}(B(\mathbf{x}))(\mathbf{y} \wedge \mathbf{z}) + \text{cycl.} \\ &= D\mathscr{R}(\mathbf{x})(\mathbf{y} \wedge \mathbf{z}) + \text{cycl.}\ . \end{aligned}$$

Thus, by the Bianchi identity $D\Omega = 0$, we conclude that the function $D\mathscr{R}$ takes values in the kernel of the mapping

$$\delta' : V^* \otimes \mathfrak{K}(\mathfrak{h}) \to \textstyle\bigwedge^3 V^* \otimes \mathfrak{h}\,, \tag{2.3.7}$$

defined as the composition

$$V^* \otimes \mathfrak{K}(\mathfrak{h}) \to V^* \otimes \textstyle\bigwedge^2 V^* \otimes \mathfrak{h} \to \textstyle\bigwedge^3 V^* \otimes \mathfrak{h}$$

of the inclusion and the anti-symmetrization mappings. Clearly, the kernel of δ' is

$$\mathfrak{K}^1(\mathfrak{h}) := \left\{\Phi \in V^* \otimes \mathfrak{K}(\mathfrak{h}) : \Phi(\mathbf{x})(\mathbf{y}, \mathbf{z}) + \Phi(\mathbf{y})(\mathbf{z}, \mathbf{x}) + \Phi(\mathbf{z})(\mathbf{x}, \mathbf{y}) = 0\,,\ \ \mathbf{x}, \mathbf{y}, \mathbf{z} \in V\right\}\,.$$

Thus, if $\mathfrak{h}$ is the holonomy Lie algebra of a torsion-free linear connection that is not locally symmetric, then necessarily $\mathfrak{K}^1(\mathfrak{h}) \neq 0$. This is usually referred to as the second Berger criterion.

---

[18] Clearly, this is the action of the Killing vector field generated by A.

Definition 2.3.3 A Lie subalgebra $\mathfrak{h} \subset \mathrm{End}(V)$ is called a Berger algebra if $\underline{\mathfrak{h}} = \mathfrak{h}$. A Berger algebra is called symmetric if $\mathfrak{K}^1(\mathfrak{h}) = 0$ and non-symmetric otherwise. Correspondingly, a Lie subgroup $H \subset \mathrm{Aut}(V)$ is referred to as a (symmetric or non-symmetric) Berger group if its Lie algebra is a (symmetric or non-symmetric) Berger algebra.

By the above discussion, we have the following.

Proposition 2.3.4 (Berger) *Let $\mathfrak{h} \subset \mathrm{End}(V)$ be a Lie subalgebra. Then,*

1. *If $\mathfrak{h}$ is the Lie algebra of the holonomy group of a torsion-free connection on some manifold, then $\mathfrak{h}$ is a Berger algebra.*
2. *If $\mathfrak{K}^1(\mathfrak{h}) = 0$, then any torsion-free connection on a manifold whose holonomy Lie algebra is contained in $\mathfrak{h}$ must be locally symmetric.*

Based upon these criteria, Berger started to tackle the above classification problem. It is natural to distinguish between the following two classes:

(a) Lie subalgebras $\mathfrak{h}$ lying in some $\mathfrak{o}(\eta)$, where η is some non-degenerate bilinear form on V. In this case, the associated H-structure defines a pseudo-Riemannian manifold. Therefore, this is called the metric case.
(b) Lie subalgebras which are not contained in any orthogonal Lie algebra. This is called the non-metric case.

Within this general analysis, Berger obtained a list of candidates for Lie subalgebras of type (a) and also an (incomplete) list for type (b).[19] These lists where refined and completed by the work of Alekseevski [14], Bryant [108, 109], Chi [132], Merkulov and Schwachhöfer [569]. The final full classification of irreducible holonomies of torsion-free affine connections was obtained by Merkulov and Schwachhöfer [441]. For an exhaustive discussion, we refer to the reviews of Bryant [110] and Schwachhöfer [570] and to the textbooks of Besse [76], Joyce [353] and Salamon [555]. In [110], the reader can find the complete classification list (divided into four parts) together with a lot of information on methods for proving that a given group in the list really occurs as a holonomy. It turns out that every such group is realized at least locally.[20]

In the remainder of this section, we exclusively consider the metric case. That is, we consider (pseudo-)Riemannian manifolds (M, g), endowed with their unique torsion-free metric connection (the Levi-Civita connection). Under this assumption, the frame bundle reduces to the orthonormal frame bundle $O(M)$ and the whole theory may be described in terms of objects living on $O(M)$. Consequently, in the case under consideration, the holonomy group is a subgroup of the structure group $\mathrm{O}(k, l)$. If the Levi-Civita connection is locally symmetric, we call (M, g) locally symmetric.

---

[19] The list provided by Theorem 2.3.19 below is included in type (a).

[20] The appropriate method working for three of the above mentioned four tables is to describe torsion-free connections with a given holonomy as solutions to an exterior differential system and to apply Cartan's existence theorem.

Definition 2.3.5 Let (M, g) be a pseudo-Riemannian manifold. The curvature mapping

$$\mathscr{R} : O(M) \to \bigwedge^2 V^* \otimes \mathfrak{o}(k, l)$$

of the Levi-Civita connection of g is called the Riemann curvature mapping. Correspondingly, the curvature tensor R is called the Riemann curvature of (M, g).

Comparing with the general case, $\mathscr{R}$ has some additional properties coming from the fact that we may use the metric η to identify V with V^*. In particular, $\mathfrak{o}(k, l) \cong \bigwedge^2 V^*$, and thus

$$\mathscr{R}(u) \in \bigwedge^2 V^* \otimes \bigwedge^2 V^* , \tag{2.3.8}$$

for every $u \in O(M)$.

Proposition 2.3.6 *The Riemann curvature mapping* $\mathscr{R}$ *of a pseudo-Riemannian manifold has the following algebraic properties. For any* $\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w} \in V$,

$$\mathscr{R}(\mathbf{x}, \mathbf{y}) = -\mathscr{R}(\mathbf{y}, \mathbf{x}) , \tag{2.3.9}$$

$$\eta(\mathscr{R}(\mathbf{x}, \mathbf{y})\mathbf{z}, \mathbf{w}) = -\eta(\mathscr{R}(\mathbf{x}, \mathbf{y})\mathbf{w}, \mathbf{z}) , \tag{2.3.10}$$

$$\eta(\mathscr{R}(\mathbf{x}, \mathbf{y})\mathbf{z}, \mathbf{w}) = \eta(\mathscr{R}(\mathbf{z}, \mathbf{w})\mathbf{x}, \mathbf{y}) , \tag{2.3.11}$$

$$\mathscr{R}(\mathbf{x}, \mathbf{y})\mathbf{z} + \mathscr{R}(\mathbf{y}, \mathbf{z})\mathbf{x} + \mathscr{R}(\mathbf{z}, \mathbf{x})\mathbf{y} = 0 . \tag{2.3.12}$$

Proof Formulae (2.3.9) and (2.3.10) follow immediately from (2.3.8) and formula (2.3.12) is a direct consequence of the fact that $\mathscr{R}$ takes values in the kernel $\mathfrak{K}(\mathfrak{h})$ of the mapping (2.3.5). It remains to prove (2.3.11). For that purpose, we write down the following four versions of (2.3.12).

$$\begin{aligned}
0 &= \eta(\mathscr{R}(\mathbf{x}, \mathbf{y})\mathbf{z}, \mathbf{w}) + \eta(\mathscr{R}(\mathbf{y}, \mathbf{z})\mathbf{x}, \mathbf{w}) + \eta(\mathscr{R}(\mathbf{z}, \mathbf{x})\mathbf{y}, \mathbf{w}) , \\
0 &= \eta(\mathscr{R}(\mathbf{y}, \mathbf{z})\mathbf{w}, \mathbf{x}) + \eta(\mathscr{R}(\mathbf{z}, \mathbf{w})\mathbf{y}, \mathbf{x}) + \eta(\mathscr{R}(\mathbf{w}, \mathbf{y})\mathbf{z}, \mathbf{x}) , \\
0 &= -\eta(\mathscr{R}(\mathbf{z}, \mathbf{w})\mathbf{x}, \mathbf{y}) - \eta(\mathscr{R}(\mathbf{w}, \mathbf{x})\mathbf{z}, \mathbf{y}) - \eta(\mathscr{R}(\mathbf{x}, \mathbf{z})\mathbf{w}, \mathbf{y}) , \\
0 &= -\eta(\mathscr{R}(\mathbf{w}, \mathbf{x})\mathbf{y}, \mathbf{z}) - \eta(\mathscr{R}(\mathbf{x}, \mathbf{y})\mathbf{w}, \mathbf{z}) - \eta(\mathscr{R}(\mathbf{y}, \mathbf{w})\mathbf{x}, \mathbf{z}) .
\end{aligned}$$

Summation of these equations and using (2.3.9) and (2.3.10) yields the assertion. ■

Remark 2.3.7

1. By Proposition 2.3.6,

   $$\mathscr{R} : O(M) \to S^2\left(\bigwedge^2 V^*\right) , \tag{2.3.13}$$

   where $S^2\left(\bigwedge^2 V^*\right) = \bigwedge^2 V^* \overset{s}{\otimes} \bigwedge^2 V^*$ is the symmetrized tensor product. By (2.1.25), $\mathscr{R}$ has the following equivariance property, see Exercise 2.3.2,

   $$\mathscr{R}(\Psi_a(u))(\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{v}) = \mathscr{R}(u)(a\mathbf{x}, a\mathbf{y}, a\mathbf{u}, a\mathbf{v}) , \tag{2.3.14}$$

for $a \in \mathrm{O}(k,l)$ and $\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{v} \in V$.

2. By (2.1.27), the Riemann curvature R fulfils identities corresponding to (2.3.9)–(2.3.12) with $\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w} \in V$ replaced by $X, Y, Z, W \in \mathrm{T}_m M$ and η replaced by g. Thus, in particular, $\mathsf{R} \in \Gamma^\infty\big(S^2(\bigwedge^2 \mathrm{T}^*M)\big)$. For a local frame $\{e_i\}$, using (2.1.52) we write
$$\mathsf{R}_{ijkl} \equiv \mathsf{g}(\mathsf{R}(e_i, e_j)e_k, e_l) = \mathsf{R}^m{}_{ijk}\, \mathsf{g}_{ml} \,.$$

In this notation, the algebraic properties (2.3.9)–(2.3.12) read
$$\mathsf{R}_{ijkl} = -\mathsf{R}_{jikl}\,, \quad \mathsf{R}_{ijkl} = -\mathsf{R}_{ijlk}\,, \quad \mathsf{R}_{ijkl} = \mathsf{R}_{klij}\,, \tag{2.3.15}$$
$$\mathsf{R}_{ijkl} + \mathsf{R}_{jkil} + \mathsf{R}_{kijl} = 0 \tag{2.3.16}$$

◆

Using the above properties, the space of Riemann curvature mappings $\mathfrak{K}(\mathfrak{o}(k,l))$ may be characterized as follows. By standard representation theory of the group $\mathrm{O}(k,l)$, for $n \geq 4$, one obtains the following decompositions into $\mathrm{O}(k,l)$-irreducible modules [76, 555]:
$$\textstyle\bigwedge^3 V^* \otimes V^* = \bigwedge^2 V^* \oplus \bigwedge^4 V^* \oplus U\,, \tag{2.3.17}$$
$$S^2\left(\textstyle\bigwedge^2 V^*\right) = \mathbb{R} \oplus \Sigma_0^2 \oplus \textstyle\bigwedge^4 V^* \oplus W\,, \tag{2.3.18}$$

where Σ_0^2 stands for the space of traceless endomorphisms of $\mathbb{R}^n$ (viewed as symmetric 2-tensors) and where U and W are orthogonal complements. By dimension counting, U and W are not isomorphic.

Proposition 2.3.8 *The space of Riemann curvature mappings is given by*
$$\mathfrak{K}(\mathfrak{o}(k,l)) = \ker\varphi \,\cap\, S^2\left(\textstyle\bigwedge^2 V^*\right)\,, \tag{2.3.19}$$

where
$$\varphi : \textstyle\bigwedge^2 V^* \otimes \bigwedge^2 V^* \to \bigwedge^4 V^*\,, \quad \varphi(\xi \otimes \tau) := \xi \wedge \tau\,. \tag{2.3.20}$$

Proof Under the identifications $\mathfrak{o}(k,l) \cong \bigwedge^2 V^*$ and $V \cong V^*$, $\mathfrak{K}(\mathfrak{o}(k,l))$ coincides with the kernel of the mapping $\chi : \bigwedge^2 V^* \otimes \bigwedge^2 V^* \to \bigwedge^3 V^* \otimes V^*$ given by
$$\chi(\alpha \otimes (\zeta \wedge \tau)) := (\alpha \wedge \zeta) \otimes \tau - (\alpha \wedge \tau) \otimes \zeta\,.$$

Now, consider the decompositions (2.3.17) and (2.3.18). Viewing χ as an $\mathrm{O}(k,l)$-intertwining mapping and using Schur's Lemma, together with the fact that χ is surjective, we conclude that χ must be zero on the irreducible subspaces $\mathbb{R}$, Σ_0^2 and W. By dimension counting, these subspaces span the kernel of χ. Moreover, restricted to $S^2(\bigwedge^2 V^*)$, χ maps onto $\bigwedge^4 V^*$ and coincides with φ. ■

Combining (2.3.19) and (2.3.18), for $n \geq 4$, we obtain[21]

$$\mathfrak{K}(\mathfrak{o}(k,l)) = \mathbb{R} \oplus \Sigma_0^2 \oplus W\,. \tag{2.3.21}$$

This yields a decomposition of the Riemann curvature into its irreducible components with respect to the action of $\mathrm{O}(k,l)$. The component Σ_0^2 corresponds to the contraction to $V^* \otimes V^*$ defined by taking the trace of the mapping $\mathbf{z} \mapsto \mathscr{R}(\mathbf{z},\mathbf{x})\mathbf{y}$ and restricting it to $S^2(V^*)$.

Definition 2.3.9 (*Ricci tensor*) Let (M,g) be a pseudo-Riemannian manifold and let $\mathscr{R}$ be its Riemann curvature mapping. The mapping

$$\widetilde{\mathsf{Ric}} : O(M) \to S^2(V^*)\,, \quad \widetilde{\mathsf{Ric}}(u)(\mathbf{x},\mathbf{y}) := \operatorname{tr}\{\mathbf{z} \mapsto \mathscr{R}(u)(\mathbf{z},\mathbf{x})\mathbf{y}\} \tag{2.3.22}$$

is called the Ricci curvature mapping. Correspondingly,

$$\mathsf{Ric} : \mathrm{T}_m M \times \mathrm{T}_m M \to \mathbb{R}\,, \quad \mathsf{Ric}(X,Y) := \operatorname{tr}\{Z \mapsto \mathsf{R}(Z,X)Y\} \tag{2.3.23}$$

is called the Ricci tensor of (M,g).

Note that Ric is of the same geometric type as the metric. Thus, viewing it as a mapping $\mathrm{T}_m M \to \mathrm{T}_m^* M$ and using $\mathsf{g}^{-1} : \mathrm{T}_m^* M \to \mathrm{T}_m M$, we can define a scalar on M.

Definition 2.3.10 (*Scalar curvature*) Let (M,g) be a pseudo-Riemannian manifold and let Ric be its Ricci tensor. The function

$$\mathsf{Sc} : M \to \mathbb{R}\,, \quad \mathsf{Sc}(m) := \operatorname{tr}(\mathsf{g}^{-1} \circ \mathsf{Ric})(m) \tag{2.3.24}$$

is called the scalar curvature of (M,g). The corresponding equivariant function $\widetilde{\mathsf{Sc}} : O(M) \to \mathbb{R}$ is called the scalar curvature mapping.

The scalar curvature corresponds to the first component in the decomposition (2.3.21). The component corresponding to the third summand is called the Weyl tensor. In Sect. 2.8, the above decomposition will be discussed in detail for the case $n = 4$.

Remark 2.3.11 Denoting $\mathsf{R}_{ij} = \mathsf{Ric}(e_i, e_j)$, we obtain the following local expressions for the Ricci tensor and the scalar curvature,

$$\mathsf{R}_{ij} = \mathsf{g}^{kl}\,\mathsf{R}_{kijl}\,, \quad \mathsf{Sc} = \mathsf{g}^{ij}\,\mathsf{R}_{ij}\,. \tag{2.3.25}$$

In particular, for a holonomic frame, we obtain

$$\mathsf{R}_{ij} = \partial_i\,\Gamma^l{}_{jl} - \partial_j\,\Gamma^l{}_{il} + \Gamma^l{}_{jm}\Gamma^m{}_{il} - \Gamma^l{}_{im}\Gamma^m{}_{jl}\,. \tag{2.3.26}$$

---

[21] For $k + l = 3$, one obtains $\mathfrak{K}(\mathfrak{o}(k,l)) = \mathbb{R} \oplus \Sigma_0^2$. For $k + l = 4$, this result belongs to Singer and Thorpe [592].

For an orthonormal local frame, we have $\mathsf{R}_{ij} = \eta^{kl}\,\mathsf{R}_{kijl}$. This yields the following useful formula

$$\mathsf{Ric}(X, Y) = \eta^{kl}\mathsf{g}(\mathsf{R}(e_k, X)Y, e_l)\,, \quad X, Y \in \mathfrak{X}(M)\,. \tag{2.3.27}$$

◆

There is an important special class of Riemannian manifolds characterized by the fact that their curvature has a trivial Σ_0^2-component in the decomposition (2.3.21).

Definition 2.3.12 (*Einstein manifold*) A (pseudo-)Riemannian manifold (M, g) is called Einstein if its Ricci tensor is a constant multiple of the metric at each point of M.

Note that for an n-dimensional Einstein space (M, g) we have

$$\mathsf{Ric} = \frac{\mathsf{Sc}}{n}\,\mathsf{g}\,, \tag{2.3.28}$$

where Sc is constant. In Sect. 2.5, we will see a large class of Einstein manifolds.

In the next step, we show which impact the above additional structures have on the analysis of the Berger criteria in the metric case. For a chosen orthonormal frame $u_0 \in P_{u_0}(\Gamma)$, let us consider the holonomy bundle $P_{u_0}(\Gamma) \subset O(M)$. Let us denote

$$H = \mathscr{H}_{u_0}(\Gamma)\,, \quad \mathfrak{h} = \mathfrak{h}_{u_0}(\Gamma)\,.$$

On $P_{u_0}(\Gamma)$, the curvature takes values in $\mathfrak{h} \subset \mathfrak{o}(k, l) \cong \bigwedge^2(V^*)$. This fact, together with (2.3.19), implies the following.

Proposition 2.3.13 *For any point $u \in P_{u_0}(\Gamma)$, the Riemann curvature $\mathscr{R}(u)$ belongs to the space*

$$\mathfrak{K}(\mathfrak{h}) = \ker\varphi \,\cap\, S^2(\mathfrak{h})\,. \tag{2.3.29}$$

■

It turns out that for many subgroups $H \subset \mathrm{O}(k, l)$, the restriction of φ to $S^2(\mathfrak{h})$ is injective. This implies $\mathfrak{K}(\mathfrak{h}) = 0$ and, thus, $\underline{\mathfrak{h}} = 0$. Then, the first Berger criterion implies that, in this case, H cannot occur as a holonomy group.

In the same way, the covariant derivative $D\mathscr{R}$ may be dealt with. By the above discussion, we have the following.

Proposition 2.3.14 *For any point $u \in P_{u_0}(\Gamma)$, the covariant derivative of $\mathscr{R}(u)$ takes values in*

$$\mathfrak{K}^1(\mathfrak{h}) = \ker\delta' \,\cap\, \big(V^* \otimes \mathfrak{K}(\mathfrak{h})\big)\,, \tag{2.3.30}$$

where $\delta' : V^* \otimes \mathfrak{K}^1(\mathfrak{o}(k, l)) \to \bigwedge^3 V^* \times \mathfrak{o}(k, l)$, cf. formula (2.3.7). ■

As already mentioned above, the condition $\mathfrak{K}^1(\mathfrak{h}) = 0$ distinguishes a special class of possible candidates. By Proposition 2.3.4, in this case the Riemannian manifold is necessarily locally symmetric. We exclude this class of spaces for a while, postponing its presentation to Sect. 2.5.

Finally, we show that we may limit our attention to the case where the representation of the holonomy group H on $V \equiv \mathbb{R}^n$ is irreducible. We consider the Riemannian metric case and comment on the pseudo-Riemannian case at the end. Under this assumption, the holonomy group is a subgroup of $\mathrm{O}(n)$. Let us assume, on the contrary, that the representation of H is reducible, that is, there exists a proper subspace $W \subset V$ invariant under H. Since we assume that η be definite, there exists an invariant orthogonal complement $W^\perp \subset V$. Proceeding further in this manner, we obtain an invariant orthogonal decomposition

$$V = W_0 \oplus W_1 \oplus \ldots \oplus W_k \,, \tag{2.3.31}$$

with W_0 carrying the trivial representation[22] (acting as the identity) and W_k carrying nontrivial irreducible representations of H for all $k \geq 1$. The following theorem belongs to de Rham [150]. It simplifies the holonomy classification problem essentially.

Theorem 2.3.15 (de Rham Splitting Theorem) *Let* (M, g) *be a Riemannian manifold. If the holonomy group* H *acts reducibly on* $\mathbb{R}^n$*, then the restricted holonomy group*[23] H^0 *of* (M, g) *is isomorphic to a product,*

$$H^0 = \{e\} \times H_1 \times \ldots \times H_k \,,$$

and M *is locally isomorphic to a product of Riemannian manifolds,*

$$M_0 \times M_1 \times \ldots \times M_k \,,$$

with M_0 *being flat.*

Proof By the above discussion, $\mathscr{R} : O(M) \to \bigwedge^2 V^* \otimes \mathfrak{o}(n)$ and $\mathscr{R}(u)(\mathbf{x}, \mathbf{y})$ takes values in $\mathfrak{h} \equiv \mathfrak{h}_{u_0}(\Gamma)$, for any $u \in P_{u_0}(\Gamma)$ and any $\mathbf{x}, \mathbf{y} \in V$. Since the decomposition (2.3.31) is invariant, we have

$$\mathscr{R}(u)(\mathbf{x}, \mathbf{y})_{\restriction W_0} = 0 \,, \quad \mathscr{R}(u)(\mathbf{x}, \mathbf{y})_{\restriction W_i} \subset W_i \,, \tag{2.3.32}$$

for $1 \leq i \leq k$. We decompose $\mathbf{x} = \sum \mathbf{x}_i$ and $\mathbf{y} = \sum \mathbf{y}_i$ with respect to (2.3.31) and insert this decomposition into $\mathscr{R}(u)(\mathbf{x}, \mathbf{y})$. This yields

$$\mathscr{R}(u)(\mathbf{x}, \mathbf{y}) = \sum_i \mathscr{R}(u)(\mathbf{x}_i, \mathbf{y}_i) + \sum_{i \neq j} \mathscr{R}(u)(\mathbf{x}_i, \mathbf{y}_j) \,.$$

---

[22] Clearly, W_0 may be zero.

[23] By Theorem 1.7.9, this is the identity connected component of H.

By (2.3.12) and (2.3.32), we have $\mathscr{R}(u)(W_i, W_j)W_k = 0$ for i, j and k pairwise distinct. Next, consider the case $i = j \neq k$. Then, again by (2.3.12),

$$\mathscr{R}(u)(\mathbf{x}_i, \mathbf{y}_i)\mathbf{z}_k = 0 \,, \quad \mathscr{R}(u)(\mathbf{y}_i, \mathbf{z}_k)\mathbf{x}_i = -\mathscr{R}(u)(\mathbf{z}_k, \mathbf{x}_i)\mathbf{y}_i \,.$$

The first of these equations implies $\mathscr{R}(u)(W_i, W_i)W_k = 0$ for $i \neq k$. Using (2.3.11), from the second equation we obtain

$$\eta\big(\mathscr{R}(u)(\mathbf{z}_k, \mathbf{x}_i)\mathbf{y}_i, \mathbf{x}_i\big) = \eta\big(\mathscr{R}(u)(\mathbf{z}_k, \mathbf{y}_i)\mathbf{x}_i, \mathbf{x}_i\big) = \eta\big(\mathscr{R}(u)(\mathbf{x}_i, \mathbf{x}_i)\mathbf{z}_k, \mathbf{y}_i\big) \,,$$

and the anti-symmetry of $\mathscr{R}$ implies $\mathscr{R}(u)(W_k, W_i)W_i = 0$ for $i \neq k$. We conclude

$$\mathscr{R}(u)(\mathbf{x}, \mathbf{y}) = \sum_i \mathscr{R}(u)(\mathbf{x}_i, \mathbf{y}_i) \,.$$

Now, according to the equivariance of $\mathscr{R}$, as u ranges over $\pi^{-1}(m) \cap P_{u_0}(\Gamma)$ and $\mathbf{x}$, $\mathbf{y}$ over V, for every i, the mappings $\mathscr{R}(u)(\mathbf{x}_i, \mathbf{y}_i)$ span an ideal $\mathfrak{h}_i(m) \subset \mathrm{End}(W_i)$ of $\mathfrak{h}$. Finally, varying m yields ideals $\mathfrak{h}_i$ and, by (2.3.1), the decomposition

$$\mathfrak{h} = \mathfrak{h}_1 \oplus \ldots \oplus \mathfrak{h}_k \,.$$

This proves the first assertion. To prove the second assertion, first note that the splitting (2.3.31) induces a splitting of the horizontal distribution Γ on $P_{u_0}(\Gamma)$,

$$\Gamma = \Gamma_1 \oplus \ldots \oplus \Gamma_k \,, \quad \Gamma_i := \Gamma \cap \theta^{-1}(W_i) \,.$$

By H-equivariance, this splitting induces a family of distributions $D_i = \pi'(\Gamma_i)$ on M such that

$$\mathrm{T}M = D_1 \oplus \ldots \oplus D_k \,.$$

Moreover, corresponding to (2.3.31), let us decompose

$$\theta = \theta_1 + \ldots + \theta_k \,, \quad \omega = \omega_1 + \ldots + \omega_k \,, \quad \Omega = \Omega_1 + \ldots + \Omega_k \,,$$

with $\theta_i \in \Omega^1(P_{u_0}(\Gamma)) \otimes W_i$ and ω_i , $\Omega_i \in \Omega^*(P_{u_0}(\Gamma)) \otimes \mathfrak{h}_i$. We define the distributions

$$\hat{\Gamma}_i := \Gamma_i \oplus V_i$$

on $P_{u_0}(\Gamma)$, with V_i being the vertical distribution spanned by the Killing vector fields generated from elements of $\mathfrak{h}_i$. Clearly, Γ_i is spanned by the horizontal standard vector fields generated by any basis of W_i. Thus, $\hat{\Gamma}_i$ annihilates both θ_j, ω_j, and Ω_j for any $j \neq i$ and, by point 2 of Remark 2.1.14 and (1.4.5), for every i the distribution $\hat{\Gamma}_i$ is involutive. Consequently, by the Frobenius Theorem, it is integrable and, for every i, we have

$$\mathrm{d}\theta_i + \omega_i \wedge \theta_i = 0\,, \quad \Omega_i = \mathrm{d}\omega_i + \frac{1}{2}[\omega_i, \omega_i]\,. \qquad (2.3.33)$$

Let $P_i \subset P_{u_0}(\Gamma)$ be an integral manifold of $\hat{\Gamma}_i$. Integrability of $\hat{\Gamma}_i$ clearly induces integrability of D_i and the integral manifolds U_i of D_i fulfil $U_i = \pi(P_i) \subset M$. Moreover, for every i, the restriction $\pi_i : P_i \to U_i$ of π defines a principal H_i-bundle and, by (2.3.33), ω_i is a torsion-free connection on P_i with restricted holonomy group H_i.

To summarize, for every $m \in M$, there exists a neighbourhood $U \cong U_1 \times \ldots \times U_k$ of m in M, with the U_i being integral manifolds of D_i, and the Levi-Civita connection restricted to U being a product of the Levi-Civita connections on the components U_i. ■

Definition 2.3.16 A Riemannian manifold (M, g) which is locally isomorphic to a product of Riemannian manifolds is called locally reducible. It is called irreducible if it is not locally reducible.

Clearly, by Theorem 2.3.15, if (M, g) is irreducible, then the restricted holonomy group necessarily acts irreducibly. Under additional assumptions, de Rham [150] was able to prove the following global version of Theorem 2.3.15.

Theorem 2.3.17 (Global de Rham Splitting Theorem) *Let (M, g) be a geodesically complete simply connected Riemannian manifold and assume that the holonomy group*[24] *of the Levi-Civita connection acts reducibly. Then, (M, g) is the direct product of geodesically complete simply connected irreducible Riemannian manifolds (M_i, g_i),*

$$(M, \mathsf{g}) = (M_0, \mathsf{g}_0) \times (M_1, \mathsf{g}_1) \times \ldots \times (M_k, \mathsf{g}_k)\,.$$

Here, (M_0, g_0) is a Euclidean vector space whose dimension is possibly zero. ■

Remark 2.3.18 Both versions of the de Rham Splitting Theorem have been extended to the case of an indefinite metric by Wu [682, 683]. ♦

Summarizing our discussion, for finding the possible holonomy groups of a Riemannian manifold (M, g), it is reasonable to make the following assumptions:

(a) M is simply connected. This ensures that the holonomy group is connected and that it coincides with the restricted holonomy group.
(b) (M, g) is irreducible. This implies that the holonomy group acts irreducibly.
(c) (M, g) is not locally symmetric. This requires $\mathfrak{K}^1(\mathfrak{h}) \neq 0$.

Under these assumptions, for the Riemannian case, Berger obtained the following.

Theorem 2.3.19 (Berger) *Let (M, g) be an n-dimensional simply connected irreducible Riemannian manifold which is not locally symmetric. Then, its holonomy group H belongs to one of the following classes:*

---

[24] By Remark 1.7.11, if M is simply connected, then the holonomy group and the restricted holonomy group coincide.

1. $H = \mathrm{SO}(n),\ n \geq 2$, *(generic Riemannian manifold)*
2. $H = \mathrm{U}(m),\ n = 2m \geq 4$, *(generic Kähler manifold)*
3. $H = \mathrm{SU}(m),\ n = 2m \geq 4$, *(special Kähler manifold)*
4. $H = \mathrm{Sp}(m) \cdot \mathrm{Sp}(1),\ n = 4m \geq 8$, *(quaternionic Kähler manifold)*
5. $H = \mathrm{Sp}(m),\ n = 4m \geq 8$, *(Hyper-Kähler manifold)*
6. $H = G_2,\ n = 7$, *(special holonomy)*
7. $H = \mathrm{Spin}(7),\ n = 8$, *(special holonomy).* ■

For the proof, which is beyond the scope of this book, we refer to [68, 69, 555].

Remark 2.3.20

1. An elegant proof of Theorem 2.3.19 is obtained from the following result of Simons [591]: if M is irreducible, then either the holonomy group H acts transitively on S^{n-1} or its identity component acts trivially on the space of curvature tensors $\mathfrak{K}(\mathfrak{h})$. Then, Theorem 2.3.19 is obtained by using the classification of simple Lie algebras and their representations.
2. According to Examples 2.2.22 and 2.2.27, it was clear from the beginning that the groups $\mathrm{SO}(n)$ and $\mathrm{U}(n)$ must occur in the above list. For a detailed discussion of examples for all the groups occuring in Theorem 2.3.19, we refer to [555]. ♦

Exercises

2.3.1 Show that the commutators of horizontal standard vector fields corresponding to a torsion-free connection are vertical.

2.3.2 Confirm the equivariance property (2.3.14). *Hint:* Under the identification $\mathfrak{o}(n) \cong (\mathbb{R}^n)^* \wedge (\mathbb{R}^n)^*$, the adjoint representation is mapped onto the second exterior power of the dual of the basic representation.

2.3.3 Show that, in terms of the Riemann curvature R, the Bianchi identity (2.1.16) reads

$$(\nabla_X \mathsf{R})(Y, Z) + (\nabla_Y \mathsf{R})(Z, X) + (\nabla_Z \mathsf{R})(X, Y) = 0\,. \tag{2.3.34}$$

2.4 Sectional Curvature

In this section, we discuss a generalization of the classical Gaussian curvature of surfaces in $\mathbb{R}^3$. It reduces the study of the Riemann curvature to the study of real valued functions. Let (M, g) be a pseudo-Riemannian manifold. Let $\Sigma_m \subset \mathrm{T}_m M$ be a 2-dimensional subspace such that $\mathsf{g}_{\restriction \Sigma_m}$ is non-degenerate. Let $\{X, Y\}$ be an arbitrary basis of Σ_m. We put

$$\mathsf{K}(\Sigma_m) := \frac{\langle \mathsf{R}(X, Y)Y, X\rangle}{\| X \|^2 \| Y \|^2 - \langle X, Y\rangle^2}\,, \tag{2.4.1}$$

where $\| \cdot \|^2$ and $\langle \cdot, \cdot \rangle$ are the quadratic form and the bilinear form, respectively, induced from g. It can be easily shown that $\mathsf{K}(\Sigma_p)$ is well defined, that is,

(a) the right hand side of (2.4.1) does not depend on the choice of the basis. This is a simple consequence of the symmetry properties of R given by point 2 of Remark 2.3.7 and is, thus, left to the reader (Exercise 2.4.1).
(b) Σ_m is non-degenerate iff $\| X \|^2 \| Y \|^2 - \langle X, Y \rangle^2 \neq 0$, (Exercise 2.4.2).

Note that K may be viewed as a mapping from the Graßmann manifold $G_2(\mathrm{T}_m M)$ to $\mathbb{R}$. Let $G_2^0(\mathrm{T}_m M) \subset G_2(\mathrm{T}_m M)$ be the subset of non-degenerate subspaces.

Definition 2.4.1 The mapping $\mathsf{K} : G_2^0(\mathrm{T}_m M) \to \mathbb{R}$ given by (2.4.1) is called the sectional curvature of the pseudo-Riemannian manifold at $m \in M$.

Clearly, in the Riemannian case, every 2-dimensional subspace of $\mathrm{T}_m M$ is non-degenerate.

Proposition 2.4.2 *The curvature tensor* R *is completely determined by the sectional curvature. If the mapping* K *is constant, that is,* $\mathsf{K}(\Sigma_m) = k(m)$ *for every* $\Sigma_m \in G_2^0(\mathrm{T}_m M)$, *then*

$$\mathsf{R}_m(X, Y)Z = k(m)\big(\langle Y, Z \rangle X - \langle X, Z \rangle Y\big) . \tag{2.4.2}$$

Conversely, if (2.4.2) *is fulfilled, then all non-degenerate planes have sectional curvature* $k(m)$.

Proof The proof of the first assertion is the consequence of the following simple polarization argument. Denote $\alpha(X, Y) := \langle \mathsf{R}(X, Y)X, Y \rangle$, for any $X, Y \in \mathrm{T}_m M$. Then, by direct inspection,

$$\begin{aligned} -6\langle \mathsf{R}(X, Y)Z, W \rangle = {} & \alpha(X + W, Y + Z) - \alpha(X + W, Y) - \alpha(X + W, Z) \\ & - \alpha(X, Y + Z) - \alpha(W, Y + Z) + \alpha(X, Z) + \alpha(W, Y) \\ & - \alpha(Y + W, X + Z) + \alpha(Y + W, X) + \alpha(Y + W, Z) \\ & + \alpha(Y, X + Z) + \alpha(W, X + Z) - \alpha(Y, Z) - \alpha(W, X) , \end{aligned}$$

showing that R is determined by α and, thus, by K. We prove the second statement. For that purpose, denote

$$\mathsf{R}_0(X, Y)Z := \langle Y, Z \rangle X - \langle X, Z \rangle Y .$$

Note that R_0 shares the symmetry properties (2.3.9), (2.3.10) and (2.3.12) of R.[25] Assume that $\mathsf{K}(\Sigma_m) = k(m)$ for all non-degenerate planes. If X, Y span a non-degenerate plane, then by (2.4.1),

$$\langle \mathsf{R}(X, Y)Y, X \rangle = k(m)\big(\langle Y, Y \rangle X - \langle X, Y \rangle Y\big) = \langle k(m)\mathsf{R}_0(X, Y)Y, X \rangle .$$

---

[25] It also shares the symmetry property (2.3.11), but this is not needed here.

Thus, the tensor $\hat{\mathsf{R}} := \mathsf{R} - k(m)\mathsf{R}_0$ has the above symmetry properties and fulfils

$$\langle \hat{\mathsf{R}}(X, Y)Y, X\rangle = 0\,. \tag{2.4.3}$$

If X and Y span a degenerate plane, we can choose sequences $X_n \to X$ and $Y_n \to Y$ of tangent vectors such that X_n and Y_n span non-degenerate planes for each n.[26] Then, $\langle \hat{\mathsf{R}}(X_n, Y_n)Y_n, X_n\rangle = 0$ for all n and, thus, (2.4.3) holds for degenerate planes as well. Finally, note that this equation is also true for pairs X, Y which are linearly dependent. We conclude that (2.4.3) holds for all $X, Y \in \mathrm{T}_m M$. Now, the assertion is a consequence of the following simple algebraic fact (Exercise 2.4.3): If

$$\tilde{\mathsf{R}} : \mathrm{T}_m M \times \mathrm{T}_m M \times \mathrm{T}_m M \times \mathrm{T}_m M \to \mathbb{R}$$

is a quadrilinear mapping sharing the symmetry properties (2.3.9), (2.3.10) and (2.3.12) of R, then $\langle \tilde{\mathsf{R}}(X, Y)Y, X\rangle = 0$ implies $\tilde{\mathsf{R}} = 0$.

The converse statement is trivial. ■

Proposition 2.4.2 leads us to an important class of pseudo-Riemannian manifolds.

Definition 2.4.3 If $\mathsf{K}(\Sigma_m) = k(m)$ for every $\Sigma_m \in G_2^0(\mathrm{T}_m M)$, then we say that (M, g) is a space of constant curvature at m. Let k be a real number. We say that (M, g) is a space of constant curvature k if $\mathsf{K}(\Sigma_m) = k$ at every point $m \in M$.

Remark 2.4.4

1. By the proof of Proposition 2.4.2, for a space of constant curvature, we have

$$\mathsf{R}(X, Y)Z = k\big(\langle Y, Z\rangle X - \langle X, Z\rangle Y\big)\,, \quad k \in \mathbb{R}\,. \tag{2.4.4}$$

2. By a theorem of Schur, see Theorem 2.2. in Chap. V of [381], if (M, g) is a space of constant curvature at every point of M and $\dim M \geq 3$, then M is a space of constant curvature, that is, the mapping $m \to k(m)$ is constant.
3. It is not hard to construct models of spaces of constant curvature. The simplest Riemannian example is the n-sphere of radius r embedded in the standard way in $\mathbb{R}^{n+1}$. This is a space of constant curvature equal to $\frac{1}{r^2}$. The simplest pseudo-Riemannian model is the pseudo-Euclidean space $(\mathbb{R}^n_s, \mathsf{g}^n_s)$ with the signature $(n - s, s)$. It is easy to show that this is a space of constant curvature equal to 0. In Sect. 2.5, we will see a large class of spaces of constant curvature. For an exhaustive presentation of this subject we refer to [676].
4. In the indefinite case, there is a lot of subtleties and there is quite a number of classical papers on that subject, see [63, 145, 257, 395, 490] and further references therein. ♦

---

[26] By property (b) above, in any fixed basis of $\mathrm{T}_m M$, $\| X \|^2 \| Y \|^2 - \langle X, Y\rangle^2$ is a polynomial in the components of X and Y whose zero set does not contain any open subset.

Exercises

2.4.1 Prove that (2.4.1) does not depend on the choice of the basis.

2.4.2 Show that the restriction of a pseudo-Riemannian metric to a 2-dimensional subspace $\Sigma_m \subset \mathrm{T}_m M$ is non-degenerate iff $\parallel X \parallel^2 \parallel Y \parallel^2 - \langle X, Y\rangle^2 \neq 0$.

2.4.3 Prove the following. If $\tilde{\mathsf{R}} : \mathrm{T}_m M \times \mathrm{T}_m M \times \mathrm{T}_m M \times \mathrm{T}_m M \to \mathbb{R}$ is a quadrilinear mapping sharing the symmetry properties (2.3.9), (2.3.10) and (2.3.12) of R, then $\langle \tilde{\mathsf{R}}(X, Y)Y, X\rangle = 0$ implies $\tilde{\mathsf{R}} = 0$.

2.5 Symmetric Spaces

In this section, we take up the discussion from Sect. 2.3. We analyze the special case $\mathfrak{K}^1(\mathfrak{h}) = 0$, that is, we analyze the condition

$$D\mathscr{R} = 0\,, \tag{2.5.1}$$

defining locally symmetric manifolds, cf. Definition 2.3.2. Thus, we give up assumption (c) prior to Theorem 2.3.19, but we keep on assuming the following.

(a) M is simply connected, which ensures that the holonomy group H is connected and that it coincides with the restricted holonomy group.
(b) (M, g) is irreducible, which implies that H acts irreducibly.

Moreover, as above, we limit our attention to the Riemannian metric case, that is, $H \subset \mathrm{O}(n)$ is a compact Lie subgroup acting irreducibly on $V \equiv \mathbb{R}^n$. Then, by the Holonomy Principle, cf. Proposition 1.7.20, the space of parallel sections of

$$E = O(M) \times_{\mathrm{O}(n)} S^2\left(\bigwedge\nolimits^2 V^*\right)$$

is in one-to-one correspondence with the space of holonomy-invariant vectors in $S^2\left(\bigwedge^2 V^*\right)$ as follows. Any $\mathscr{R}$ satisfying (2.5.1) is constant on $P_{u_0}(\Gamma)$ and, restricted to $P_{u_0}(\Gamma)$, it takes values in $\mathfrak{K}(\mathfrak{h})$ given by (2.3.29). Thus, the Holonomy Principle assigns to $\mathscr{R}$ the H-invariant element

$$F := \mathscr{R}(u) \in \mathfrak{K}(\mathfrak{h}), \quad u \in P_{u_0}(\Gamma)\,. \tag{2.5.2}$$

Lemma 2.5.1 *Let $H \subset \mathrm{O}(n)$ be a closed subgroup and let $F \in \mathfrak{K}(\mathfrak{h})$ be an H-invariant element. Then, $\mathfrak{g} = \mathfrak{h} \oplus V$ carries the structure of a Lie algebra given by*

$$[A, \mathbf{x}] = -[\mathbf{x}, A] = A\mathbf{x}\,, \quad [\mathbf{x}, \mathbf{y}] = -F(\mathbf{x}, \mathbf{y})\,, \quad A \in \mathfrak{h}\,,\ \mathbf{x}, \mathbf{y} \in V\,.$$

Proof Bilinearity and anti-symmetry are obvious. We prove that the Jacobi identity holds. For that purpose, we have to consider three cases:
(a) Let $\mathbf{x}, \mathbf{y}, \mathbf{z} \in V$. Since $F(\mathbf{x}, \mathbf{y}) \in \mathfrak{h} \subset \mathrm{End}(V)$, the definition of $\mathfrak{K}(\mathfrak{h})$ implies

$$[[\mathbf{x}, \mathbf{y}], \mathbf{z}] + [[\mathbf{y}, \mathbf{z}], \mathbf{x}] + [[\mathbf{z}, \mathbf{x}], \mathbf{y}] = 0 .$$

(b) Let $\mathbf{x}, \mathbf{y} \in V$. By the H-invariance of F, cf. (2.1.25), we have

$$F(\mathbf{x}, \mathbf{y}) = \mathrm{Ad}(a^{-1}) \circ F(a\mathbf{x}, a\mathbf{y}) , \quad a \in H \subset \mathrm{O}(n) .$$

Differentiating this equation, we obtain

$$[F(\mathbf{x}, \mathbf{y}), A] + F(A\mathbf{x}, \mathbf{y}) + F(\mathbf{x}, A\mathbf{y}) = 0$$

for any $A \in \mathfrak{h}$. This implies

$$[[\mathbf{x}, \mathbf{y}], A] + [[\mathbf{y}, A], \mathbf{x}] + [[A, \mathbf{x}], \mathbf{y}] = 0 .$$

(c) Let $\mathbf{x} \in V$ and $A, B \in \mathfrak{h}$. Then, by definition of the Lie bracket of $\mathfrak{h} \subset \mathrm{End}(V)$,

$$[A, B](\mathbf{x}) = A(B\mathbf{x}) - B(A\mathbf{x}) .$$

This proves the third case. ■

To make contact with the standard notation, we denote $V = \mathfrak{m}$. Then,

$$\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m} \tag{2.5.3}$$

and the commutation relations of $\mathfrak{g}$ fulfil:

$$[\mathfrak{h}, \mathfrak{h}] \subset \mathfrak{h} , \quad [\mathfrak{h}, \mathfrak{m}] \subset \mathfrak{m} , \quad [\mathfrak{m}, \mathfrak{m}] \subset \mathfrak{h} . \tag{2.5.4}$$

Moreover, by the Ambrose-Singer Theorem,

$$[\mathfrak{m}, \mathfrak{m}] = \mathfrak{h} . \tag{2.5.5}$$

Associated with the decomposition (2.5.3), there is a linear mapping

$$\lambda : \mathfrak{g} \to \mathfrak{g} , \quad \lambda(A, \mathbf{x}) := (A, -\mathbf{x}) , \quad A \in \mathfrak{h} , \mathbf{x} \in \mathfrak{m} . \tag{2.5.6}$$

By (2.5.4), λ is an involutive Lie algebra homomorphism (Exercise 2.5.1). Conversely, we have the following.

Lemma 2.5.2 *Any involutive Lie algebra homomorphism* λ *of a Lie algebra* $\mathfrak{g}$ *induces a decomposition* $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ *fulfilling* (2.5.4).

Proof Since $\lambda^2 = \mathrm{id}$, λ is diagonalizable and we may decompose $\mathfrak{g}$ into the eigenspaces $\mathfrak{h}$ and $\mathfrak{m}$ of λ corresponding to the eigenvalues $+1$ and -1, respectively. Now, the first relation in (2.5.4) is obvious. To check the remaining two, we calculate

$$\lambda([A, \mathbf{x}]) = [\lambda(A), \lambda(\mathbf{x})] = -[A, \mathbf{x}] , \quad A \in \mathfrak{h} , \ \mathbf{x} \in \mathfrak{m} ,$$

that is, $[A, \mathbf{x}] \in \mathfrak{m}$. Similarly, $\lambda([\mathbf{x}, \mathbf{y}]) = [\mathbf{x}, \mathbf{y}] \in \mathfrak{h}$ for any $\mathbf{x}, \mathbf{y} \in \mathfrak{m}$. ■

Definition 2.5.3 Let $\mathfrak{g}$ be a Lie algebra and let λ be an involutive automorphism of $\mathfrak{g}$. Then, the pair $(\mathfrak{g}, \lambda)$ is called a symmetric Lie algebra. In addition,

1. if the set of fixed points $\mathfrak{h}$ of λ is a compactly embedded Lie subalgebra[27] of $\mathfrak{g}$, then $(\mathfrak{g}, \lambda)$ is called an orthogonal symmetric Lie algebra,
2. if $\mathfrak{h} \cap \mathfrak{z} = \{0\}$, where $\mathfrak{z}$ is the center of $\mathfrak{g}$, then $(\mathfrak{g}, \lambda)$ is called effective.
3. if $(\mathfrak{g}, \lambda)$ is effective and $\mathrm{ad}([\mathfrak{m}, \mathfrak{m}])$ acts irreducibly on $\mathfrak{m}$, then $(\mathfrak{g}, \lambda)$ is called irreducible.

Proposition 2.5.4 *The Lie algebra* $\mathfrak{g}$ *constructed in Lemma 2.5.1, endowed with the involutive automorphism* λ *given by* (2.5.6)*, is an irreducible orthogonal symmetric Lie algebra.*

Proof By construction, $(\mathfrak{g}, \lambda)$ is symmetric. Since, by assumption, $H \subset \mathrm{O}(n)$ is a compact Lie subgroup acting faithfully on $\mathbb{R}^n$, $\mathrm{ad}(\mathfrak{h})$ is compact and, thus, $(\mathfrak{g}, \lambda)$ is orthogonal. Suppose $A \in \mathfrak{h} \cap \mathfrak{z}$. Then,

$$A\mathbf{x} = [A, \mathbf{x}] = 0$$

for every $\mathbf{x} \in \mathfrak{m}$ and, thus, $A = 0$. Thus, $(\mathfrak{g}, \lambda)$ is effective. Finally, by assumption, H acts irreducibly on $\mathfrak{m}$. Thus, $\mathrm{ad}(\mathfrak{h})$ acts irreducibly on $\mathfrak{m}$, too. This, together with (2.5.5) implies that $(\mathfrak{g}, \lambda)$ is irreducible. ■

In the sequel, the pair $(\mathfrak{g}, \lambda)$ constructed above will be called the canonical symmetric Lie algebra associated with the locally symmetric Riemannian manifold we started with. The decomposition (2.5.3) will be called the canonical decomposition of $(\mathfrak{g}, \lambda)$.

The following proposition characterizes irreducible symmetric Lie algebras.

Proposition 2.5.5 *Let* $(\mathfrak{g}, \lambda)$ *be an irreducible symmetric Lie algebra and let* $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ *be the decomposition induced by* λ*. Then, one of the following cases occurs:*

1. $\mathfrak{g}$ *is a simple Lie algebra.*
2. $\mathfrak{g} = \tilde{\mathfrak{g}} \oplus \tilde{\mathfrak{g}}$ *with* $\tilde{\mathfrak{g}}$ *simple, fulfilling* $\mathfrak{h} = \big\{(A, A) : A \in \tilde{\mathfrak{g}}\big\}$ *and* $\lambda(A, B) = (B, A)$ *for any* $A, B \in \tilde{\mathfrak{g}}$.
3. $[\mathfrak{m}, \mathfrak{m}] = 0$.

For the proof we refer the reader to [381].[28]

---

[27] That is, the group of transformations of $\mathfrak{g}$ generated by $\mathrm{ad}(\mathfrak{h})$ is compact.

[28] Cf. Proposition 7.5 in Vol. 2, Chap. XI of [381].

Remark 2.5.6

1. Assume that either point 1 or point 2 of Proposition 2.5.5 holds. Then, since $[\mathfrak{m}, \mathfrak{m}] \oplus \mathfrak{m}$ is an ideal in $\mathfrak{g}$, we have $\mathfrak{h} = [\mathfrak{m}, \mathfrak{m}]$. Thus, an effective symmetric Lie algebra is irreducible iff $\mathfrak{h} = [\mathfrak{m}, \mathfrak{m}]$, that is, iff $\mathfrak{g}$ is of the form described either by point 1 or by point 2. In particular, if $(\mathfrak{g}, \lambda)$ is irreducible, then $\mathfrak{g}$ is semisimple.
2. Conversely, if $(\mathfrak{g}, \lambda)$ is an orthogonal symmetric Lie algebra and $\mathfrak{g}$ is simple, then $\mathrm{ad}(\mathfrak{h})$ acts irreducibly on $\mathfrak{m}$, see Proposition 7.4 in Vol. 2, Chap. XI of [381]. ♦

Proposition 2.5.5 and property (2.5.5) imply that the canonical symmetric Lie algebra $(\mathfrak{g}, \lambda)$ is semisimple. Consequently, by Proposition I/5.4.10, the Killing form

$$\mathsf{k} : \mathfrak{g} \times \mathfrak{g} \to \mathbb{R}, \quad \mathsf{k}(X, Y) = \mathrm{tr}(\mathrm{ad}(X)\mathrm{ad}(Y)),$$

of $\mathfrak{g}$ is non-degenerate. Moreover, the relations (2.5.4) imply that the decomposition (2.5.3) is orthogonal with respect to k (Exercise 2.5.2). Equivalently, k is λ-invariant. This implies that the restrictions $\mathsf{k}^{\mathfrak{h}}$ and $\mathsf{k}^{\mathfrak{m}}$ of k to $\mathfrak{h}$ and $\mathfrak{m}$, respectively, are both non-degenerate and λ-invariant, too. Moreover, they have the following properties:

(a) By Corollary I/5.5.8, $\mathsf{k}^{\mathfrak{h}}$ is negative semidefinite and, since $(\mathfrak{g}, \lambda)$ is effective, it is negative definite.

(b) Since $\mathrm{ad}(\mathfrak{h})$ acts irreducibly on $\mathfrak{m}$ and since both $\mathsf{k}^{\mathfrak{m}}$ and the scalar product η on $\mathfrak{m}$ induced from the metric g are $\mathrm{ad}(\mathfrak{h})$-invariant, by Schur's Lemma, they must be proportional to each other,

$$\eta(\mathbf{x}, \mathbf{z}) = -c\, \mathsf{k}^{\mathfrak{m}}(\mathbf{x}, \mathbf{z}), \quad \mathbf{x}, \mathbf{z} \in \mathfrak{m}, \ c \in \mathbb{R}, c \neq 0. \tag{2.5.7}$$

Thus, since η is positive definite, $\mathsf{k}^{\mathfrak{m}}$ is either positive or negative definite.

Definition 2.5.7 An effective orthogonal symmetric Lie algebra $(\mathfrak{g}, \lambda)$ with $\mathfrak{g}$ semisimple is said to be of compact or of non-compact type, if the restriction of the Killing form of $\mathfrak{g}$ to $\mathfrak{m}$ is, respectively, negative definite or positive definite.

Remark 2.5.8 Combining Proposition 2.5.5 with Propositions 7.4 and 7.5 in in Vol. 2, Chap. XI of [381], one can show that any irreducible orthogonal symmetric Lie algebra is either of compact or of non-compact type. ♦

Next, we show that, given an irreducible orthogonal symmetric Lie algebra $(\mathfrak{g}, \lambda)$, one can construct a special type of homogeneous Riemannian manifold.

Let $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ be the decomposition induced from λ. Let $\tilde{G}$ be the connected simply connected Lie group with Lie algebra $\mathfrak{g}$ and let $\tilde{H}$ be the connected Lie subgroup corresponding to $\mathfrak{h}$. Then, the space of left cosets $M := \tilde{G}/\tilde{H}$ is a simply connected manifold endowed with the natural left $\tilde{G}$-action given by left translations. Let

$$\tilde{Z} = \left\{ g \in \tilde{G} : g(m) = m \ \text{ for all } \ m \in M \right\}$$

be the kernel of this action. Since, by assumption, $(\mathfrak{g}, \lambda)$ is effective, $\tilde{Z}$ must be discrete. Thus, M is an almost effective $\tilde{G}$-manifold. We pass to an effective action by setting $G := \tilde{G}/\tilde{Z}$ and $H := \tilde{H}/\tilde{Z}$. Then, $M = G/H$, G and H are connected, and we have the natural left effective action

$$\delta : G \times G/H \to G/H\,, \quad (a, [g]) \mapsto \delta_a([g]) := [ag]\,.$$

By point 4 of Example 1.1.4, the natural projection $\pi : G \to M$ endows G with the structure of a principal H-bundle P and the tangent mapping π' identifies $\mathfrak{m}$ and $\mathrm{T}_{[\mathbb{1}]}M$ as vector spaces. Under this identification, the isotropy representation

$$H \to \mathrm{Aut}(\mathrm{T}_{[\mathbb{1}]}M)\,, \quad h \mapsto (\delta_h)'_{\mathbb{1}}\,,$$

is given by $\mathrm{Ad}(H)$ acting on $\mathfrak{m}$, cf. point 1 of Remark I/6.2.10. Correspondingly,

$$G \times_{\mathrm{Ad}(H)} \mathfrak{m} \to \mathrm{T}M\,, \quad [(a, \mathbf{x})] \mapsto [\mathrm{L}'_a(\mathbf{x})], \tag{2.5.8}$$

is an isomorphism. Since $(\mathfrak{g}, \lambda)$ is orthogonal and irreducible, there exists an $\mathrm{Ad}(H)$-invariant scalar product η on $\mathfrak{m}$ which is unique up to a positive factor. Clearly, η induces an H-invariant scalar product on $\mathrm{T}_{[\mathbb{1}]}M$ which, using the left G-action δ, can be extended to a G-invariant Riemannian metric g on M. To summarize, we have constructed a simply connected transitive and effective G-manifold (M, g) with G acting by isometries.

Consider the bundle of orthonormal frames $O(M)$ of (M, g). Note that any η-orthonormal basis $(\mathbf{e}_1, \ldots, \mathbf{e}_n)$ of $\mathfrak{m}$ induces via π' a g-orthonormal frame $(e_1, \ldots, e_n)$ at $[\mathbb{1}] \in M$ and, thus, an injective bundle morphism

$$\vartheta : P \to O(M)\,, \quad \vartheta(a) := (\delta'_a(e_1), \ldots, \delta'_a(e_n))\,, \tag{2.5.9}$$

projecting onto the identical diffeomorphism of M. The corresponding Lie group homomorphism $\tau : H \to O(n) \subset \mathrm{GL}(n, \mathbb{R}) \cong \mathrm{Aut}(\mathrm{T}_m M)$ is given by the adjoint action of H on $\mathfrak{m} \cong \mathrm{T}_{[\mathbb{1}]}M$. To summarize, P is a subbundle of $O(M)$.

Now, decompose the Maurer–Cartan form $\theta^G \in \Omega^1(G, \mathfrak{g})$ with respect to (2.5.3):

$$\theta^G = \theta_{\mathfrak{h}} + \theta_{\mathfrak{m}}\,.$$

By Example 1.3.19, $\theta_{\mathfrak{h}}$ coincides with the canonical G-invariant connection[29] ω^c on P. Recall that the corresponding horizontal distribution is generated by $\mathfrak{m}$, that is, by left invariant vector fields $a \mapsto (\mathbf{x}_*)_a = L'_a(\mathbf{x})$ with $\mathbf{x} \in \mathfrak{m}$.

Lemma 2.5.9 *Under the morphism* (ϑ, τ), $\theta_{\mathfrak{m}}$ *corresponds to the soldering form* θ *on* $O(M)$, *that is,* $\vartheta^*\theta = \theta_{\mathfrak{m}}$.

---

[29] Note that this is a special case of the canonical invariant connection defined in point 2 of Remark 1.9.14. It is obtained by setting $G = H$ and $\lambda = \mathrm{id}$ there.

Proof By $\mathfrak{m}$-valuedness of $\theta_\mathfrak{m}$ and horizontality of θ, both $\vartheta^*\theta$ and $\theta_\mathfrak{m}$ vanish on the left invariant vector fields generated by elements of $\mathfrak{h}$. Thus, let $\mathbf{x}_*$ be generated by $\mathbf{x} \in \mathfrak{m}$. Then, clearly $\theta_\mathfrak{m}(\mathbf{x}_*) = \mathbf{x}$. On the other hand,

$$(\vartheta^*\theta)_g(\mathbf{x}_*) = \vartheta(g)^{-1}(\rho' \circ \vartheta'(\mathbf{x}_*)) = \vartheta(g)^{-1}(\pi'(\mathbf{x}_*)) = \vartheta(g)^{-1}(\delta'_g \circ \pi'(\mathbf{x})) = \mathbf{x}\,,$$

where $\rho : O(M) \to M$ is the canonical projection. ■

Proposition 2.5.10 *The Riemannian manifold (M, g) has the following properties:*

1. *Under the morphism (ϑ, τ), the Levi-Civita connection ω^0 of (M, g) corresponds to the canonical connection ω^c, that is, $\vartheta^*\omega^0 = \omega^c$.*
2. *The Riemann curvature of (M, g) is constant and given by the linear mapping*

$$F : \bigwedge{}^2\mathfrak{m} \to \mathfrak{h}\,, \quad F(\mathbf{x}, \mathbf{y}) = -[\mathbf{x}, \mathbf{y}]\,. \tag{2.5.10}$$

3. *The holonomy group based at $\vartheta(\mathbb{1})$ of ω^0 is H and the holonomy bundle coincides with P.*
4. *The Riemann curvature of (M, g) is parallel, that is, (M, g) is locally symmetric.*
5. *For any $\mathbf{x} \in \mathfrak{m}$, $t \mapsto \pi(L_g \exp(t\mathbf{x}))$ is a geodesic through $[g] \in M$. Conversely, every geodesic through $[g]$ is of this form. In particular, M is geodesically complete.*

Proof 1. We decompose the commutator $[\theta^G, \theta^G] \in \Omega^2(G, \mathfrak{g})$ with respect to (2.5.3). By (2.5.4),

$$[\theta^G, \theta^G]_\mathfrak{h} = [\theta_\mathfrak{h}, \theta_\mathfrak{h}] + [\theta_\mathfrak{m}, \theta_\mathfrak{m}]\,, \quad [\theta^G, \theta^G]_\mathfrak{m} = 2[\theta_\mathfrak{h}, \theta_\mathfrak{m}]\,. \tag{2.5.11}$$

Since the Levi-Civita connection is uniquely characterized by its covariant derivative D_{ω^0} on $\mathrm{T}M$, it is enough to show that the covariant derivative D_{ω^c} induced by ω^c via the isomorphism (2.5.8) coincides with D_{ω^0}. This is done by showing that the extension of ω^c to $O(M)$ is metric and torsionless. By Proposition 1.2.6, we may view any vector field X on M as an H-equivariant mapping $\tilde{X} : G \to \mathfrak{m}$ and, thus,

$$D_{\omega^c}\tilde{X} = \mathrm{d}\tilde{X} + \mathrm{ad}(\omega^c) \circ \tilde{X} = \mathrm{d}\tilde{X} + [\theta_\mathfrak{h}, \tilde{X}]\,,$$

cf. Eq. (1.4.2). Let η be the (unique up to a positive factor) $\mathrm{Ad}(H)$-invariant scalar product on $\mathfrak{m}$. By $\mathrm{Ad}(H)$-invariance, we obtain

$$\eta(D_{\omega^c}\tilde{X}, \tilde{Y}) + \eta(\tilde{X}, D_{\omega^c}\tilde{Y}) = \mathrm{d}(\eta(\tilde{X}, \tilde{Y}))\,.$$

This shows that the extension of ω^c to $O(M)$ is metric. It remains to show that this extension is torsionless: restricting the Maurer–Cartan equation to $\mathfrak{m}$ and using (2.5.11) we get

$$D_{\omega^c}\theta_\mathfrak{m} = \mathrm{d}\theta_\mathfrak{m} + [\theta_\mathfrak{h}, \theta_\mathfrak{m}] = 0\,.$$

But, by Lemma 2.5.9, $\vartheta^*\theta = \theta_\mathfrak{m}$ and, thus, $\vartheta^*\Theta = 0$. By uniqueness of the Levi-Civita connection, the assertion follows.

2. By the Structure Equation, the curvature form of ω^c is given by[30]

$$\Omega^c = -\frac{1}{2}[\theta_\mathfrak{m}, \theta_\mathfrak{m}]\,.$$

By point 1, $\vartheta^*\Omega^0 = \Omega^c$. These two facts immediately imply (2.5.10).

3. By point 2 and by the Ambrose-Singer Theorem, the Lie algebra of the holonomy group of ω^0 is $[\mathfrak{m}, \mathfrak{m}]$. By point 1 of Remark 2.5.6, $[\mathfrak{m}, \mathfrak{m}] = \mathfrak{h}$ and, thus, the Lie algebra of the holonomy group of ω^0 coincides with $\mathfrak{h}$. Since, by construction, M is simply connected, the holonomy group of ω^0 is connected and coincides with the restricted holonomy group. On the other hand, since H is connected, too, we obtain the assertion. It follows that P coincides with the holonomy bundle of ω^0.

4. Since the curvature is constant on P and, thus, H-invariant, the Holonomy Principle 1.7.20 implies the assertion.

5. By Proposition 2.1.22, the geodesics of (M, g) are given by the projections of integral curves of horizontal standard vector fields on $L(M)$. Since they are horizontal, these curves may be chosen to lie in P. The restriction of $B(\mathbf{y})$, $\mathbf{y} \in \mathbb{R}^n$, to P is given by the left-invariant vector field generated by $\mathbf{x} = y^i\mathbf{e}_i \in \mathfrak{m}$, where $\{\mathbf{e}_i\}$ is a basis in $\mathfrak{m}$. Thus, here, the geodesics are given as projections of (global) one-parameter subgroups $t \mapsto \exp(t\mathbf{x})$ and their left translates by arbitrary group elements $g \in G$. ■

By point 3 of Proposition 2.5.10, the irreducibility of $(\mathfrak{g}, \lambda)$ implies that (M, g) is irreducible. Together with points 4 and 5, this yields the following.

Corollary 2.5.11 *(M, g) is a complete irreducible locally symmetric Riemannian manifold.* ■

Next, we show that the involutive automorphism λ induces a special symmetry for any point $m \in M$. Since any automorphism of a Lie algebra is the differential of a unique automorphism of the corresponding simply connected Lie group,[31] λ induces a unique automorphism σ of $\tilde{G}$. By (2.5.6), it fulfils $\sigma(\tilde{H}) = \tilde{H}$. Thus, σ descends to an involutive diffeomorphism $s : M \to M$. By construction,

$$s'_{[\mathbb{1}]} : \mathrm{T}_{[\mathbb{1}]}M \to \mathrm{T}_{[\mathbb{1}]}M\,, \quad s'_{[\mathbb{1}]}(X) = -X\,. \tag{2.5.12}$$

Thus, under the identification $\mathrm{T}_{[\mathbb{1}]}M = \mathfrak{m}$, we have $s'_{[\mathbb{1}]} = \lambda_{\restriction\mathfrak{m}}$.

Lemma 2.5.12 *The origin $[\mathbb{1}]$ of M is an isolated fixed point of s. Moreover, s is an isometry of the Riemannian metric g.*

---

[30] Since ω^c is a G-invariant connection, this is a special case of point 4 of Remark 1.9.14.

[31] For a proof, see e.g. Theorem 3.27 in [652].

Proof The proof of the first assertion is left to the reader (Exercise 2.5.4). To prove the second statement, we have to show that the mapping

$$s'_m : \mathrm{T}_m M \to \mathrm{T}_m M$$

is isometric. For the point $m = [\mathbb{1}]$, this follows immediately from (2.5.12), because at the origin g coincides with η and the latter is λ-invariant. To prove the invariance for an arbitrary point $m = [g]$, note that for any $g, h \in G$,

$$s(\delta_g[h]) = s([gh]) = [\sigma(g)\sigma(h)] = \delta_{\sigma(g)}[\sigma(h)] = \delta_{\sigma(g)} s([h]) ,$$

that is, $s \circ \delta_g = \delta_{\sigma(g)} \circ s$. Differentiation of this identity yields

$$s'_{[g]} \circ (\delta_g)'_{[\mathbb{1}]} = (\delta_{\sigma(g)})'_{[\mathbb{1}]} \circ s'_{[\mathbb{1}]} .$$

By construction, g is G-invariant and, thus, $(\delta_g)'_{[\mathbb{1}]}$ and $(\delta_{\sigma(g)})'_{[\mathbb{1}]}$ leave g invariant. This yields the assertion. ■

Remark 2.5.13 For every $g \in \tilde{Z}$, we have $\big(\sigma(g)\big)(m) = s \circ g \circ s(m) = s^2(m) = m$. Hence, $\sigma(\tilde{Z}) = \tilde{Z}$ and σ descends to an automorphism of G, denoted by the same symbol. One has $\sigma(H) = H$. ♦

Next, for any $m = [g] \in M$, we define[32]

$$s_m : M \to M , \quad s_m := \delta_g \circ s \circ \delta_{g^{-1}} . \tag{2.5.13}$$

Differentiating (2.5.13), we obtain $s'_m = \delta'_g \circ s'_{[\mathbb{1}]} \circ \delta'_{g^{-1}}$ for any $m = [g] \in M$. Thus, by Lemma 2.5.12, by formula (2.5.12) and by the G-invariance of g, for any $m \in M$, s_m is an involutive isometry of g fulfilling (Exercise 2.5.5)

$$s_m(m) = m , \quad (s_m)'_m = -\,\mathrm{id} . \tag{2.5.14}$$

The following remark yields a geometric interpretation of the symmetry s_m.

Remark 2.5.14 Let $t \to \gamma(t)$ be a geodesic of (M, g) with $\gamma(0) = m$. Since an isometry transforms geodesics to geodesics, $t \mapsto \tau(t) := s_m(\gamma(t))$ is a geodesic, too. By (2.5.14), its tangent vector at $t = 0$ satisfies

$$\dot{\tau}(0) = (s_m)'_m \, \dot{\gamma}(0) = -\dot{\gamma}(0) . \tag{2.5.15}$$

Now, the uniqueness property of geodesics, see Corollary 2.1.23, implies $\tau(t) = \gamma(-t)$. Thus, for any $m \in M$,

---

[32] Clearly, this definition does not depend on the choice of the representative.

$$s_m(\gamma(t)) = \gamma(-t)\,, \tag{2.5.16}$$

that is, s_m reverses the geodesics through m. ◆

Definition 2.5.15 (*Riemannian globally symmetric space*) A Riemannian manifold (M, g) is called globally symmetric if for each $m \in M$ there exists an involutive isometry $s_m : M \to M$ such that m is an isolated fixed point of s_m. The mapping s_m is called the symmetry of (M, g) at m.

Taking into account that, in the above construction of (M, g), the scalar product on $\mathfrak{m}$ is unique up to a positive constant and that a change of this constant implies a conformal transformation of g, we obtain the following.

Proposition 2.5.16 *To any irreducible*[33] *orthogonal symmetric Lie algebra* $(\mathfrak{g}, \lambda)$ *there corresponds a unique homothetic equivalence class* $(M, [\mathsf{g}])$ *of simply connected irreducible Riemannian globally symmetric spaces.* ■

It should be clear that the locally symmetric Riemannian manifold we started with and the Riemannian globally symmetric space constructed here are deeply related. Indeed, let (M, g) be a locally symmetric space. Let $(\mathfrak{g}, \lambda)$ be its canonical symmetric Lie algebra with canonical decomposition $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$. Let $\eta \in S^2(\mathfrak{m}^*)$ be the scalar product on $\mathfrak{m}$ defined by g and let $F \in \mathfrak{K}(\mathfrak{h}) \subset \bigwedge^2 \mathfrak{m}^* \otimes \mathfrak{h}$ be the Riemann curvature of (M, g). Let G/H be the Riemannian globally symmetric space constructed from $(\mathfrak{g}, \lambda)$. Then, for any chosen point $m \in M$, via

$$\mathrm{T}_m M \cong \mathfrak{m} \cong \mathrm{T}_{[1]} G/H$$

we obtain an isometric isomorphism between $\mathrm{T}_m M$ and $\mathrm{T}_{[1]} G/H$ and, by point 2 of Proposition 2.5.10, M and G/H have the same Riemann curvature given by the mapping F. By standard arguments,[34] this implies the following.

Corollary 2.5.17 *Every point of a locally symmetric space* (M, g) *admits a neighbourhood isometric to a neighbourhood of the origin of the Riemannian globally symmetric space constructed from the canonical symmetric Lie algebra of* (M, g).

Note, however, that not every locally symmetric space is a Riemannian globally symmetric space. It is even not necessarily homogeneous. As an example,[35] let M be a compact Riemann surface with genus ≥ 2, equipped with a Riemannian metric of constant curvature equal to -1. Then, the isometry group of M is finite and, thus, M is not homogeneous and, consequently, also not globally symmetric.

As an immediate consequence of the existence of the symmetries s_m, we obtain

Proposition 2.5.18 *Any Riemannian globally symmetric space* (M, g) *is complete.*

---

[33] Remember that irreducibility includes effectiveness, cf. Definition 2.5.3.

[34] See Theorem 7.4 in Chap. VI of [381].

[35] This example is taken from [73].

Proof Consider any geodesic $t \mapsto \gamma(t)$ defined on the interval $[0, t_0[$. Apply the symmetry $s_{\gamma(t_0-\varepsilon)}$ to γ with some ε fulfilling $0 < \varepsilon < \frac{t_0}{2}$. By (2.5.16), this operation extends the domain of γ to $[0, 2t_0 - 2\varepsilon[$. Continuing this procedure, we obtain completeness of (M, g). ■

Next, given a Riemannian globally symmetric space (M, g), for every geodesic $t \mapsto \gamma(t)$ we consider the family of isometries

$$T^{\gamma}_t := s_{\gamma(\frac{t}{2})} \circ s_{\gamma(0)}\,, \tag{2.5.17}$$

called the transvections along γ. The following properties are immediate consequences of (2.5.15) and (2.5.16) and are, therefore, left to the reader (Exercise 2.5.3).

Proposition 2.5.19 *Let (M, g) be a Riemannian globally symmetric space and let $t \mapsto \gamma(t)$ be a geodesic. Then,*

1. *T^{γ}_t acts on γ by translations, that is, $T^{\gamma}_t(\gamma(s)) = \gamma(t+s)$.*
2. *$(T^{\gamma}_t)'_{\gamma(s)}$ acts by parallel translation from $\gamma(s)$ to $\gamma(t+s)$ along γ, that is, for any parallel vector field X along γ,*

$$(T^{\gamma}_t)'_{\gamma(s)}(X(\gamma(s)) = X(\gamma(t+s))\,.$$

3. *$\left\{T^{\gamma}_t\right\}_{t\in\mathbb{R}}$ is a 1-parameter group of isometries, that is, $T^{\gamma}_{t+s} = T^{\gamma}_t \circ T^{\gamma}_s$.* ■

Recall from Example 2.2.16 that the isometry group $I(M)$ of a Riemannian manifold M is a Lie group. Let us denote its identity component by $I_0(M)$. By point 3 of Proposition 2.5.19, for any geodesic γ, the transvections T^{γ}_t form a subgroup (called the transvection group) of $I_0(M)$. On the other hand, by a classical theorem of Hopf and Rinow,[36] any two points of a complete Riemannian manifold may be joined by a geodesic. Using these two facts, we obtain the following.

Corollary 2.5.20 *Let (M, g) be a Riemannian globally symmetric space. Then,*

1. *Geodesics in M are images of 1-parameter groups of isometries.*
2. *The identity component $I_0(M)$ acts transitively on M.* ■

Proposition 2.5.21 *Let (M, g) be an irreducible Riemannian globally symmetric space and let G be a Lie group acting transitively and isometrically on M. If G acts effectively, then G coincides with $I_0(M)$.*

Proof Clearly, $I_0(M)$ is the largest connected group of isometries of (M, g). Denote $G' = I_0(M)$ and let $\mathfrak{g}'$ be its Lie algebra. Conjugation by s defines an automorphism σ' of G' which clearly restricts to the automorphism σ of G, cf. Remark 2.5.13. The canonical decompositions $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ and $\mathfrak{g}' = \mathfrak{h}' \oplus \mathfrak{m}'$ necessarily fulfil $\mathfrak{m}' = \mathfrak{m}$. Here $\mathfrak{h}'$ is the Lie algebra of the stabilizer of the chosen point on M under G'. Thus, by Remark 2.5.6,

---

[36] See, e.g. [352].

$$\mathfrak{h} = [\mathfrak{m}, \mathfrak{m}] = [\mathfrak{m}', \mathfrak{m}'] = \mathfrak{h}' .$$

This implies $\mathfrak{g}' = \mathfrak{g}$ and, thus, $G' = G$. ■

Thus, in the construction leading to Proposition 2.5.16, the Lie group G actually coincides with $I_0(M)$. Now, we are able to prove the converse of Proposition 2.5.16.

Proposition 2.5.22 *To any simply connected irreducible Riemannian globally symmetric space there corresponds a unique irreducible orthogonal symmetric Lie algebra.*

Proof Let (M, g) be a simply connected irreducible Riemannian globally symmetric space. By Corollary 2.5.20, $G = I_0(M)$ acts transitively and effectively on M. Let H be the isotropy group of this Lie group action at a chosen point $o \in M$. By the homotopy sequence of the fibration $H \to G \to G/H$, the simply-connectedness of G/H and the connectedness of G imply that H is connected. Moreover, by Theorem 3.4 in Chap. VI of [381], the isotropy subgroup $I(M)_m$ at any point $m \in M$ is compact. Hence, $H = G \cap I(M)_o$ is compact, too. Thus, $M = G/H$ and, by standard arguments, $\pi : G \to M$ is a submersion. In particular, $\pi' : \mathrm{T}_1 G \to \mathrm{T}_o M$ is an H-equivariant surjective linear mapping whose kernel coincides with $\mathrm{T}_1 H$.

Let s be the symmetry at o. Since s is an involutive diffeomorphism, the mapping $g \mapsto \sigma(g) := s \circ g \circ s^{-1}$ defines an involutive automorphism of G. Let $\mathfrak{g}$ and $\mathfrak{h}$ be the Lie algebras of G and H, respectively. Clearly, $\lambda := \sigma'$ is an involutive automorphism of $\mathfrak{g}$. Let $\mathfrak{m}$ be the eigenspace of λ corresponding to the eigenvalue -1. By (2.5.14), $\pi'(\mathfrak{m}) = \mathrm{T}_o M$. We prove that $\mathfrak{h}$ is the eigenspace of λ corresponding to the eigenvalue $+1$: let

$$G^\sigma := \{g \in G : \sigma(g) = g\}$$

be the fixed point set of σ. By (2.5.14), s_o' commutes with the isotropy representation of H at o and, thus, H is contained in G^σ. Conversely, if $g \in G^\sigma$, then it commutes with s and, thus, for any 1-parameter subgroup $t \mapsto g_t$ of G^σ,

$$s \circ g_t(o) = g_t \circ s(o) = g_t(o) ,$$

that is, the orbit $g_t(o)$ is left invariant pointwise by s. Now, by Lemma 2.5.12, o is an isolated fixed point. Thus, $g_t(o)$ must coincide with o. But, $g_t(o) = o$ implies that the 1-parameter subgroup $t \mapsto g_t$ is contained in H. Since a connected Lie group is generated by its 1-parameter subgroups, we have $(G^\sigma)^0 \subset H$. Thus,

$$(G^\sigma)^0 \subset H \subset G^\sigma .$$

This relation implies that $\mathfrak{h}$ coincides with the $(+1)$-eigenspace of λ, indeed. To summarize, the decomposition $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ is canonical with respect to λ, that is, $(\mathfrak{g}, \lambda)$ is a symmetric Lie algebra. Since H is compact, $\mathrm{ad}(\mathfrak{h})$ is a compactly embedded Lie subalgebra of $\mathfrak{g}$, that is, $(\mathfrak{g}, \lambda)$ is orthogonal. It remains to prove that $(\mathfrak{g}, \lambda)$ is irreducible. Since g is G-invariant, we are in the situation described by Proposition

2.5.10. By this proposition, H coincides with the holonomy group of the Levi-Civita connection of g. Thus, the irreducibility of (M, g), together with the effectiveness of the action of G on M, implies the irreducibility of $(\mathfrak{g}, \lambda)$. ■

Remark 2.5.23 In the course of the above proof, we have found the following structure: a triple (G, H, σ) fulfilling

1. G is a connected Lie group and H is a closed subgroup,
2. σ is an involutive automorphism of G such that $(G^\sigma)^0 \subset H \subset G^\sigma$,
3. $\mathrm{Ad}(H)$ is compact,

is called a Riemannian symmetric pair. This notion clearly constitutes a link between symmetric spaces and symmetric Lie algebras. ♦

Combining Proposition 2.5.16 with Proposition 2.5.22, we obtain the following.

Theorem 2.5.24 *The homothetic equivalence classes of simply connected irreducible Riemannian globally symmetric spaces are in one-to-one correspondence with the irreducible orthogonal symmetric Lie algebras.* ■

This theorem reduces the classification of symmetric spaces of the above type to the classification of irreducible symmetric Lie algebras of compact or of non-compact type. According to a beautiful duality,[37] the problem further reduces to the classification of irreducible symmetric Lie algebras of the non-compact type. The latter can be shown to be in one-to-one correspondence with the real simple Lie algebras of non-compact type. If the complexification of such a Lie algebra is simple as a complex Lie algebra, then M is said to be of type III, otherwise M is said to be of type IV. The corresponding compact irreducible symmetric spaces are obtained by duality and are referred to as of type I and II, respectively. The complete list of simply connected irreducible symmetric spaces with symmetry group being a classical Lie group is given in Tables 2.1 and 2.2.[38] Here, $\mathrm{SO}_0(p, q)$ denotes the identity component of $\mathrm{SO}(p, q)$ and $\mathrm{SO}^*(2n)$ is the subgroup of $\mathrm{SO}(2n, \mathbb{C})$ satisfying

$$g^{\mathrm{T}} \mathsf{J}_0 \overline{g} = \mathsf{J}_0 , \quad g^{\mathrm{T}} g = \mathbb{1}_{2n} .$$

For the corresponding list with exceptional Lie groups we refer to the textbook of Helgason [293]. As already mentioned, there the reader may find an exhaustive presentation of the whole subject.

Remark 2.5.25 Note that in our considerations, we have excluded the class of symmetric Lie algebras fulfilling $[\mathfrak{m}, \mathfrak{m}] = 0$, cf. case 3 in Proposition 2.5.5. Symmetric Lie algebras with this property are said to be of Euclidean type. By point 2 of Proposition 2.5.10, they are necessarily flat. One can show that if G/H is simply connected,

---

[37] See Sect. 8 of Chap. XI in [381] or Sect. 2 of Chap. V in [293].

[38] By definition, the rank is the dimension of some maximal Abelian subspace of $\mathfrak{m}$. Any two maximal Abelian subspaces of $\mathfrak{m}$ are $\mathrm{Ad}(H)$-conjugate.

then a symmetric space of this type is isometric to some Euclidean space $\mathbb{R}^n$. Clearly, $\mathbb{R}^n$ itself provides the simplest example, with the symmetry at the origin given by $s : \mathbf{x} \to -\mathbf{x}$. ◆

Next, we show that Riemannian symmetric spaces provide Riemannian manifolds of certain types met before. Recall that if $(\mathfrak{g},\lambda)$ is irreducible, then $\mathfrak{g}$ is necessarily semisimple and thus, the Killing form k is non-degenerate. As already noted, this implies

$$\eta(\mathbf{x},\mathbf{z}) = -c\,\mathsf{k}^{\mathfrak{m}}(\mathbf{x},\mathbf{z})\,, \quad \mathbf{x},\mathbf{z}\in\mathfrak{m}\,, \tag{2.5.18}$$

for some $c\in\mathbb{R}$, $c\neq 0$, cf. (2.5.7). Recall from point 2 of Proposition 2.5.10 that the curvature mapping $\mathscr{R}$ is given by the mapping F, cf. formula (2.5.10). Substituting $\mathbf{x} = F(\mathbf{u},\mathbf{v})\mathbf{w}$ into (2.5.18) and using the $\mathrm{ad}(\mathfrak{h})$-invariance of k, we obtain

$$\eta(F(\mathbf{u},\mathbf{v})\mathbf{w},\mathbf{z}) = c\,\mathsf{k}^{\mathfrak{m}}([[\mathbf{u},\mathbf{v}],\mathbf{w}],\mathbf{z}) = c\,\mathsf{k}^{\mathfrak{h}}([\mathbf{u},\mathbf{v}],[\mathbf{w},\mathbf{z}])\,. \tag{2.5.19}$$

Setting $\mathbf{x}=\mathbf{u}=\mathbf{z}$ and $\mathbf{y}=\mathbf{v}=\mathbf{w}$ in (2.5.19), we immediately obtain the following formula for the sectional curvature:

$$\eta(F(\mathbf{x},\mathbf{y})\mathbf{y},\mathbf{x}) = -c\,\mathsf{k}^{\mathfrak{h}}([\mathbf{x},\mathbf{y}],[\mathbf{x},\mathbf{y}])\,. \tag{2.5.20}$$

This yields useful formulae for the Ricci tensor and for the scalar curvature. For any orthonormal basis $\{\mathbf{e}_i\}$ of $\mathfrak{m}$,

$$\mathsf{Ric}(\mathbf{e}_i, \mathbf{e}_j) = -\sum_k \eta([[\mathbf{e}_k, \mathbf{e}_i], \mathbf{e}_j], \mathbf{e}_k)\,, \quad \mathsf{Sc} = -\sum_{k,l} \eta([[\mathbf{e}_k, \mathbf{e}_l], \mathbf{e}_l], \mathbf{e}_k)\,. \tag{2.5.21}$$

Proposition 2.5.26 *Let (M, g) be an irreducible Riemannian globally symmetric space and let $(\mathfrak{g}, \lambda)$ be the corresponding irreducible orthogonal symmetric Lie algebra.*

1. *If $(\mathfrak{g}, \lambda)$ is of compact type, then (M, g) is a compact Einstein manifold with non-negative sectional curvature and positive definite Ricci tensor.*
2. *If $(\mathfrak{g}, \lambda)$ is of non-compact type, then (M, g) is a simply connected Einstein manifold with non-positive sectional curvature and negative definite Ricci tensor. Moreover, M is diffeomorphic to a Euclidean space.*

Proof Let $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ be the canonical decomposition. By Theorem 2.5.24, $G = I_0(M)$ acts transitively and effectively on M and g is G-invariant. Since $k^{\mathfrak{h}}$ is negative definite, the statements about the sectional curvature K follow immediately from (2.5.20). Since the Ricci tensor Ric is a symmetric $\mathrm{ad}(\mathfrak{h})$-invariant bilinear form on $\mathfrak{m}$ and since $\mathrm{ad}(\mathfrak{h})$ acts irreducibly on $\mathfrak{m}$, Ric must be proportional to the metric, that is, (M, g) is an Einstein space.

1. Let $(\mathfrak{g}, \lambda)$ be of compact type. Then, K is non-negative and, thus, Ric is semi-positive definite. Since M is Einstein, Ric is either positive definite or zero. But if Ric is zero, then (2.3.27) implies that K must also be zero, which contradicts the non-degeneracy of k and, thus, the irreducibility of $(\mathfrak{g}, \lambda)$. Finally, since $\mathsf{k}^{\mathfrak{m}}$ is negative definite, k is negative definite and, since $\mathfrak{g}$ is semisimple, G is compact. Thus, M is compact.

2. Let $(\mathfrak{g}, \lambda)$ be of non-compact type. Then, by similar arguments, M is Einstein with negative definite Ricci tensor. The remaining statement follows from Theorem 8.3 in Chap. VIII of [381]. ■

In the remainder of this section, we present the symmetric space structure of a few of the types in Table 2.1 explicitly. By Theorem 2.5.24, it is enough to exhibit the corresponding symmetric Lie algebra structure. For a much more detailed discussion of examples we refer to Chap. XI of [381] and to [692]. We leave it to the reader to check the statements below (Exercise 2.5.6).

Example 2.5.27

1. Consider type I in lines 3, 4, and 7 of Table 2.1. Lines 3 and 7 correspond to the Graßmann manifolds

$$G_{\mathbb{K}}(k, n) \cong \mathrm{U}_{\mathbb{K}}(n)/(\mathrm{U}_{\mathbb{K}}(n-k) \times \mathrm{U}_{\mathbb{K}}(k))\,, \quad \mathbb{K} = \mathbb{C}, \mathbb{H}\,,$$

and line 4 corresponds to the Graßmann manifold of oriented subspaces of $\mathbb{R}^{p+q}$.[39] The corresponding symmetric Lie algebra is given by

$$\mathfrak{u}_{\mathbb{K}}(p+q) = (\mathfrak{u}_{\mathbb{K}}(p) \oplus \mathfrak{u}_{\mathbb{K}}(q)) \oplus \mathfrak{m}\,,$$

where

$$\begin{aligned} \mathfrak{u}_{\mathbb{K}}(p) \oplus \mathfrak{u}_{\mathbb{K}}(q) &= \left\{ \begin{bmatrix} A & 0 \\ 0 & B \end{bmatrix} \in \mathfrak{u}_{\mathbb{K}}(p+q) : A \in \mathfrak{u}_{\mathbb{K}}(p)\,,\ B \in \mathfrak{u}_{\mathbb{K}}(q) \right\}\,, \\ \mathfrak{m} &= \left\{ \begin{bmatrix} 0 & -X^{\dagger} \\ X & 0 \end{bmatrix} \in \mathfrak{u}_{\mathbb{K}}(p+q) : X \in L(\mathbb{K}^p, \mathbb{K}^q) \right\}\,. \end{aligned}$$

The action of $\mathrm{Ad}(H)$ on $\mathfrak{m}$ is given by

$$X \mapsto hXk^{-1}\,, \quad h \in \mathrm{U}_{\mathbb{K}}(q)\,,\ k \in \mathrm{U}_{\mathbb{K}}(p)\,,$$

and the involutive automorphism λ acts via

$$\begin{bmatrix} A & -X^{\dagger} \\ X & B \end{bmatrix} \mapsto \begin{bmatrix} A & X^{\dagger} \\ -X & B \end{bmatrix}\,.$$

The corresponding involutive automorphism σ is given by conjugation with

$$\mathbb{1}_{p,q} = \begin{bmatrix} -\mathbb{1}_p & 0 \\ 0 & \mathbb{1}_q \end{bmatrix}\,. \tag{2.5.22}$$

2. Consider the special case $p = n$ and $q = 1$ for type I in line 4 of Table 2.1:

$$\mathrm{S}^n = S_{\mathbb{R}}(1, n+1) = \mathrm{SO}(n+1)/\mathrm{SO}(n)\,.$$

The underlying symmetric Lie algebra is given by

$$\mathfrak{o}(n+1) = \mathfrak{o}(n) \oplus \mathfrak{m}\,, \tag{2.5.23}$$

where

$$\begin{aligned} \mathfrak{o}(n) &= \left\{ \begin{bmatrix} 0 & 0 \\ 0 & A \end{bmatrix} \in \mathfrak{o}(n+1) : A \in \mathfrak{o}(n) \right\}\,, \\ \mathfrak{m} &= \left\{ \begin{bmatrix} 0 & -\mathbf{x}^{\mathrm{T}} \\ \mathbf{x} & 0 \end{bmatrix} \in \mathfrak{o}(n+1) : \mathbf{x} \in \mathbb{R}^n \right\}\,. \end{aligned}$$

Then, $\mathrm{Ad}(\mathrm{SO}(n))$ gets identified with the basic representation of $\mathrm{SO}(n)$ on $\mathbb{R}^n$ and, under the identification $\mathfrak{m} \cong \mathbb{R}^n$, the Euclidean scalar product on $\mathbb{R}^n$ yields a scalar product on $\mathfrak{m}$ which coincides with the restriction of the Killing form on $\mathfrak{o}(n+1)$ to $\mathfrak{m}$ up to the factor $-2(n-1)$. The involutive automorphisms are read off from the previous point.

---

[39] Cf. Example I/7.5.6.

3. Consider type I in line 5 of Table 2.1. One easily shows that $\mathrm{SO}(2n)/\mathrm{U}(n)$ is the space of orthogonal complex structures on the $2n$-dimensional Euclidean space.[40] Here we decompose[41]

$$\mathfrak{o}(2n) = \mathfrak{u}(n) \oplus \mathfrak{m}\,,$$

with

$$\begin{aligned}\mathfrak{u}(n) &= \left\{ \begin{bmatrix} X & Y \\ -Y & X \end{bmatrix} \in \mathfrak{o}(2n) : X, Y \in \mathfrak{gl}(n,\mathbb{R})\,,\ X = -X^{\mathrm{T}}\,,\ Y = Y^{\mathrm{T}} \right\}\,,\\ \mathfrak{m} &= \left\{ \begin{bmatrix} X & Y \\ Y & -X \end{bmatrix} \in \mathfrak{o}(2n) : X, Y \in \mathfrak{gl}(n,\mathbb{R})\,,\ X = -X^{\mathrm{T}}\,,\ Y = -Y^{\mathrm{T}} \right\}\,.\end{aligned}$$

The involutive automorphism $\lambda : \mathfrak{o}(2n) \to \mathfrak{o}(2n)$ corresponding to this decomposition is given by conjugation with the matrix

$$\mathsf{J}_0 = \begin{bmatrix} 0 & -\mathbb{1} \\ \mathbb{1} & 0 \end{bmatrix}\,.$$

4. Consider type I in line 1 of Table 2.1. Recall from Sect. 7.6 of Part I that $\mathrm{U}(n)/\mathrm{O}(n)$ is the space of Lagrangian subspaces of $\mathbb{R}^{2n}$ endowed with its canonical symplectic structure. Correspondingly, $\mathrm{SU}(n)/\mathrm{SO}(n)$ is called the space of special Lagrangian subspaces. Here, we decompose

$$\mathfrak{su}(n) = \mathfrak{o}(n) \oplus \mathfrak{m}\,,$$

with

$$\begin{aligned}\mathfrak{o}(n) &= \left\{ \begin{bmatrix} X & 0 \\ 0 & X \end{bmatrix} \in \mathfrak{su}(n) : X \in \mathfrak{gl}(n,\mathbb{R})\,,\ X = -X^{\mathrm{T}}\,,\ \operatorname{tr} X = 0 \right\}\,,\\ \mathfrak{m} &= \left\{ \begin{bmatrix} 0 & Y \\ -Y & 0 \end{bmatrix} \in \mathfrak{su}(n) : Y \in \mathfrak{gl}(n,\mathbb{R})\,,\ Y = Y^{\mathrm{T}} \right\}\,.\end{aligned}$$

Here, we have used the embedding $\mathfrak{u}(n) \subset \mathfrak{o}(2n)$ from the previous point. Under this embedding, the involutive automorphism $\lambda : \mathfrak{su}(n) \to \mathfrak{su}(n)$ is given by

$$\begin{bmatrix} X & Y \\ -Y & X \end{bmatrix} \mapsto \begin{bmatrix} X & -Y \\ Y & X \end{bmatrix}\,.$$

---

[40] Cf. Example I/7.5.5.

[41] Cf. Example 2.2.19.

5. Consider type III in line 4 of Table 2.1 with $p = 1$, that is, $M = \mathrm{SO}_0(1,n)/\mathrm{SO}(n)$. On the level of Lie algebras, we have to consider the pseudo-Euclidean space $(\mathbb{R}^{1,n}, \eta)$ with $\eta = \mathbb{1}_{1,n}$ given by (2.5.22). Then,

$$\mathfrak{o}(n,1) = \left\{X \in \mathfrak{gl}(n+1,\mathbb{R}) : X^{\mathrm{T}}\mathbb{1}_{1,n} + \mathbb{1}_{1,n}X = 0\right\} .$$

Embedding $\mathfrak{o}(n) \subset \mathfrak{o}(1,n)$ via $Y \mapsto \begin{bmatrix} 1 & 0 \\ 0 & Y \end{bmatrix}$, we obtain the canonical decomposition

$$\mathfrak{o}(1,n) = \mathfrak{o}(n) \oplus \mathfrak{m} , \quad \mathfrak{m} = \left\{ \begin{bmatrix} 0 & \mathbf{u}^{\mathrm{T}} \\ \mathbf{u} & 0 \end{bmatrix} \in \mathfrak{o}(1,n) : \ \mathbf{u} \in \mathbb{R}^n \right\} .$$

It is obvious that M may be identified with the hypersurface $H_+(1,n) \subset \mathbb{R}^{1,n}$ defined by

$$\eta(\mathbf{u},\mathbf{u}) = -1 , \quad u^0 \geq 1 .$$

Therefore, M is referred to as the hyperbolic space form of $(\mathbb{R}^{1,n}, \eta)$. ◆

Remark 2.5.28 Consider the example of the n-sphere above. By Example 1.1.18, under the identification $\mathfrak{m} \cong \mathbb{R}^n$, the bundle of orthonormal frames $O(\mathrm{S}^n)$ coincides with the principal $\mathrm{SO}(n)$-bundle $\mathrm{SO}(n+1) \to \mathrm{SO}(n+1)/\mathrm{SO}(n)$ and, by Proposition 2.5.10, the Levi-Civita connection on S^n with respect to the natural metric coincides with the $\mathrm{SO}(n+1)$-invariant canonical connection on this bundle. The curvature (2.5.10) reads $F(\mathbf{x},\mathbf{y}) = \mathbf{x} \wedge \mathbf{y}$. Comparing with (2.4.2), this shows that S^n has a constant sectional curvature equal to 1. ◆

For applications of the theory of symmetric spaces in this book, see Sects. 6.8 and 7.9.

Exercises

2.5.1 Prove that λ defined by (2.5.1) is an involutive Lie algebra homomorphism.

2.5.2 Prove that the decomposition (2.5.3) is orthogonal with respect to the Killing form.

2.5.3 Prove Proposition 2.5.3.

2.5.4 Prove Lemma 2.5.12.

2.5.5 Prove the following. For an involutive isometry s with isolated fixed point m, one has $s'_m = -\,\mathrm{id}$. *Hint.* Use the eigenspace decomposition of s'_m.

2.5.6 Check the statements in Example 2.5.27.

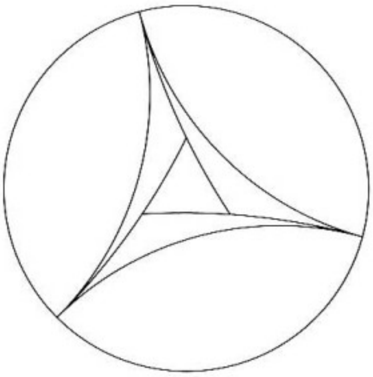

Figure 2.28. Area of general hyperbolic triangles. If you subtract a finite hyperbolic triangle from a suitable ideal triangle, you get three $\frac{2}{3}$-ideal triangles. Adding up angles and areas gives Proposition 2.4.13.

Exercise 2.4.17. What is a good definition for the area of a non-simple polygon? What is the formula for the area of a non-simple hyperbolic polygon? Compare Problem 2.3.12.

2.5. Hyperbolic Isometries

We now turn to the qualitative study of the isometries of hyperbolic space, which, as we saw in Problem 2.2.14, form a large group. We could use linear algebra for this purpose, but we'll instead use direct geometric constructions, the better to develop our hyperbolic intuition. The algebraic approach is taken in Problem 2.5.24.

We start in three dimensions. Let $g : \mathbf{H}^3 \to \mathbf{H}^3$ be an orientation-preserving isometry other than the identity. An *axis* of g is any line L that is invariant under g and on which g acts as a (possibly trivial) translation.

Proposition 2.5.1 (axis is unique). *A non-trivial orientation-preserving isometry of* $\mathbf{H}^3$ *can have at most one axis.*

Proof of 2.5.1. Suppose that L and M are distinct axes for an orientation-preserving isometry g. If g fixes both L and M pointwise, take a point x on M but not on L. Then g fixes the plane containing L and x, because it fixes three non-collinear points on it. Since g preserves orientation, it is the identity.

If, on the other hand, L is translated by g, we have $d(x, M) = d(g(x), M)$ for $x \in L$, so the function $d(x, M)$ is periodic and therefore bounded. But two distinct lines cannot remain a bounded distance from each other in both directions, since that would imply they have the same two endpoints on the sphere at infinity. $\boxed{2.5.1}$

Exercise 2.5.2. Find a non-trivial orientation-preserving isometry of $\mathbf{H}^3$ that leaves invariant more than one line.

Any orientation-preserving isometry of $\mathbf{E}^3$ is either a translation, a rotation about some axis, or a *screw motion*, that is, a rotation followed by a translation along the axis of rotation. (Exercise 2.5.6 asks you to prove this.) The situation in $\mathbf{H}^3$ is somewhat richer, and has its own special terminology.

If a non-trivial orientation-preserving isometry g of $\mathbf{H}^3$ has an axis that is fixed pointwise, it is called an *elliptic* isometry, or a *rotation* about its axis. In this case the orbit of a point p off the axis—the set of points $g^k(p)$, for $k \in \mathbf{Z}$—lies on a circle around the axis.

If g has an axis that is translated by a non-trivial amount, it is called *hyperbolic*. There are two possibilities here: the orbit of a point off the axis may lie on a plane, always on the same side of the axis; it is in fact contained in an equidistant curve, like the one shown in Figure 1.10. In this case we say that g is a *translation*. Alternatively, the orbit can be the vertices of a polygonal helix centered around the axis; in this case g is a screw motion, as can be seen by applying a compensatory translation. (An alternate usage of the word "hyperbolic" specializes it to what we're calling translations, in which case "loxodromic" designates a screw motion. This distinction is not very useful, and we'll not adopt it.)

By the proposition above, no transformation can be at the same time elliptic and hyperbolic. But there are isometries that are neither elliptic nor hyperbolic: they are called *parabolic*. For instance, any isometry of $\mathbf{H}^3$ that appears as a Euclidean translation parallel to the bounding plane in the upper half-space model is parabolic.

The proof of the next proposition describes a geometric construction to locate the axis of a non-trivial orientation-preserving isometry of $\mathbf{H}^3$, if it has one. We will need an elementary fact about pairs of lines; recall (cf. Exercise 2.3.10) that two lines in $\mathbf{H}^3$ are called *parallel* if they have a common endpoint on S^2_∞, or, equivalently, if the distance between them approaches zero at one end or the other.

Lemma 2.5.3 (common perpendicular for lines in $\mathbf{H}^3$). *Two distinct lines in $\mathbf{H}^3$ are either parallel, or they have a unique common perpendicular.*

Proof of 2.5.3. Let the lines be X and Y, and consider the distance function $d(x, y)$ between points $x \in X$ and $y \in Y$. If the lines are not parallel, this function goes to ∞ as either x or y or both go to ∞; therefore it has a minimum, attained at points x_0 and y_0.

If the minimum is zero, that is, if the lines cross, any common perpendicular must go through the intersection point, otherwise we'd have a triangle with two right angles, which is impossible by Proposition 2.4.13. As there is a unique line orthogonal to the plane spanned by X and Y and passing through their intersection point, the lemma is proved in this case. (Notice that this part is false in dimension greater than three.)

If the minimum distance is not zero, the line between x_0 and y_0 is a perpendicular by Exercise 2.4.6. If there were another common perpendicular, we'd obtain a quadrilateral in space with all right angles (although conceivably its sides could cross). Subdividing the quadrilateral by a diagonal, we'd get two plane triangles, whose angles add to at least 2π; this is again impossible. $\boxed{2.5.3}$

If L is a line in $\mathbf{H}^3$, we denote by r_L the reflection in L, which is the rotation of π about L.

Proposition 2.5.4 (finding the axis). *Any non-trivial orientation-preserving isometry g of $\mathbf{H}^3$ can be written in the form $g = r_L \circ r_M$, where the lines L and M are parallel, secant or neither depending on whether g is parabolic, elliptic or hyperbolic. The axis of g is the common perpendicular of L and M, if it exists.*

Proof of 2.5.4. Take any point p such that $g(p) \neq p$. If $g^2(p) = p$, the midpoint q of the line segment $\overline{p\,g(p)}$ is fixed by g, and the plane through q perpendicular to the line $p\,g(p)$ is invariant. Since g reverses the orientation of this plane, it must act on it as a reflection, fixing a line K. Therefore, $g = r_K$ is elliptic of order two. In this case, one can take L and M to be two orthogonal lines, both orthogonal to K at a point $x \in K$.

If p, $g(p)$ and $g^2(p) \neq p$ are collinear, p is fortuitously on the axis of g, and g is hyperbolic. We can replace p by some other point not on this axis, and reduce to the next case.

In the remaining case, we let M be the bisector of the angle $p\,g(p)g^2(p)$, so that r_M fixes $g(p)$ and interchanges p with $g^2(p)$. To define L, we look at the dihedron with edge $g(p)g^2(p)$ whose sides contain p and $g^3(p)$, respectively, and take L as the line that bisects this dihedron and is also a perpendicular bisector of the segment $\overline{p\,g(p)}$, as shown in Figure 2.29. (The dihedral angle along $p\,g(p)$ may be 0 or π, but this doesn't cause problems.) By symmetry, r_L interchanges $g(p)$ with $g^2(p)$, and also p with $g^3(p)$. Therefore, $r_L \circ r_M$ sends p to $g(p)$, $g(p)$ to $g^2(p)$ and $g^2(p)$ to $g^3(p)$. Since $r_L \circ r_M$ and g agree at three non-collinear points, they agree on the whole plane containing these three points. Therefore they agree everywhere, since they both preserve orientation.

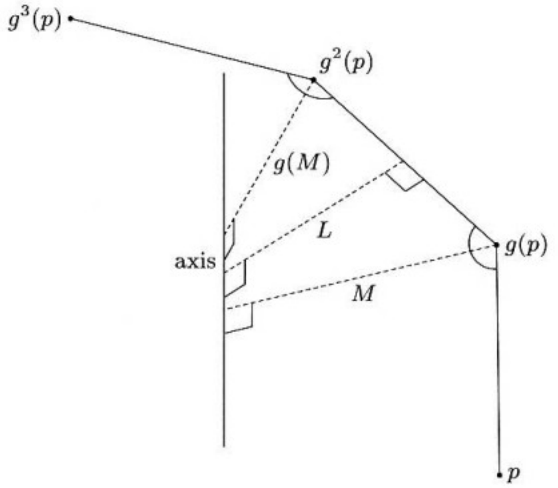

Figure 2.29. The axis of a three-dimensional isometry. The axis of an isometry g of $\mathbf{H}^3$ may be constructed, in the generic case, by connecting the orbit of a point p in a polygonal path.

The common perpendicular of L and M, if it exists, is the axis of g, because it is invariant under $r_L \circ r_M$, which acts on it as a translation. The sorting into cases now follows from Lemma 2.5.3 and from the definitions of parabolic, elliptic and hyperbolic transformations. $\boxed{2.5.4}$

Exercise 2.5.5. Using the decomposition of Proposition 2.5.4, show that any parabolic orientation-preserving isometry of $\mathbf{H}^3$ is conjugate to a Euclidean translation of the upper half-space model.

Exercise 2.5.6 (isometries of $\mathbf{E}^3$). Prove that any orientation-preserving isometry of $\mathbf{E}^3$ is either a translation, a rotation or a screw motion. Give a geometric construction for the axis of the transformation, in the latter two cases.

The proof of Proposition 2.5.4 also applies to any two-dimensional isometry, whether it preserves or reverses orientation, since such an isometry can be extended to a three-dimensional orientation-preserving isometry. But three-dimensional orientation-reversing isometries, or arbitrary isometries in higher dimension, can have fixed-point sets other than lines: for example, a reflection in a plane of any dimension, or a compound rotation about a plane of any even codimension. Any transformation with a fixed point in hyperbolic space is still called *elliptic*. An isometry that translates an axis is *hyperbolic*, and as before the axis is unique. Any other non-trivial transformation is *parabolic*.

Problem 2.5.7 (orientation-reversing isometries of $\mathbf{H}^3$). Classify orientation-reversing isometries of $\mathbf{H}^3$. One approach is to modify the construction above, and express an orientation-reversing isometry as the composition of reflection in a plane with reflection in a line. Another approach is to exploit the fact that the square of an orientation-reversing isometry is orientation-preserving. Which isometries of $\mathbf{H}^3$ have orientation-reversing square roots? What are the square roots of the identity? What are the square roots of other isometries that have them?

To study isometries in arbitrary dimension, we continue with the geometric point of view and develop a method, based on the convexity of the distance function, that will be important later, because it can be adapted to other negatively curved metrics on $\mathbf{R}^n$. For another, algebraic, method, see Problem 2.5.24.

A *convex function* on a Riemannian manifold is a real-valued function f such that, for every geodesic γ, parametrized at a constant speed, the induced function $f \circ \gamma$ is convex. In other words, for every $t \in (0, 1)$,

$$f \circ \gamma(t) \leq t f \circ \gamma(0) + (1 - t) f \circ \gamma(1).$$

If the inequality is strict for all non-constant γ, we say that f is *strictly convex*.

The *product* of two Riemannian manifolds is the product manifold, with the Riemannian metric that is the sum of the metrics on the factors. It is easy to show that a curve in the product manifold is a geodesic (parametrized at constant speed) if and only if each projection in a factor is also a geodesic (parametrized at constant speed). In particular, a geodesic in $\mathbf{H}^n \times \mathbf{H}^n$ is a curve each of whose projections is a hyperbolic line or a point.

Theorem 2.5.8 (distance function is convex). *The distance function $d(x, y)$, considered as a map $d : \mathbf{H}^n \times \mathbf{H}^n \to \mathbf{R}$, is convex.*

Chapter 1
Introduction

The field of quantum information encompasses the study of the representation, storing, processing and accessing of information by quantum mechanical systems. The field grew from the investigations of the physical limits to computation initiated by Bennett and Landauer. One of the first questions studied was whether quantum mechanics imposes any limits on what a computer can do, and it was shown by Feynman that it does not. Earlier work by Paul Benioff had explored the possibilities of quantum Turing machines. Shortly after Feynman's work, David Deutsch realized that not only is quantum mechanics not a problem for computation, it can also be an advantage. The major breakthrough in the field was Peter Shor's factoring algorithm, which showed that a quantum computer can find the prime factors of integers in a time that scales as a polynomial of the size (number of digits) of the integer.

1.1 The Qubit

The basic unit of classical information is the bit, which can be 0 or 1. The corresponding object in quantum information is the qubit, which is a two-level quantum system. The two levels are often denoted by $|0\rangle$ and $|1\rangle$, which correspond to logical 0 and 1, respectively. Natural physical systems that can be used to represent a qubit are electronic or nuclear spins, and the polarization of a photon. The key difference between a bit and a qubit, is that the latter can exist in a superposition state

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle, \tag{1.1}$$

while the former is definitely either 0 or 1. This leads to significant differences in what can be done with information represented by bits and that represented by qubits.

J. A. Bergou et al., *Quantum Information Processing*, Graduate Texts in Physics,
https://doi.org/10.1007/978-3-030-75436-5_1

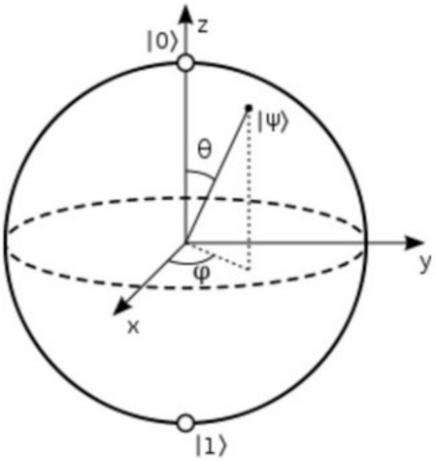

Fig. 1.1 Bloch sphere representation of the qubit in Eq. (1.2)

A convenient representation of the state of a qubit is given by the Bloch sphere. The state is parameterized by two angles, $0 \le \theta \le \pi$ and $0 \le \phi < 2\pi$,

$$|\psi\rangle = \cos(\theta/2)|0\rangle + e^{i\phi}\sin(\theta/2)|1\rangle. \tag{1.2}$$

It is represented by a point on the unit sphere whose polar angle is θ and whose azimuthal angle is ϕ. That is, the vector from the origin to the point representing the state makes an angle of θ with the z axis, and its component in the x-y plane makes an angle of ϕ with the x axis. The state $|0\rangle$ is the North Pole of the sphere, and the state $|1\rangle$ is the South Pole. The Bloch sphere of a qubit is shown in Fig. 1.1. The Bloch sphere is often useful in illustrating how the state of a qubit is changed by a quantum map.

The state of N qubits is spanned by the tensor product basis

$$\begin{aligned}|0\rangle \otimes \ldots |0\rangle \otimes |0\rangle &= |0\ldots 00\rangle\\ |0\rangle \otimes \ldots |0\rangle \otimes |1\rangle &= |0\ldots 01\rangle\\ &\vdots\\ |1\rangle \otimes \ldots |1\rangle \otimes |1\rangle &= |1\ldots 11\rangle \end{aligned} \tag{1.3}$$

Note that we have expressed these states as $|x\rangle$, where x is an N-digit binary number. The most general N-qubit state can be expressed as

$$|\Psi\rangle = \sum_{x=0}^{2^N-1} c_x|x\rangle. \tag{1.4}$$

1.1 PHOTON POLARIZATION

The electric/magnetic field of plane linearly polarized waves is described as follows [13]:

$$\boldsymbol{A}(\boldsymbol{r},t)=\boldsymbol{p}A_0\exp[j(\omega t-\boldsymbol{k}\cdot\boldsymbol{r})],\quad \boldsymbol{A}\in\{\boldsymbol{E},\boldsymbol{H}\} \tag{1.1}$$

where $\boldsymbol{E}(\boldsymbol{H})$ denotes the electric (magnetic) field, $\boldsymbol{p}$ denotes the polarization orientation, $\boldsymbol{r}=x\boldsymbol{e}_x+y\boldsymbol{e}_y+z\boldsymbol{e}_z$ is the position vector, and $\boldsymbol{k}=k_x\boldsymbol{e}_x+k_y\boldsymbol{e}_y+k_z\boldsymbol{e}_z$ denotes the wave propagation vector whose magnitude is $k=2\pi/\lambda$ (λ is the operating wavelength). For the x-polarization waves ($\boldsymbol{p}=\boldsymbol{e}_x$, $\boldsymbol{k}=k\boldsymbol{e}_z$), Eq. (1.1) becomes:

$$\boldsymbol{E}_x(z,t)=\boldsymbol{e}_xE_{0x}\cos(\omega t-kz), \tag{1.2}$$

while for y-polarization ($\boldsymbol{p}=\boldsymbol{e}_y$, $\boldsymbol{k}=k\boldsymbol{e}_z$) it becomes:

$$\boldsymbol{E}_y(z,t)=\boldsymbol{e}_yE_{0y}\cos(\omega t-kz+\delta), \tag{1.3}$$

where δ is the relative phase difference between the two orthogonal waves. The resultant wave can be obtained by combining Eqs. (1.2) and (1.3) as follows:

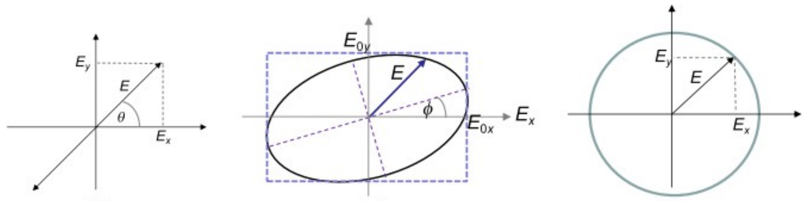
$$\boldsymbol{E}(z,t)=\boldsymbol{E}_x(z,t)+\boldsymbol{E}_y(z,t)=\boldsymbol{e}_xE_{0x}\cos(\omega t-kz)+\boldsymbol{e}_yE_{0y}\cos(\omega t-kz+\delta). \tag{1.4}$$

The *linearly polarized* wave is obtained by setting the phase difference to an integer multiple of 2π, namely $\delta=m\cdot 2\pi$:

$$\begin{aligned}&\boldsymbol{E}(z,t)=(\boldsymbol{e}_xE\cos\theta+\boldsymbol{e}_yE\sin\theta)\cos(\omega t-kz);\quad E=\sqrt{E_{0x}^2+E_{0y}^2},\\&\theta=\tan^{-1}\frac{E_{0y}}{E_{0x}}.\end{aligned} \tag{1.5}$$

By ignoring the time-dependent term, we can represent the linear polarization as shown in Fig. 1.1A. On the other hand, if $\delta\neq m\cdot 2\pi$, the *elliptical polarization* is obtained. From Eqs. (1.2) and (1.3), by eliminating the time-dependent term we obtain the following equation of ellipse:

$$\left(\frac{E_x}{E_{0x}}\right)^2+\left(\frac{E_y}{E_{0y}}\right)^2-2\frac{E_x}{E_{0x}}\frac{E_y}{E_{0y}}\cos\delta=\sin^2\delta,\tan 2\phi=\frac{2E_{0x}E_{0y}\cos\delta}{E_{0x}^2-E_{0y}^2}, \tag{1.6}$$



(A) (B) (C)

FIGURE 1.1

Various forms of polarizations: (A) linear polarization, (B) elliptic polarization, and (C) circular polarization.

which is shown in Fig. 1.1B. By setting $\delta = \pm\pi/2, \pm 3\pi/2, \ldots$ the equation of ellipse becomes:

$$\left(\frac{E_x}{E_{0x}}\right)^2 + \left(\frac{E_y}{E_{0y}}\right)^2 = 1. \tag{1.7}$$

By setting further $E_{0x} = E_{0y} = E_0$; $\delta = \pm\pi/2, \pm 3\pi/2, \ldots$ the equation of ellipse becomes the circle:

$$E_x^2 + E_y^2 = 1, \tag{1.8}$$

and corresponding polarization is known as *circular polarization* (Fig. 1.1C). *The right circularly polarized* wave is obtained for $\delta = \pi/2 + 2m\pi$:

$$\boldsymbol{E} = E_0[\boldsymbol{e}_x \cos(\omega t - kz) - \boldsymbol{e}_y \sin(\omega t - kz)]. \tag{1.9}$$

Otherwise, for $\delta = -\pi/2 + 2m\pi$, the polarization is known as left circularly polarized.

Very often, the *Jones vector representation* of the polarization wave is used:

$$\boldsymbol{E}(t) = \begin{bmatrix} E_x(t) \\ E_y(t) \end{bmatrix} = E \begin{bmatrix} \sqrt{1-\kappa} \\ \sqrt{\kappa} e^{j\delta} \end{bmatrix} e^{j(\omega t - kz)}, \tag{1.10}$$

where κ is the power-splitting ratio between states of polarizations (SOPs), with the complex phasor term being typically omitted in practice.

Another interesting representation is *Stokes vector representation*:

$$\boldsymbol{S}(t) = \begin{bmatrix} S_0(t) \\ S_1(t) \\ S_2(t) \\ S_3(t) \end{bmatrix}, \tag{1.11}$$

where the parameter S_0 is related to the optical intensity by:

$$S_0(t) = |E_x(t)|^2 + |E_y(t)|^2. \tag{1.12a}$$

The parameter $S_1 > 0$ is related to the preference for horizontal polarization and is defined by:

$$S_1(t) = |E_x(t)|^2 - |E_y(t)|^2. \tag{1.12b}$$

The parameter $S_2 > 0$ is related to the preference for $\pi/4$ SOP:

$$S_2(t) = E_x(t)E_y^*(t) + E_x^*(t)E_y(t). \tag{1.12c}$$

Finally, the parameter $S_3 > 0$ is related to the preference for right circular polarization and is defined by:

$$S_3(t) = j\left[E_x(t)E_y^*(t) - E_x^*(t)E_y(t)\right]. \tag{1.12d}$$

The parameter S_0 is related to other Stokes parameters by:

$$S_0^2(t) = S_1^2(t) + S_2^2(t) + S_3^2(t). \tag{1.13}$$

The *degree of polarization* is defined by:

$$p = \frac{\left[S_1^2 + S_2^2 + S_3^2\right]^{1/2}}{S_0}, \quad 0 \le p \le 1 \tag{1.14}$$

For $p = 1$ the polarization does not change in time. The Stokes vector can be represented in terms of Jones vector parameters as:

$$s_1 = 1 - 2\kappa, \;\; s_2 = 2\sqrt{\kappa(1-\kappa)}\cos\delta, \;\; s_3 = 2\sqrt{\kappa(1-\kappa)}\sin\delta. \tag{1.15}$$

After *normalization* with respect to S_0, the normalized Stokes parameters are given by:

$$s_i = \frac{S_i}{S_0}; \;\; i = 0, 1, 2, 3. \tag{1.16}$$

If the normalized Stokes parameters are used, the polarization state can be represented as a point on a *Poincaré sphere*, as shown in Fig. 1.2. The points located at the opposite sides of the line crossing the center represent the orthogonal polarizations.

The polarization ellipse is very often represented in terms of ellipticity and azimuth, which are illustrated in Fig. 1.3. The ellipticity is defined by the ratio of half-axes lengths. The corresponding angle is called the ellipticity angle and denoted by ε. The small ellipticity means that the polarization ellipse is highly elongated, while for zero ellipticity the polarization is linear. For $\varepsilon = \pm\pi/4$, the polarization is circular. For $\varepsilon > 0$, the polarization is right elliptical. On the other hand, the azimuth angle η defines the orientation of the main axis of ellipse with respect to E_x.

FIGURE 1.3

The ellipticity and azimuth of the polarization ellipse.

The parameters of the polarization ellipse can be related to the Jones vector parameters by:

$$\sin 2\,\varepsilon = 2\sqrt{\kappa(1-\kappa)}\sin\delta, \quad \tan 2\,\eta = \frac{2\sqrt{\kappa(1-\kappa)}\sin\delta}{1-2\kappa}. \tag{1.17}$$

Finally, the parameters of the polarization ellipse can be related to the Stokes vector parameters by:

$$s_1 = \cos 2\eta\,\cos 2\varepsilon,\;\; s_2 = \sin 2\eta\,\cos 2\varepsilon,\;\; s_3 = \sin 2\varepsilon, \tag{1.18}$$

and corresponding geometrical interpretation is provided in Fig. 1.2.

Let us now observe the *polarizer—analyzer ensemble*, shown in Fig. 1.4. When an electromagnetic wave passes through the polarizer, it can be represented as a vector in the x—y plane, transversal to the propagation direction, as given by Eq. (1.5), where the angle θ depends on the filter orientation. By introducing the unit vector $\widehat{p} = (\cos\theta, \sin\theta)$, Eq. (1.5) can be rewritten as:

$$\boldsymbol{E} = E_0\widehat{p}\cos(\omega t - kz). \tag{1.19}$$

If $\theta = 0$ rad, the light is polarized along the x-axis, while for $\theta = \pi/2$ rad it is polarized along the y-axis. The *natural light* is *unpolarized* as it represents

incoherent superposition of 50% of light polarized along the x-axis and 50% of light polarized along the y-axis. After the analyzer, whose axis makes an angle ϕ with respect to the x-axis, which can be represented by the unit vector $\widehat{n} = (\cos\phi, \sin\phi)$, the output electric field is given by:

$$\begin{aligned} \boldsymbol{E}' = (\boldsymbol{E}\cdot\widehat{n})\widehat{n} &= E_0 \cos(\omega t - kz)(\widehat{p}\cdot\widehat{n})\widehat{n} \\ &= E_0 \cos(\omega t - kz)[(\cos\theta, \sin\theta)\cdot(\cos\phi, \sin\phi)]\widehat{n} \\ &= E_0 \cos(\omega t - kz)[\cos\theta\cos\phi + \sin\theta\sin\phi]\widehat{n} \\ &= E_0 \cos(\omega t - kz)\cos(\theta - \phi)\widehat{n}. \end{aligned} \tag{1.20}$$

The intensity of the analyzer output field is given by:

$$I' = |\boldsymbol{E}'|^2 = I\cos^2(\theta - \phi), \tag{1.21}$$

which is commonly referred to as *Malus' law*.

The polarization decomposition by a birefringent plate is now studied (Fig. 1.5). Experiment shows that photodetectors PD_x and PD_y are never triggered simultaneously, which indicates that an entire photon reaches either PD_x or PD_y (a photon never splits). Therefore the corresponding probabilities that a photon is detected by photodetector PD_x and PD_x can be determined by:

$$p_x = \Pr(\mathrm{PD}_x) = \cos^2\theta, \quad p_y = \Pr(\mathrm{PD}_y) = \sin^2\theta. \tag{1.22}$$

If the total number of photons is N, the number of detected photons in x-polarization will be $N_x \cong N\cos^2\theta$, and the number of detected photons in y-polarization will be $N_y \cong N\sin^2\theta$. In the limit, as $N \to \infty$ we would expect Malus' law to be obtained.

Let us now study polarization decomposition and recombination by means of birefringent plates, as illustrated in Fig. 1.6. Classical physics prediction of total probability of a photon passing the polarizer–analyzer ensemble is given by:

$$p_{\mathrm{tot}} = \cos^2\theta\cos^2\phi + \sin^2\theta\sin^2\phi \neq \cos^2(\theta - \phi), \tag{1.23}$$

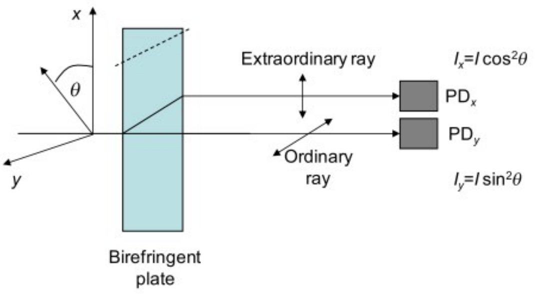

FIGURE 1.5

Polarization decomposition by a birefringent plate. *PD*, Photodetector.

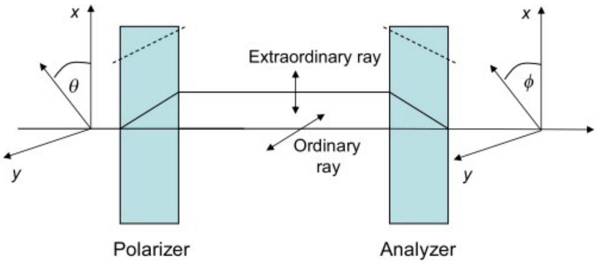

FIGURE 1.6

Polarization decomposition and recombination by a birefringent plate.

which is inconsistent with Malus' law, given by Eq. (1.21). To reconstruct the results from wave optics, it is necessary to introduce into quantum mechanics a concept of probability amplitude that α is detected as β, which is denoted as $a(\alpha \rightarrow \beta)$, and is a complex number. The probability is obtained as the squared magnitude of probability amplitude:

$$p(\alpha \rightarrow \beta) = |a(\alpha \rightarrow \beta)|^2. \tag{1.24}$$

The relevant probability amplitudes related to Fig. 1.6 are:

$$\begin{aligned} a(\theta \rightarrow x) &= \cos\theta \quad a(x \rightarrow \phi) = \cos\phi \\ a(\theta \rightarrow y) &= \sin\theta \quad a(x \rightarrow \phi) = \sin\phi \end{aligned} \tag{1.25}$$

The basic principle of quantum mechanics is to sum up the probability amplitudes for indistinguishable paths:

$$a_{\text{tot}} = \cos\theta\cos\phi + \sin\theta\sin\phi = \cos(\theta - \phi). \tag{1.26}$$

The corresponding total probability is:

$$p_{\text{tot}} = |a_{\text{tot}}|^2 = \cos^2(\theta - \phi), \tag{1.27}$$

and this result is consistent with Malus' law!

Based on the previous discussion, the *state vector* of photon polarization is given by:

$$|\psi\rangle = \begin{pmatrix} \psi_x \\ \psi_y \end{pmatrix}, \tag{1.28}$$

where ψ_x is related to x-polarization and ψ_y is related to y-polarization, with the normalization condition as follows:

$$|\psi_x|^2 + |\psi_y|^2 = 1. \tag{1.29}$$

In this representation, the x- and y-polarization photons can be represented by:

$$|x\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, |y\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \tag{1.30}$$

and the right and left circular polarization photons are represented by:

$$|R\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ j \end{pmatrix}, |L\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ -j \end{pmatrix}. \tag{1.31}$$

In Eqs. (1.28)–(1.31) we used Dirac notation to denote the column vectors (kets). In Dirac notation, with each column vector ("ket") $|\psi\rangle$, we associate a row vector ("bra") $\langle\psi|$ as follows:

$$\langle\psi| = \begin{pmatrix} \psi_x^* & \psi_y^* \end{pmatrix}. \tag{1.32}$$

The *scalar (dot) product* of ket $|\phi\rangle$ bra $\langle\psi|$ is defined by "brackets" as follows:

$$\langle\phi|\psi\rangle = \phi_x^*\psi_x + \phi_y^*\psi_y = \langle\psi|\phi\rangle^*. \tag{1.33}$$

The normalization condition can be expressed in terms of scalar product by:

$$\langle\psi|\psi\rangle = 1. \tag{1.34}$$

Based on Eqs. (1.30) and (1.31) it is evident that:

$$\langle x|x\rangle = \langle y|y\rangle = 1, \quad \langle R|R\rangle = \langle L|L\rangle = 1.$$

Because the vectors $|x\rangle$ and $|y\rangle$ are *orthogonal*, their dot product is zero:

$$\langle x|y\rangle = 0, \tag{1.35}$$

and they form the *basis*. Any state vector $|\psi\rangle$ can be written as a *linear superposition* of basis kets as follows:

$$|\psi\rangle = \begin{pmatrix} \psi_x \\ \psi_y \end{pmatrix} = \psi_x|x\rangle + \psi_y|y\rangle. \tag{1.36}$$

We can now use Eqs. (1.34) and (1.36) to derive an important relation in quantum mechanics, known as *completeness relation*. The projections of state vector $|\psi\rangle$ along basis vectors $|x\rangle$ and $|y\rangle$ are given by:

$$\langle x|\psi\rangle = \psi_x\underbrace{\langle x|x\rangle}_{1} + \psi_y\underbrace{\langle x|y\rangle}_{0} = \psi_x, \quad \langle y|\psi\rangle = \psi_x\langle y|x\rangle + \psi_y\langle y|y\rangle = \psi_y. \tag{1.37}$$

By substituting Eq. (1.37) into Eq. (1.36) we obtain:

$$|\psi\rangle = |x\rangle\langle x|\psi\rangle + |y\rangle\langle y|\psi\rangle = \underbrace{(|x\rangle\langle x| + |y\rangle\langle y|)}_{I}|\psi\rangle, \tag{1.38}$$

and from the right side of Eq. (1.38) we derive the completeness relation:

$$|x\rangle\langle x| + |y\rangle\langle y| = I. \tag{1.39}$$

The probability that the photon in state $|\psi\rangle$ will pass the x-polaroid is given by:

$$p_x = \frac{|\psi_x|^2}{|\psi_x|^2 + |\psi_y|^2} = |\psi_x|^2 = |\langle x|\psi\rangle|^2, \tag{1.40}$$

the probability amplitude of the photon in state $|\psi\rangle$ to pass the x-polaroid is:

$$a_x = \langle x|\psi\rangle. \tag{1.41}$$

Let $|\phi\rangle$ and $|\psi\rangle$ be two physical states. The probability amplitude of finding ϕ in ψ, denoted as $a(\phi \rightarrow \psi)$, is given by:

$$a(\phi \rightarrow \psi) = \langle \phi|\psi\rangle, \tag{1.42}$$

and the probability for ϕ to pass the ψ test is given by:

$$p(\phi \rightarrow \psi) = |\langle \phi|\psi\rangle|^2. \tag{1.43}$$

1.2 THE CONCEPT OF QUBIT

Based on the previous section, it can be concluded that the quantum bit, also known as qubit, lies in a 2D Hilbert space H, isomorphic to C^2-space, where C is the complex number space, and can be represented as:

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle = \begin{pmatrix} \alpha \\ \beta \end{pmatrix}; \quad \alpha, \beta \in C; \quad |\alpha|^2 + |\beta|^2 = 1, \tag{1.44}$$

where $|0\rangle$ and $|1\rangle$ states are computational basis (CB) states, and $|\psi\rangle$ is a superposition state. If we perform the measurement of a qubit, we will get $|0\rangle$ with probability $|\alpha|^2$ and $|1\rangle$ with probability $|\beta|^2$. Measurement changes the state of a qubit from a superposition of $|0\rangle$ and $|1\rangle$ to the specific state consistent with the measurement result. If we parametrize the probability amplitudes α and β as follows:

$$\alpha = \cos\left(\frac{\theta}{2}\right), \quad \beta = e^{j\phi} \sin\left(\frac{\theta}{2}\right), \tag{1.45}$$

where θ is a polar angle and ϕ is an azimuthal angle, we can geometrically represent the qubit by the Bloch sphere (or the Poincaré sphere for the photon) as illustrated in Fig. 1.7. (Note that the Bloch sphere from Fig. 1.7 is a little bit different from that of the Poincaré sphere from Fig. 1.2.) Bloch vector coordinates are given by ($\cos\phi \sin\theta$, $\sin\phi \sin\theta$, $\cos\theta$). This Bloch vector representation is related to CB by:

$$|\psi(\theta, \phi)\rangle = \cos(\theta/2)|0\rangle + e^{j\phi} \sin(\theta/2)|1\rangle \doteq \begin{pmatrix} \cos(\theta/2) \\ e^{j\phi} \sin(\theta/2) \end{pmatrix}, \tag{1.46}$$

the 6 radical planes. Its barycentric coordinates are computed from Eq. (4.14) and (4.15). The point z_0 is interior to the convex domain of the 4-order intersection. This latter is partitioned into four parts, each one being the intersection of one sphere and one trihedron originating in z_0.

These trihedra, which intersect respectively the spheres 1, 2, 3, 4, are:

$$\{z_0 \to x^{(123)}, z_0 \to x^{(124)}, z_0 \to z^{(134)}\},$$
$$\{z_0 \to x^{(123)}, z_0 \to x^{(124)}, z_0 \to z^{(234)}\},$$
$$\{z_0 \to x^{(123)}, z_0 \to x^{(134)}, z_0 \to z^{(234)}\},$$
$$\{z_0 \to x^{(124)}, z_0 \to x^{(134)}, z_0 \to z^{(234)}\}.$$

It follows that the calculation of V_{1234} and S_{1234} can be done through the calculation of the portion of the area of a sphere defined by its intersection with a trihedron having its origin in the interior of the sphere. This latter calculation is done analytically in Sect. 4.2.6 using the Gauss–Bonnet theorem. An analytical treatment of the four-sphere intersection without invoking the Gauss–Bonnet theorem was reported [27].

4.2.6 Intersection of a Sphere with a Dihedron or with Trihedron

We consider a sphere of center c and radius R intersecting a salient trihedron of origin z inside the sphere. The trihedron intersects the boundary of the sphere at x_1, x_2, x_3, these three points being ordered in the direct sense when referred to z as origin. We look for the calculation of the volume V_{st} of the intersection and for the surface S_{st} of the spherical triangle on the boundary of the sphere. This spherical triangle is bounded by the oriented arcs of circle (x_1,x_2), (x_2,x_3), (x_3,x_1). These arcs have respective radii h_{12}, h_{23}, h_{31} and respective angles b_{12}, b_{23}, b_{31}, each of these angles being in $[0;\pi]$. The trihedron intersects each of the planes respectively tangent to the sphere at x_1, x_2, x_3, thus defining the respective angles a_1, a_2, a_3, each of these angles being in $[0;\pi]$. We define c_{12}, c_{23}, c_{31} as the projections of c on the planes containing the respective triplets (x_1,z,x_2), (x_2,z,x_3), (x_3,z,x_1). We also define the angles associated to the three lens: $\theta_{ij} = \widehat{x_i, c, c_{ij}} = \widehat{x_j, c, c_{ij}}$, $(i,j) = (1,2)$ or $(i,j) = (2,3)$ or $(i,j) = (3,1)$, such that $\cos\theta_{ij}$ is positive when the vector $c_{ij} - c$ of origin c has the same sense than the direct normal to the plane of the oriented arc (x_i,x_j), and $\cos\theta_{ij}$ is negative when $c_{ij} - c$ has a sense opposite to this normal. We have also $\sin\theta_{ij} = h_{ij}/R$. The sphere has a constant Gaussian curvature and each arc of circle has a constant geodesic curvature. Thus, the Gauss–Bonnet theorem [26, 52] leads to a simple expression of S_{st} in Eq. (4.22), in which the first term in parenthesis is the spherical excess:

$$\frac{S_{st}}{R^2} = (a_1 + a_2 + a_3 - \pi) - (b_{12}\cos\theta_{12} + b_{23}\cos\theta_{23} + b_{31}\cos\theta_{31}). \qquad (4.22)$$

V_{zx} being the signed volume of the oriented tetrahedron $(x_1 - z, x_2 - z, x_3 - z)$ and V_{cx} being the signed volume of the oriented tetrahedron $(x_1 - c, x_2 - c, x_3 - c)$, the volume V_{st} is given below [37]:

$$V_{st} = \frac{R^3}{6}\left[\cos\theta_{12}\sin^2\theta_{12}(\sin b_{12} - b_{12}) \right. \\ + \cos\theta_{23}\sin^2\theta_{23}(\sin b_{23} - b_{23}) \\ \left. + \cos\theta_{31}\sin^2\theta_{31}(\sin b_{31} - b_{31})\right] + V_{zx} - V_{cx} + \frac{S_{st}R}{3}. \tag{4.23}$$

When z lies at c, we retrieve the expression given by Girard's theorem [48]: $\frac{S_{st}}{R^2}$ is the spherical excess and $V_{st} = \dfrac{S_{st}R}{3}$.

Remark: rather than looking for the validity of Eq. (4.23) from integrating S_{st} as stated in [37], we give a hint of proof as follows. We define the point x_0 at the intersection of the half line of origin c passing through z with the boundary of the sphere, and we add the three signed contributions to V_{st} due to the trihedra $\{z \to x_1, z \to x_2, z \to x_0\}$ and $\{z \to x_2, z \to x_3, z \to x_0\}$ and $\{z \to x_3, z \to x_1, z \to x_0\}$, a contribution being negative when the bounding arcs are not oriented in the conventional sense. For each trihedra, say, $\{z \to x_1, z \to x_2, z \to x_0\}$, the volume of the intersection with the sphere is $V_{sc012} - V_{cz12} - V_{c12}$, in which V_{sc012} is the volume of the domain bounded by $c - x_0$, $c - x_1$, $c - x_2$ and by the spherical triangle (x_0, x_1, x_2) intercepted by the trihedron $\{z \to x_1, z \to x_2, z \to x_0\}$ and of area computable by Eq (4.22). Despite that this domain is not bounded by a trihedron, V_{sc012} is computable by trivial integration in respect to the radius of the sphere. V_{cz12} is the volume of the tetrahedron (c, z, x_1, x_2). V_{c12} is the volume of the portion of the cone of origin c with height $R\cos\theta_{12}$ and of basis the circular segment of area $(b_{12} - \sin b_{12})(R\sin\theta_{12})^2/2$, i.e., $V_{c12} = \cos\theta_{12}\sin^2\theta_{12}(b_{12} - \sin b_{12})R^3/6$. The rest of the calculation is easy.

The case of the six trihedra listed at the end of Sect. 4.2.4 is of interest. It is such that one of the arcs, say, (x_2, x_3), lies on a great circle of the sphere: z, x_2, x_3, c, c_{12}, c_{31}, are coplanar, and c_{23} coincides with c, then $a_2 = \pi/2$, $a_3 = \pi/2$, and $\theta_{23} = \pi/2$.

Grouping each trihedra with its symmetric image through the plane of the great circle let us to the expressions of the volume V_{sd} of the intersection of a sphere and a dihedron and for the surface S_{sd} of the associated portion of spherical area. Keeping the notations used in Eqs. (4.22) and (4.23):

$$\frac{S_{sd}}{R^2} = 2a_1 - 2(b_{12}\cos\theta_{12} + b_{31}\cos\theta_{31}), \tag{4.24}$$

$$V_{sd} = \frac{R^3}{3}\left[\cos\theta_{12}\sin^2\theta_{12}(\sin b_{12} - b_{12}) \right. \\ \left. + \cos\theta_{31}\sin^2\theta_{31}(\sin b_{31} - b_{31})\,\right] + 2(V_{zx} - V_{cx}) + \left.\frac{S_{sd}R}{3}\right]. \tag{4.25}$$

Care: in Eqs. (4.24) and (4.25), b_{12} and b_{31} are the angles of the half arcs (not the full arcs) bounding the intersection of the sphere with the dihedron. It is also recalled that the arcs must be correctly oriented and that $\cos\theta_{12}$ and $\cos\theta_{31}$ can be negative.

When z is outside the sphere, the intersection with a dihedron reduces to simpler cases such as a sphere minus two lens, and the intersection with a trihedron can be reduced to intersections with appropriate dihedra or trihedra for which Eqs. (4.22)–(4.25) can be used. More generally we can extend volumes and surfaces computations to the intersections of a sphere with a tetrahedron, a convex polyhedron, and with any union of convex polyhedra. These computations are based on Eqs. (4.22)–(4.25) but are not needed in the framework of this chapter.

4.2.7 Intersections of Order 5 and Higher

By iterating Eqs. (4.12) and (4.13) until order n, the volume and the surface of the union of the n spheres can be expressed from the inclusion–exclusion principle as follows:

$$V = \sum_{1\le i\le n} V_i - \sum_{1\le i_1<i_2\le n} V_{i_1 i_2} + \sum_{1\le i_1<i_2<i_3\le n} V_{i_1 i_2 i_3} + \cdots + (-1)^{n-1} V_{i_1 i_2 \cdots i_n}, \quad (4.26)$$

$$S = \sum_{1\le i\le n} S_i - \sum_{1\le i_1<i_2\le n} S_{i_1 i_2} + \sum_{1\le i_1<i_2<i_3\le n} S_{i_1 i_2 i_3} + \cdots + (-1)^{n-1} S_{i_1 i_2 \cdots i_n}. \quad (4.27)$$

Setting $d = 3$ and $n \geq 5$, the existence of intersections of order n is deduced from Helly's theorem [14]. It means that the intersection of five spheres is not empty if and only if each of the five subsets of four spheres gives rise to a non-empty intersection. If $n \geq 6$, the intersection of six spheres is not empty if and only if each of the six subsets of five spheres gives rise to a nonempty intersection.

For practical computations, we need Theorem 4.5:

Theorem 4.5. *When $n \geq 5$ spheres in E^3 have a common non-empty intersection, there are m (with $1 \leq m \leq 3$) of these spheres such that their union J contains the intersection I of the $n - m$ remaining spheres.*

Proof. Assume initially that $n = 5$ spheres have a common non-empty intersection. From Helly's theorem, each of the five subsets of four spheres gives rise to a nonempty intersection. If one of these subsets of four spheres is such that the union of $m = 1, 2$, or three spheres contains the intersection of the $4-m$ remaining spheres, the union of these m spheres contains the intersection of the $5-m$ remaining spheres and the theorem stands. As stated in Sect. 4.2.5, a set of four spheres giving rise to a nonempty intersection which is not in one of these latter configurations is in the general configuration.

Now we need to prove the theorem when the five subsets of four spheres are in the case of a general configuration. For this latter, the four contact point pairs between three spheres are such that one of these contact points lies inside the fourth sphere

4.2.6 Intersection of a Sphere with a Dihedron or with Trihedron.

The sphere has a constant Gaussian curvature and each arc of circle has a constante

(%" * &
! +,-.+ + +/ ! + %" 6! ! B! ! , ! 3 ! 7
! # ! 0 0 0#
* " " 9 # ! 0! ! 7 ! #

It can be further generalized to

$$\left\| \sum_{i=1}^{n} x_i \right\| \leq \sum_{i=1}^{n} \|x\| \ .$$

Now, let $\| \ \|$ be the norm derived from the above inner product. By direct calculations, one can check that the following *parallelogram identity*,

$$\|x+y\|^2 + \|x-y\|^2 = 2(\|x\|^2 + \|y\|^2) \ , \tag{2.7}$$

is valid (in any Hilbert space). However, if it is not valid for a particular norm, then we can conclude that this norm *cannot* be obtained from an inner product. The identity (2.7) implies the *parallelogram inequality*:

$$\|x+y\|^2 \leq 2(\|x\|^2 + \|y\|^2) \ , \tag{2.8}$$

which sometimes might be more useful than the triangle inequality (2.6).

A clear and brief reference to such topics can be found in (Rudin, 1976, Ch 1,2,4) or more advance sources, e.g. (Dieudonné, 1969a, Ch I–VI) and (Kantorovich and Akilov, 1982, Part I).

2.4 Euclidean spaces of matrices and their norms

Let $x, y \in \mathbb{R}^n$ be written in coordinate form as $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$, respectively. Then $\mathbb{R}^n$ becomes an Euclidean space with the following (Euclidean) inner product of any two $x, y \in \mathbb{R}^n$:

$$\langle x, y \rangle = \sum_{i=1}^{n} x_i y_i \ . \tag{2.9}$$

The vectors x and y are called *orthogonal* when $\langle x, y \rangle = 0$. With $x = y$, (2.9) becomes $\langle x, x \rangle = \sum_{i=1}^{n} x_i^2$, which defines the Euclidean norm of $x \in \mathbb{R}^n$:

$$\|x\|_2 = \sqrt{\sum_{i=1}^{n} x_i^2} \ . \tag{2.10}$$

The matrices in $\mathcal{M}(n)$ and $\mathcal{M}(n,p)$ can be considered vectors (points) in $\mathbb{R}^{n^2}$ and $\mathbb{R}^{np}$, respectively, with the corresponding definitions of scalar product and norm. Thus, $\mathcal{M}(n)$ and $\mathcal{M}(n,p)$ possess all of the nice properties of the Euclidean space. For example, they are complete normed spaces (as any other finite-dimensional normed space). Also, every bounded and closed set $\mathcal{U} \subset \mathbb{R}^n$ is *compact*, i.e. every infinite sequence of points $x_1, \dots, x_n, \dots \in \mathcal{U}$ contains a subsequence converging in $\mathcal{U}$. The compact sets are very useful. Indeed, consider compact $\mathcal{U} \subset \mathbb{R}^n$ and continuous $f : \mathbb{R}^n \to \mathbb{R}^p$, then

- $f(\mathcal{U}) \subset \mathbb{R}^p$ is compact;
- for $p = 1$, $f(\mathcal{U})$ is a closed interval $[a,b] \in \mathbb{R}$, and thus it reaches its minimal and maximal values, a and b, respectively;
- f is uniformly continuous on $\mathcal{U}$.

There are a plenty of other norms that can be defined in $\mathbb{R}^n$. The most popular ones are

- ℓ_1-*norm*, also known as the *sum-norm*, *Manhattan* or *taxicab norm*:

$$\|x\|_1 = \sum_{i=1}^{n} |x_i| \ ; \tag{2.11}$$

- $\ell_\infty-$*norm*, also known as the *max-norm*:

$$\|x\|_\infty = \max_{1 \le i \le n} |x_i| \ ; \tag{2.12}$$

- ℓ_p-*norm*, for $1 < p < \infty$:

$$\|x\|_p = \left(\sum_{i=1}^{n} |x_i|^p \right)^{1/p} \ . \tag{2.13}$$

The following *Hölder inequality* for ℓ_p-norms is very important:

$$|\langle x, y \rangle| \le \|x\|_p \|y\|_q \ , \text{ for } \frac{1}{p} + \frac{1}{q} = 1 \ , \tag{2.14}$$

and gives the Cauchy–Schwartz inequality (2.4) for $p = q = 2$.

The good news is that all norms in $\mathbb{R}^n$ (and in any finite-dimensional space) are equivalent in the following sense. If $\| \ \|_\dagger$ and $\| \ \|_\ddagger$ are two norms, then there exist constants α and β, such that

$$\alpha\| \ \|_\dagger \le \| \ \|_\ddagger \le \beta\| \ \|_\dagger \ .$$

For example, if $x \in \mathbb{R}^n$, then

$$\begin{gathered}\|x\|_2 \le \|x\|_1 \le \sqrt{n}\|x\|_2 \ , \\ \|x\|_\infty \le \|x\|_2 \le \sqrt{n}\|x\|_\infty \ , \\ \|x\|_\infty \le \|x\|_1 \le n\|x\|_\infty \ .\end{gathered}$$

This implies that convergence and continuity in $\mathbb{R}^n$ do not depend on the adopted norm. For example, proving the continuity of the linear mapping $A \in \mathcal{L}(\mathbb{R}^n, \mathbb{R}^p)$ is particularly simple with respect to the max-norm (2.12) in $\mathbb{R}^n$. In fact, the continuity of A at $0_n \in \mathbb{R}^n$ is sufficient for its continuity in every point. Indeed, for any $x \in \mathbb{R}^n$, i.e. $x = \sum_1^n x_i e_i$, we have

$$\begin{aligned}\|Ax\| &= \left\| A\left(\sum_{i=1}^n x_i e_i\right)\right\| = \left\|\sum_{i=1}^n x_i A e_i\right\| \\ &\le \left(\sum_{i=1}^n \|Ae_i\|\right) \max_{1\le i\le n} |x_i| \le \lambda\|x\|_\infty \ ,\end{aligned}$$

which implies continuity at 0_n. Now, for any $y \in \mathbb{R}^p$, substitute above $x := x - y$, which leads to

$$\|Ax - Ay\| \le \lambda\|x - y\|_\infty \ ,$$

implying continuity at y. The inequality is valid for all $x, y \in \mathbb{R}^n$, and thus it implies *uniform continuity*. As the constant λ is the same for all $x, y \in \mathbb{R}^n$, then A is also *Lipschitz continuous* with *Lipschitz constant* λ. The inequality $\|Ax\| \le \lambda\|x\|_\infty$ (for all $x \in \mathbb{R}^n$) also shows that $\|A\| \le \lambda$, i.e. A is *bounded*. The opposite is also true: if A is linear and bounded, then it is continuous at 0_n.

The case $A \in \mathcal{L}(\mathbb{R}^n, \mathbb{R})$, when A is linear functional, is of particular interest. Let $x \in \mathbb{R}^n$ and $x = \sum_1^n x_i e_i$. Then, making use of the inner product (2.9), we find

$$Ax = A\left(\sum_{i=1}^n x_i e_i\right) = \sum_{i=1}^n x_i A(e_i) = \sum_{i=1}^n x_i a_i = \langle a, x\rangle \ ,$$

which gives the general form of any linear functional $A \in \mathcal{L}(\mathbb{R}^n, \mathbb{R})$. The space of all linear functionals $\mathcal{L}(\mathbb{R}^n, \mathbb{R})$ is called the *dual or conjugate space* of $\mathbb{R}^n$ and is denoted by $(\mathbb{R}^n)^*$. In general, $\mathcal{L}(\mathcal{E}, \mathbb{R})$ is denoted by $\mathcal{E}^*$. If $\mathbb{R}^n$ is Euclidean with (2.9), then $(\mathbb{R}^n)^*$ is also $n-$dimensional Euclidean space. The vector $a = (Ae_1, \ldots, Ae_n)$ is specific for every A, and can be considered as a vector from $(\mathbb{R}^n)^*$. In tensor algebra, vectors from both $\mathbb{R}^n$ and $(\mathbb{R}^n)^*$ are considered simultaneously. In order to distinguish them, the vectors from $(\mathbb{R}^n)^*$ are called *covariant*, while the "standard" vectors of $\mathbb{R}^n$ are called *contravariant*. Consider the following Cartesian product $\mathcal{F}$ of p copies of the real vector space $\mathcal{E}$ and q copies of its dual $\mathcal{E}^*$:

$$\mathcal{F} = \underbrace{\mathcal{E} \times \ldots \times \mathcal{E}}_{p} \times \underbrace{\mathcal{E}^* \times \ldots \times \mathcal{E}^*}_{q} \ .$$

Then, the linear functional (some authors prefer bi-linear functional):

$$T : \mathcal{F} \to \mathbb{R} \ (\text{or } T : (\mathcal{E})^p \times (\mathcal{E}^*)^q \to \mathbb{R}) \tag{2.15}$$

is called $(p, q)-$tensor. All such tensors (linear functionals) form a vector space denoted by $\mathcal{T}_p^q(\mathcal{E})$. The tensor theory is important part of (multi)linear algebra, e.g. (Bourbaki, 1974, Ch3) or (Kostrikin and Manin, 1997, Ch4). Details related to modern applications of tensors in data analysis and their computational aspects can be found in (Hackbusch, 2012; Landsberg, 2012). Some elements of tensor decomposition applied to MDA problems are discussed briefly in Section 10.8.

The above definitions of inner product (2.9) and norm (2.10) can be elaborated to treat $\mathcal{M}(n)$ and $\mathcal{M}(n, p)$ directly as metric or normed spaces without going through vectorization. For any $A, B \in \mathcal{M}(m, n)$, one can define

$$\langle A, B \rangle_F = \text{trace}(A^\top B) \ , \tag{2.16}$$

which is known as the *Frobenius inner product*. Then, the corresponding norm in $\mathcal{M}(n)$ and $\mathcal{M}(m, n)$ is the *Frobenius norm* defined as

$$\|A\|_F = \sqrt{\text{trace}(A^\top A)} \ , \tag{2.17}$$

and one can check that it fulfils the three conditions for a norm.

Then, the corresponding metric in $\mathcal{M}(n)$ and $\mathcal{M}(m, n)$ is defined by

$$d(A, B) = \|A - B\|_F = \sqrt{\text{trace}(A^\top B)} \ . \tag{2.18}$$

Let λ_i be the eigenvalues of $A \in \mathcal{S}(n)$. It follows from (2.17) that $\|A\|_F = \sqrt{\sum_i \lambda_i^2}$. This implies that $|\lambda| \leq \|A\|_F$ for any eigenvalue λ of A, as well as $|\mathrm{trace}(A)| \leq \sqrt{n}\,\|A\|_F$. Moreover, if $\|A\|_F < 1$, then $I_n + A > 0$ (is PD).

Such type of norms (with matrix argument) are called *matrix norms* (Horn and Johnson, 2013, 5.6). Other popular choices, apart from (2.17), are

- 1-norm of $A \in \mathcal{M}(m, n)$:

$$\|A\|_1 = \sum_{i,j} |a_{ij}| \ ; \tag{2.19}$$

- ∞-norm of $A \in \mathcal{M}(m, n)$:

$$\|A\|_\infty = \max_{i,j} |a_{ij}| \ ; \tag{2.20}$$

- p-norm of $A \in \mathcal{M}(m, n)$, for $1 < p < \infty$:

$$\|A\|_p = \max_{\|x\|_p = 1} \|Ax\|_p \ , \tag{2.21}$$

  where $\| \ \|_p$ on the right-hand side of (2.21) is the corresponding ℓ_p-norm of $n \times 1$ vectors. Note that $\|A\|_2 \leq \sqrt{\|A\|_1 \|A\|_\infty}$. The special case of $p = 2$ is very important and is also well known as the *spectral norm* of $A \in \mathcal{M}(m, n)$, because $\|A\|_2 = \sqrt{\lambda_{\max}(A^\top A)}$ or

$$\|A\|_2 = \sigma_{\max}(A), \text{ the largest singular value of } A \ . \tag{2.22}$$

The equivalence of the different matrix norms is quantified by inequalities, many of which are listed in (Horn and Johnson, 2013, 5.6.P23). Several other useful inequalities between matrix norms are provided in (Golub and Van Loan, 2013, Ch 2.3). For example, if $A \in \mathcal{M}(m, n)$, then

$$\|A\|_2 \leq \|A\|_F \leq \sqrt{\mathrm{rank}(A)}\|A\|_2 \leq \sqrt{\min\{m, n\}}\|A\|_2 \ .$$

Further details about norms of matrices and matrix inequalities can be found in (Bhatia, 1997, Ch IV), (Horn and Johnson, 2013, Ch 5), (Magnus and Neudecker, 1988, Ch 11), as well as in (Marshall et al., 2011).

2. *Construct $T(A) \xleftarrow{\bar{n}} F \xrightarrow{g} C$ as the pullback of $T(A) \xrightarrow{T(f)} T(B) \xleftarrow{\bar{m}} C$ (cf. square (2) below); by the universal property of pullbacks, this in addition entails the existence of a morphism $A \xrightarrow{n} F$.*

Then (n, g) is the FPC of (f, m), and n is in $\mathcal{M}$.

$$\begin{tikzcd}
 & & & A \arrow[r, "f"] \arrow[d, dashed, tail, "\exists! n"] \arrow[dd, tail, bend right, "\eta_A"'] & B \arrow[d, tail, "m"] & \\
A \arrow[r, "f"] & B \arrow[d, tail, "m"] & {} \arrow[r, squiggly] & F \arrow[r, dashed, "g"] \arrow[d, "\bar{n}"] \arrow[dr, phantom, "\text{PB} \; (2)"] & C \arrow[d, "\bar{m}"] \arrow[dr, phantom, "\text{PB} \; (1)"] & B \arrow[l, tail, "m"'] \arrow[d, equal] \\
 & C & & T(A) \arrow[r, "T(f)"] & T(B) & B \arrow[l, tail, "\eta_B"']
\end{tikzcd} \tag{3}$$

This guarantee for the existence of FPCs will prove quintessential for constructing $\mathcal{M}$-multi-pushout complements, which are defined as follows:

Definition 6. *For a category* $\mathbf{C}$ *with an $\mathcal{M}$-partial map classifier, the $\mathcal{M}$-multi-pushout complement ($\mathcal{M}$-multi-POC) $\mathcal{P}(f, b)$ of a composable sequence of morphisms $A \xrightarrow{f} B$ and $B \xrightarrow{b} D$ with $b \in \mathcal{M}$ is defined as*

$$\mathcal{P}(f, b) := \{(A \xrightarrow{a} P, P \xrightarrow{d} D) \in \mathsf{mor}(\mathbf{C})^2 \mid a \in \mathcal{M} \wedge (d, b) = \mathsf{PO}(a, f)\} \,. \tag{4}$$

Proposition 2. *In a quasi-topos* $\mathbf{C}$ *and for $\mathcal{M} = \mathsf{rm}(\mathbf{C})$ the class of regular monomorphisms, let $\mathcal{P}(f, b)$ be an $\mathcal{M}$-multi-POC.*

- **Universal property of** $\mathcal{P}(f, b)$: *for every diagram such as in (5)(i) where (1) + (2) is a pushout along an $\mathcal{M}$-morphism n, and where $m = m' \circ b$ for some $m', b \in \mathcal{M}$, there exists an element (a, d) of $\mathcal{P}(f, b)$ and an $\mathcal{M}$-morphism $p \in \mathcal{M}$ such that the diagram commutes and (2) is a pushout. Moreover, for any $p' \in \mathcal{M}$ and for any other element $(a', d')$of $\mathcal{P}(f, b)$ with the same property, there exists an isomorphism $\delta \in \mathsf{iso}(\mathbf{C})$ such that $\delta \circ a = a'$ and $d' \circ \delta = d$.*
- **Algorithm to compute** $\mathcal{P}(f, b)$*:*
  1. *Construct (n, g) in diagram (5)(ii) by taking the FPC of (f, b).*
  2. *For every pair of morphisms (a, p) such that $a \in \mathcal{M}$ and $a \circ p = n$, take the pushout (1), which by universal property of pushouts induces an arrow $D \xrightarrow{e} C$; if $e \in \mathsf{iso}(\mathbf{C})$, (a, d) is a contribution to the $\mathcal{M}$-multi-POC of (f, b).*

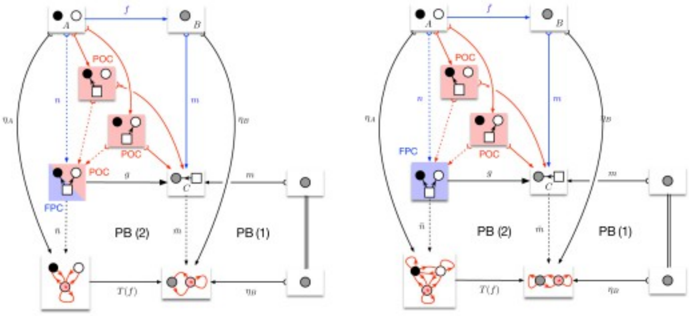
$$\begin{tikzcd}
A \arrow[r, "f"] \arrow[d, dashed, tail, "\exists! a"] \arrow[dd, tail, bend right, "n"'] \arrow[dr, phantom, "(1)"] & B \arrow[d, tail, "b"] \arrow[dd, tail, bend left, "m"] & & A \arrow[r, "f"] \arrow[d, tail, "a"] \arrow[dd, tail, bend right, "n"'] \arrow[dr, phantom, "\text{PO} \; (1)"] & B \arrow[d, tail, "b"] \arrow[dd, tail, bend left, "m"] \\
P \arrow[r, dashed, "\exists! d"] \arrow[d, dashed, "\exists! p"] \arrow[dr, phantom, "(2)"] & D \arrow[d, dashed, tail, "m'"] & & P \arrow[r, "d"] \arrow[d, "p"] \arrow[dr, phantom, "(2)"] & D \arrow[d, "e"] \\
Q \arrow[r, "q"] & E & & F \arrow[r, "g"] & C
\end{tikzcd} \tag{5}$$

(i) (ii)

Proof. The universal property of $\mathcal{P}(f,b)$ follows from pushout-pullback decomposition: pushouts along $\mathcal{M}$-morphisms are pullbacks, so (1) + (2) is a pullback; taking the pullback (p,d) of (q,m') yields by the universal property of pullbacks a morphism a (which is unique up to isomorphism), and thus by pullback-pullback decomposition that (1) and (2) are pullbacks. By stability of $\mathcal{M}$-morphisms under pullbacks, both a and p are in $\mathcal{M}$, and finally by pushout-pullback decomposition, both (1) and (2) are pushouts. This proves that (a,d) is in $\mathcal{P}(f,b)$.

To prove that the algorithm provided indeed computes $\mathcal{P}(f,b)$, note first that by the universal property of FPCs, whenever in a diagram as in (5)(ii) we have that $D \cong C$ and $b \in \mathcal{M}$, since pushouts along $\mathcal{M}$-morphisms are pullbacks, square (1) is a pullback, which entails by the universal property of FPCs that there exists a morphism p such that $p \circ a = n$. By stability of $\mathcal{M}$-morphisms under pullbacks, we find that a must be in $\mathcal{M}$, so indeed every possible contribution to $\mathcal{P}(f,b)$ must give rise to a diagram as in (5)(ii), which proves the claim.

An example of an $\mathcal{M}$-multi-POC construction both in **SGraph** and in **Graph** is given in the diagram below. Note that in **Graph**, the $\mathcal{M}$-multi-POC does not contain the FPC contribution (since in **Graph** the pushout of the relevant span would yield to a graph with a multi-edge).



(6)

Definition 7 ($\mathcal{M}$-FPC-augmentations). *In a quasi-topos*[3] **C** *with* $\mathcal{M} = \mathsf{rm}(\mathbf{C})$*, consider a pushout square along an* $\mathcal{M}$*-morphism such as square* (1) *in the diagram below (where* $\alpha, \bar{\alpha} \in \mathcal{M}$*):*

$$\begin{tikzcd}
A \arrow[r, "a"] \arrow[d, tail, "\alpha"] \arrow[dd, tail, bend right=60, "n\circ\alpha"'] \arrow[dr, phantom, "\substack{\text{PO}\\(1)}"] & B \arrow[d, tail, "\bar{\alpha}"] \arrow[dd, tail, bend left=60, "e\circ\bar{\alpha}"] \\
C \arrow[r, "\bar{a}"] \arrow[d, tail, "n"] \arrow[dr, phantom, "(2)"] & D \arrow[d, "e"] \\
F \arrow[r, "f"] & E
\end{tikzcd} \tag{7}$$

---

[3] As demonstrated in [26, Fact 3.4], every finitary $\mathcal{M}$-adhesive category **C** possesses an (extremal $\mathcal{E}$, $\mathcal{M}$)-factorization, so if **C** is known to possess FPCs as required by the construction, this might allow to generalize the $\mathcal{M}$-FPC-PO-augmentation construction to this setting.

We define an $\mathcal{M}$-FPC augmentation (FPA) *of the pushout square* (1) *as a diagram formed from an epimorphism* $e \in \mathsf{epi}(\mathbf{C})$ *and that satisfies the following properties:*

- *The morphism* $e \circ \bar{\alpha}$ *is an* $\mathcal{M}$*-morphism.*
- $(\bar{\alpha}, id_B)$ *is a pullback of* $(e, e \circ \bar{\alpha})$*.*
- *Square* (1) + (2) *is an FPC, and the induced morphism* n *that exists*[4] *by the universal property of FPCs, here w.r.t. the FPC* $(n \circ \alpha, f)$ *of* $(a, e \circ \bar{\alpha})$*, is an* $\mathcal{M}$*-morphism.*

For a pushout as in (1)*, we denote by* $\mathsf{FPA}(\alpha, a)$ *its class of FPAs:*

$$\mathsf{FPA}(\alpha, a) := \{(n, f, e) \mid e \in \mathsf{epi}(\mathbf{C}) \wedge e \circ \bar{\alpha}, n \in \mathcal{M} \wedge (f, n \circ \alpha) = FPC(a, e \circ \bar{\alpha})\} \quad (8)$$

As induced by the properties of pushouts and of FPCs, FPAs are defined up to universal isomorphisms (in D*,* E *and* F*), and for a given pushout square there will in general exist multiple non-isomorphic such augmentations.*

The final technical ingredient for our rewriting theoretic constructions is a notion of *multi-sum* adapted to the setting of quasi-topoi, a variation on the general theory of multi-(co-)limits due to Diers [20].

Definition 8. *In a quasi-topos* $\mathbf{C}$*, the multi-sum* $\sum_{\mathcal{M}}(A, B)$ *of two objects* $A, B \in \mathsf{obj}(\mathbf{C})$ *is defined as a family of cospans of regular monomorphisms* $A \xrightarrow{f} Y \xleftarrow{g} B$ *with the following universal property: for every cospan* $A \xrightarrow{a} Z \xleftarrow{b} B$ *with* $a, b \in \mathsf{rm}(\mathbf{C})$*, there exists an element* $A \xrightarrow{f} Y \xleftarrow{g} B$ *in* $\sum_{\mathcal{M}}(A, B)$ *and a regular monomorphism* $Y \xrightarrow{y} Z$ *such that* $a = y \circ f$ *and* $b = y \circ g$*, and moreover* (f, g) *as well as* y *are unique up to universal isomorphisms.*

$$\begin{tikzcd}
A \arrow[dr, "in_A"] \arrow[ddr, "y_A"'] \arrow[dddr, bend right, "a"'] & & B \arrow[dl, "in_B"'] \arrow[ddl, "y_B"] \arrow[dddl, bend left, "b"] \\
& A+B \arrow[d, "e"] \arrow[dd, bend left, "{[a,b]}"] & \\
& Y \arrow[d, "m"] & \\
& Z &
\end{tikzcd}
\quad \rightsquigarrow \quad
\begin{tikzcd}
& & X & & \\
& & \varnothing \arrow[u, "\iota_X"] \arrow[dll, "\iota_A"'] \arrow[drr, "\iota_B"] & & \\

& & Z & &
\end{tikzcd}
\quad (9)$$

(*i*) (*ii*)

---

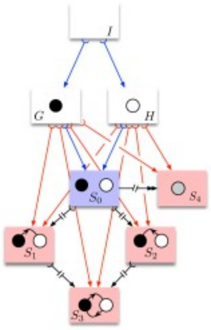
[4] Note that square (1) pasted with the pullback square formed by the morphisms $\overline{\alpha}, id_B, e, e \circ \bar{\alpha}$ yields a pullback square that is indeed of the right form to warrant the existence of a morphism n into the FPC square (1) + (2).

Lemma 1. *If* $\mathbf{C}$ *is a quasi-topos, the multi-sum* $\sum_{\mathcal{M}}(A, B)$ *arises from the epi-*$\mathcal{M}$*-factorization of* $\mathbf{C}$ *(for* $\mathcal{M} = \mathsf{rm}(\mathbf{C})$*; compare [29]).*

- ***Existence:*** *Let* $A \xrightarrow{in_A} A + B \xleftarrow{in_B} B$ *be the disjoint union of* A *and* B*. Then for any cospan* $A \xrightarrow{a} Z \xleftarrow{b} B$ *with* $a, b \in \mathcal{M}$*, the epi-*$\mathcal{M}$*-factorization of the induced arrow* $A + B \xrightarrow{[a,b]} Z$ *into an epimorphism* $A + B \xrightarrow{e} Y$ *and an* $\mathcal{M}$*-morphism* $Y \xrightarrow{m} Z$ *yields a cospan* $(y_A = e \circ in_A, y_B = e \circ in_B)$*, which by the decomposition property of* $\mathcal{M}$*-morphisms is a cospan of* $\mathcal{M}$*-morphisms (cf. (9)(i)).*
- ***Construction:*** *For objects* $A, B \in \mathsf{obj}(\mathbf{C})$*, every element* $A \xrightarrow{q_A} Q \xleftarrow{q_B} B$ *in* $\sum_{\mathcal{M}}(A, B)$ *is obtained from a pushout of some span* $A \xleftarrow{x_A} X \xrightarrow{x_B} B$ *with* $x_A, x_B \in \mathcal{M}$ *and a morphism* $P \xrightarrow{q} Q$ *in* $\mathsf{mono}(\mathbf{C}) \cap \mathsf{epi}(\mathbf{C})$ *(cf. (9)(ii)).*

Proof. See [7, Appendix B].

Since in an adhesive category all monos are regular [34], in this case the multi-sum construction simplifies to the statement that every monic cospan can be uniquely factorized as a cospan obtained as the pushout of a monic span composed with a monomorphism. It is however worthwhile emphasizing that for generic quasi-topoi $\mathbf{C}$ one may have $\mathcal{M} \neq \mathsf{mono}(\mathbf{C})$, as is the case in particular for the quasi-topos **SGraph** of simple graphs. We illustrate this phenomenon in the diagram on the right via presenting the multi-sum construction for $A = B = \bullet$. Note in particular the monic-epis that extend the two-vertex graph S_0 into the graphs S_1, S_2 and S_3, all of which have the same vertices as S_0 (recalling that a morphism in **SGraph** is monic/epic if it is so on vertices), yet additional edges, so that in particular none of the morphisms $S_0 \to S_j$ for $j = 1, 2, 3$ is edge-reflecting.



3 Non-linear Sesqui- and Double-Pushout Rewriting

In much of the traditional work on graph- and categorical rewriting theories [22], while it was appreciated early in its development that in particular SqPO-rewriting permits the cloning of subgraphs [17], and that both SqPO- and DPO-semantics permit the fusion of subgraphs (i.e. via input-linear, but output-non-linear rules), the non-uniqueness of pushout complements along non-monic morphisms for the DPO- and the lack of a concurrency theorem in the SqPO-case in general has prohibited a detailed development of non-linear rewriting theories to date. Interestingly, the SqPO-type concurrency theorem for linear rules as developed in [2] exhibits the same obstacle for the generalization to non-linear rewriting as the DPO-type concurrency theorem, i.e., the non-uniqueness

Collection. Aida, the founder of Saijō school, left behind several hundreds volumes, which are on line at *Yamagata University Academic Repository*. Toyoyoshi proposed many problems involving congruent circles, whose manuscripts can be seen in *Digital Library Department of Mathematics, Kyoto University*. More than a hundred titles are online at *Kotenseki Sogo Database in Waseda University*. Also several hundreds of books and manuscripts are online at *Shimoura Collection in Museum of Science Tokyo University of Science*. The first and the last collections can also be found at the site of *National Institute of Japanese literature*.

Wasan Geometry

Let us see the catalog pages at the opening of a popular book of formulas (Yamamoto, 1841) (see Figs. 1, 2, 3, 4, 5, and 6). The figures are arranged to be read top-to-bottom and right-to-left. There are a hundred and two figures, and a formula is stated on later pages for each of the figures. For example, for the leftmost figure at the top in Fig. 5 consisting of an ellipse and a square, the formula states that the side of the square equals $ab/\sqrt{a^2+b^2}$, where a and b are the major axis and the minor axis of the ellipse. As this example shows, which is also stated as a problem and its answer, most geometric problems attempt to discover certain dimensions of geometric figures such as the diameter of a circle, a major (or minor) axis of an ellipse, the side of a rectangle, etc. The catalog also shows that figures involving touching circles constitute the major parts of Wasan geometry. Touching spheres were also considered (see Fig. 5, right). As in Figs. 5 and 6, ellipses, which were considered as sections of cylinders, were studied often, but hyperbolas and parabolas were not outside of several exceptions such as Iwai (no date), a sangaku problem (Gunma Wasan Kenkyūkai, 1987, p. 89), and also see Mikami (1913-2). Also rhombuses were considered, but parallelograms barring a couple of exceptions, such as Gunma Wasan Kenkyūkai (1987, p. 72) and Kimura (1855), were not. Wasan plane geometry is not a triangle geometry, i.e., Wasan mathematicians did not study about one triangle but studied some relationships which arose when several elementary figures such as triangles, rectangles, and circles got together. For a lot of notable problems in Wasan geometry, see the nice collection (Fukagawa and Pedoe, 1989).

Problems Involving Congruent Circles

We state results of Wasan geometry as problems and answers to distinguish them from the others. In this section, we consider problems of Wasan geometry involving several congruent circles. Those problems were considered especially by mathematicians in Shiseisanka school and Toyoyoshi in Miki school. Since the problems are easily generalized today, we consider the problems together with their generalization. We will see that the 3-4-5 triangle is often associated with several interesting special cases.

Fig. 1 Catalog page 1

Congruent circles in Wasan geometry are circles in line in many cases as in Fig. 7, which we define as follows. Let $\alpha_1, \alpha_2, \cdots, \alpha_n$ be congruent circles touching a line t from the same side such that α_1 and α_2 touch, and $\alpha_i (\neq \alpha_{i-2})$ $(i = 3, 4, \cdots, n)$ touches α_{i-1}. In this case, we call the circles $\alpha_1, \alpha_2, \cdots, \alpha_n$ congruent circles on a line or congruent circles on t. The next proposition is very useful for problems in Wasan geometry involving externally touching circles.

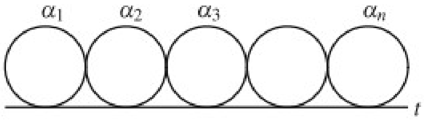
Fig. 7 Congruent circles on t



α_1
α_2
α_3
α_n
t

Proposition 1. *If two externally touching circles of radii r_1 and r_2 touch a line at two points P and Q, then $|PQ| = 2\sqrt{r_1 r_2}$.*

Congruent Circles on a Line and a Circle

If $\beta_1, \beta_2, \cdots, \beta_n$ $(n \geq 2)$ are congruent circles of radius b on a line t, and a circle α of radius a touches β_1, β_n, and t, we denote the configuration consisting of α, $\beta_1, \beta_2, \cdots, \beta_n$ and t by $A(n)$ (see Fig. 8). If $n = 2$, the circle α coincides with the incircle of the curvilinear triangle made by β_1, β_2, and t. If $n = 3$, the circles α and β_2 coincide, and we get the trivial relation $a = b$. The relation between a and b was considered in the case $n = 2, 4, 5$ for $A(n)$ in Wasan geometry. The next theorem can easily be proved by Proposition 1 (Okumura, 2017a):

Theorem 1. *A circle of radius a and n $(n \geq 2)$ congruent circles of radius b on a line can form $A(n)$ if and only if*

$$\frac{a}{b} = \left(\frac{n-1}{2}\right)^2. \tag{1}$$

Figure 9 shows $A(5)$ appeared in the problem proposed by Shinohara in 1809 (Shimura, no date). Since $a/b = 1/4$ for $A(2)$, and $a/b = 4$ for $A(5)$, we can construct a recursive configuration arising from Shinohara's figure (see Fig. 10), where the horizontal parallel segments are removed. The configuration $A(n)$ has several interesting properties, one of which is as follows (Okumura, 2017a):

Theorem 2. *Assume that $\beta_1^n, \beta_2^n, \cdots, \beta_n^n$ $(n \geq 2)$ are congruent circles on a line t forming $A(n)$ with a circle α and t. If γ is the incircle of the curvilinear triangle made by α, β_1^n and t, then there are congruent circles $\gamma = \beta_1^{n+2}, \beta_2^{n+2}, \cdots, \beta_{n+2}^{n+2}$ on t such that they form $A(n+2)$ with α and t.*

Assume that a circle α, its tangent t, and congruent circles β_1^3, $\beta_2^3 (= \alpha)$, β_3^3 on t form $A(3)$. Starting with this figure, and using Theorem 2 repeatedly, we get Fig. 11. With this construction, we can define the configuration $A(1)$ as the figure consisting of α, t, and β_1^1, where β_1^1 is the tangent of α parallel to t (see Fig. 12).

Congruent Circles on a Line with Two Congruent Circles on a Line

Let β_1 and β_2 be congruent circles of radius b on a line t, and let $\gamma_1, \gamma_2, \cdots, \gamma_n$ be congruent circles of radius c on t such that they lie inside of the curvilinear triangle made by β_1, β_2, and t and γ_1 touches β_1 and γ_n touches β_2. The configuration consisting of β_1, β_2, γ_1, γ_2, $\cdots$, γ_n, and t is denoted by $B(n)$ (see Fig. 13). The configuration $B(1)$ coincides with $A(2)$. The relation between b and c was considered in the case in which $n = 1, 5$ and n is even in Wasan geometry. If we divide $B(n)$ by the perpendicular from the point of tangency of β_1 and β_2 to t, we get two congruent figures. Toyoyoshi considered one of the resulting figure and got a relation essentially the same as (2) in the next theorem in the case n being even (Toyoyoshi, no date) (see Fig. 14).

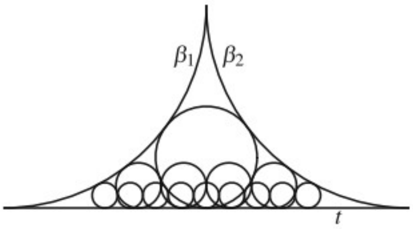

Fig. 15 $B(1) \cup B(4) \cup B(9)$

Theorem 3. *Two circles of radius b and n congruent circles of radius c on a line can form* $B(n)$ *if and only if*

$$\frac{b}{c} = (\sqrt{n} + 1)^2. \tag{2}$$

A similar theorem to Theorem 2 for $B(n)$ also holds (Okumura, 2017a) (see Fig. 15).

Theorem 4. *Assume that* $\gamma_1, \gamma_2, \cdots, \gamma_{n^2}$ *are congruent circles on a line t forming* $B(n^2)$ *with two congruent circles* β_1 *and* β_2 *and t for a positive integer n, where* β_1 *touches* γ_1*. If* δ *is the incircle of the curvilinear triangle made by* β_1, γ_1, *and t, then there are congruent circles* $\delta = \delta_1, \delta_2, \cdots, \delta_{(n+1)^2}$ *on t such that they form* $B((n+1)^2)$ *with* β_1, β_2, *and t.*

Congruent Circles on a Line and Congruent Squares

Congruent squares are derived from the configurations $A(n)$ and $B(n)$. We consider the following problem (Aida, 1788) (see Fig. 16).

Problem 1. Let β_1 and β_2 be congruent circles of radius b on a line t. If $ABCD$ is a square inside of the curvilinear triangle made by β_1, β_2, and t such that the side DA lies on t and the points C and B lie on β_1 and β_2, respectively. Show that $2b = 5|AB|$.

The problem is the case $n = 1$ in the next theorem (Okumura, 2018a) (see Fig. 17).

Theorem 5. *Assume that congruent circles* β_1 *and* β_2 *of radius b on a line t and congruent circles* $\gamma_1, \gamma_2, \cdots, \gamma_n$ *on t form* $B(n)$ *with t, where* γ_1 *and* γ_n *touch* β_1 *and* β_2 *at points C and B, respectively. If A is the foot of perpendicular from B to t, the following relations hold.*

β_3
β_4
C
B
t
A

(i) $n|AB| = |BC|$.
(ii) $2b = (1 + (\sqrt{n} + 1)^2)|AB|$.

If D is the foot of perpendicular from C to t in the theorem, then the rectangle $ABCD$ can be divided into n congruent squares of side length $|AB|$. The theorem also shows that the incircle of the curvilinear triangle formed by β_1, β_2, and t touches β_1 and β_2 at C and B, respectively, in Problem 1. For the configuration $A(n)$, we also have a similar theorem (see Fig. 18).

Theorem 6. *Assume that a circle α of radius a and congruent circles $\beta_1, \beta_2, \cdots, \beta_n$ on t form $A(n)$ with t, where α touches β_1 and β_n at points C and B, respectively. If A is the foot of perpendicular from B to t, the following relations hold.*

(i) $(n - 1)|AB| = |BC|$.
(ii) $2a = \left(1 + \left(\frac{n-1}{2}\right)^2\right)|AB|$.

Two Congruent Circles on a Line

We consider the next problem (Furuya, 1854) (see Fig. 19). There are several sangaku problems and books stating the same problem.

Problem 2. Let α and β be externally touching circles of radii a and b, respectively, with an external common tangent t. Let γ and γ' be two congruent circles on t of radius c such that they lie inside of the curvilinear triangle made by α, β, and t, γ touches α, and γ' touches β. Find c in terms of a and b.

The part (iii) of the next theorem gives an answer of the problem (Okumura, 2017b) (see Fig. 20).

Theorem 7. *Let α, β, γ, γ', and t be as in Problem 2. Assume that δ and δ' are two congruent circles on t of radius d such that α and β lie inside of the curvilinear triangle made by δ, δ', and t, δ touches α, and δ' touches β. Then the following relations hold.*

(i) $\sqrt{a} + \sqrt{b} = \sqrt{d} - \sqrt{c}$.

(ii) $ab = cd$.

(iii) $c = \dfrac{w - \sqrt{w^2 - 4ab}}{2}$ *and* $d = \dfrac{w + \sqrt{w^2 - 4ab}}{2}$, *where* $w = a + b + 4\sqrt{ab}$.

Fig. 19 A pair of two congruent circles on t

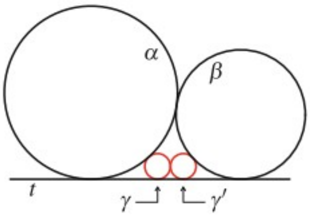

Fig. 20 Two pairs of two congruent circles on t

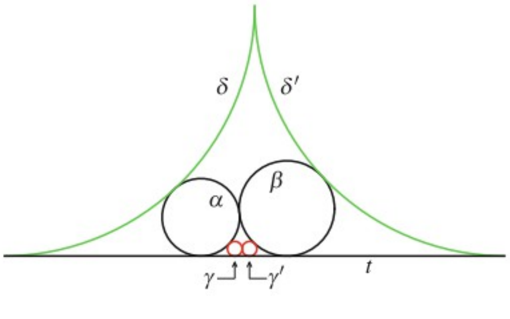

Congruent Circles on a Line with Two Intersecting Congruent Circles

We generalize the next problem (Takeda, 1825), which can also be found in several Wasan books (see Fig. 21).

Problem 3. For two intersecting circles δ_1 and δ_2 of radius s, there are four congruent smaller circles of radius r such that two of them touch each other and δ_1 and δ_2 internally, each of the other two circles touches δ_1 and δ_2 externally, and one of the external common tangents of δ_1 and δ_2. Show $s = 6r$.

Problem 3 is the case $n = 1$ in the next theorem (Okumura, 2018g) (see Fig. 22).

Theorem 8. *For a rectangle $ABCD$ satisfying $s = |BC| > |AB|$, let δ be the circle of center B passing through C. If $\gamma_1, \gamma_2, \cdots, \gamma_n$ are congruent circles of radius r on DA lying inside of the curvilinear triangle made by CD, DA, and δ such that γ_1 touches CD and γ_n touches δ, and $\gamma'_1, \gamma'_2, \cdots, \gamma'_n$ are congruent circles of radius r on DA touching DA from the same side as γ_1 such that γ'_1 touches δ internally from the side opposite to D and γ'_n touches AB from the same side as D, then the following statements hold.*

(i) $s = 2(2n + 1)r$.
(ii) *There is a circle of radius r touching γ_n, γ'_1 and DA.*

Two Sets of Congruent Circles on a Line and Two Circles

We consider the next sangaku problem stated in a collection of problems proposed by mathematicians in Shiseisanka school (no author's name, no datea) (see Fig. 23). The problem is also cited in Saitama Prefectural Library (1969).

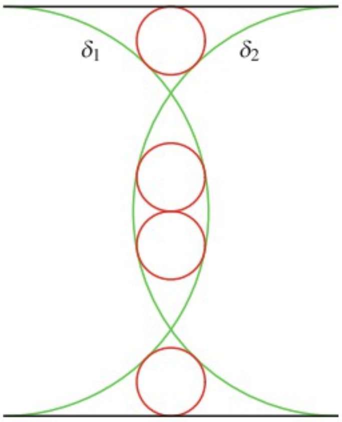

Fig. 21 $n = 1$

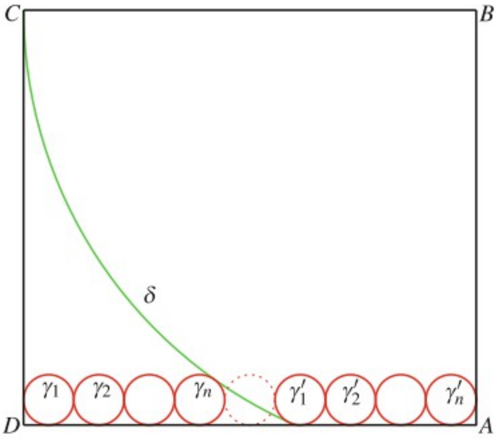

Fig. 22 $n = 4$

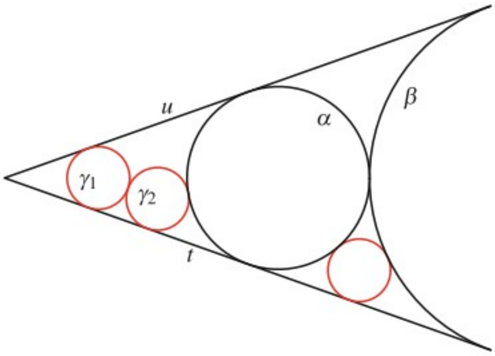

Fig. 23 Two congruent circles on t and one circle on t of the same radius

Problem 4. Let α and β be externally touching circles of radii a and b ($a < b$), respectively, with external common tangents t and u. Congruent circles γ_1 and γ_2 on t lie inside of the curvilinear triangle made by t, u, and α such that γ_1 touches u and γ_2 touches α, and the incircle of the curvilinear triangle made by α, β, and t is congruent to γ_1. Show that $b = 2a$.

The problem can be solved by Proposition 1. It is involving two larger circles and two sets of congruent circles on a line of the same radius, one is $\{\gamma_1, \gamma_2\}$, and the other is the set consisting of incircle of the curvilinear triangle made by α, β, and t, though the latter consists of only one circle. It suggests that there may be some interesting simple relationships between the ratio of the radii of the two larger circles and the numbers of congruent circles of the two sets of the circles of the same radius, if we consider similar figures. The next theorem shows one of such relationships (Okumura and Sodeyama, 1998) (see Fig. 24).

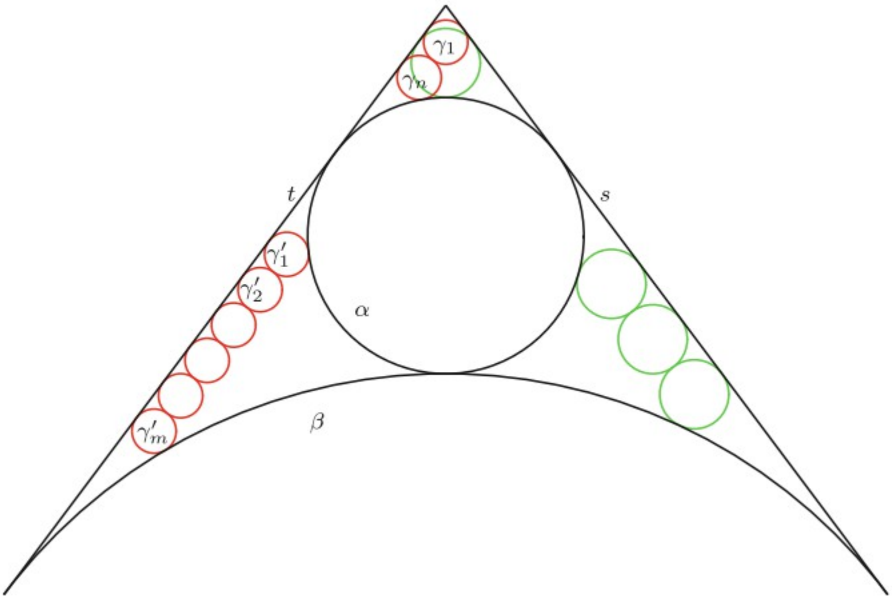

Fig. 24 $(n, m) = (2, 6)$ (left), $(n, m) = (1, 3)$ (right)

Theorem 9. *Let α and β be externally touching circles of radii a and b $(a < b)$, respectively, with external common tangents t and u. Congruent circles $\gamma_1, \gamma_2, \cdots, \gamma_n$ on t lie inside of the curvilinear triangle made by t, u, and α such that γ_1 touches u and γ_n touches α, also congruent circles $\gamma'_1, \gamma'_2, \cdots, \gamma'_m$ on t lie inside of the curvilinear triangle made by α, β and t such that γ'_1 touches α and γ'_m touches β, where γ_1 and γ'_1 are also congruent. Then $b = 4a$ if and only if $3n = m$.*

Notice that the point of intersection of t and u, the center of α, and the point of tangency of α and t form a 3-4-5 triangle in Fig. 24.

A Square and Three Congruent Circles in an Isosceles Triangle

We consider the next problem (Takigawa, 1827), which can be found in several Wasan books (see Fig. 25).

Problem 5. For an isosceles triangle EFG with base EF, let $ABCD$ be a square such that B and C lie on the sides FG and GE, respectively, and DA lies on the side EF, where the triangles ABF and BCG have the same inradius r. Show that $4r = |AB|$.

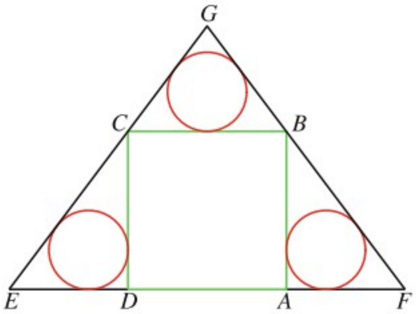

Fig. 25 $n = 1$

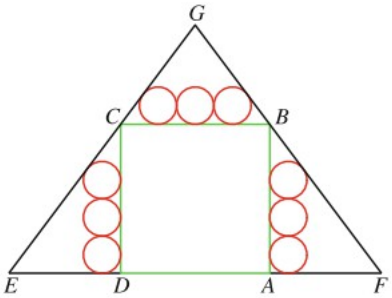

Fig. 26 $n = 3$

For a triangle EFG, let $\gamma_1, \gamma_2, \cdots, \gamma_n$ be congruent circles on EF of radius r lying inside of EFG such that γ_1 touches GE, and γ_n touches FG. In this case we say that EFG has n circles of radius r on EF. Problem 5 is the case $n = 1$ in the next theorem (Okumura, 2018b) (see Fig. 26).

Theorem 10. *For an isosceles triangle EFG with base EF, let $ABCD$ be a square such that B and C lie on the sides FG and GE, respectively, and DA lies on the side EF. If the triangle ABF has n circles of radius r on AB and the triangle BCG has n circles of radius r on BC, then $2(n+1)r = |AB|$ and $|EF| : |FG| = 6 : 5$.*

The theorem shows that the shape of the isosceles triangle EFG is fixed for any positive integer n, which is divided into two 3-4-5 triangles by the perpendicular bisector of the base.

Congruent Circles in a Rectangle

Let $ABCD$ be a rectangle of center O and circumcircle δ of radius s. If the triangle OAB has n circles of radius r on AB and a circle of radius r touches the side BC at the midpoint and the minor arc of δ cut by BC, then the configuration is denoted by $S(n)$. Furthermore if the triangle OBC has m circles of radius r on BC for $S(n)$, we denote the configuration by $S(n, m)$. The following problem was proposed on the

Fig. 27 $S(2), k = 1$

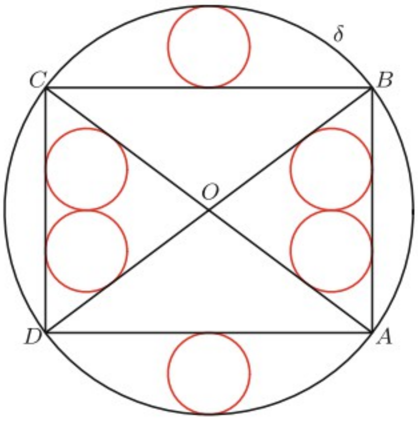

Fig. 28 $S(12), k = 3$

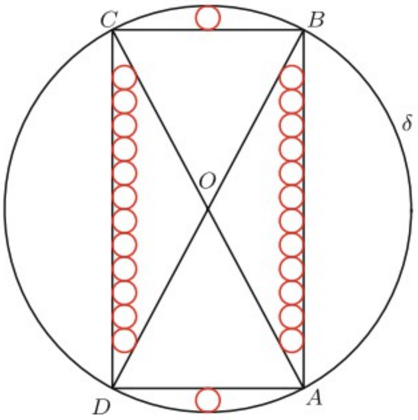

occasion of the 150th anniversary of the death of Kōwa (or Takakazu) Seki (Okayu, 1855) (see Fig. 27).

Problem 6. Show $s/r = 5$ for $S(2)$.

Problem 6 is the case $k = 1$ in the next theorem (Okumura, 2018d) (see Fig. 28).

Theorem 11. *The configuration $S(n)$ can be constructed for any positive integer n, and the shape is determined uniquely by n, where s/r is an integer if and only if there is a positive integer k such that $n = k(k+1)$. In this event $s/r = (k+1)^2 + 1$.*

The configuration $S(n, m)$ exists if and only if $(n, m) = (2, 2), (6, 5)$, where the triangle ABC is a 3-4-5 triangle in both the cases (Okumura, 2018e) (see Figs. 29 and 30).

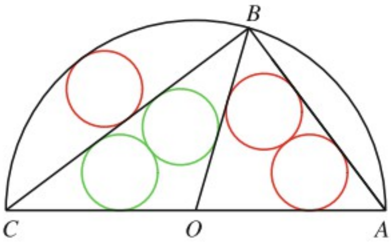

Fig. 30 $S(6, 5)$

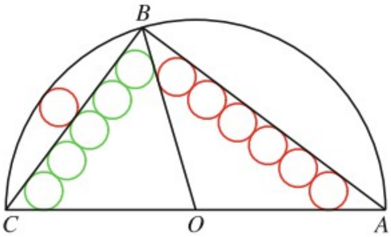

The Arbelos in Wasan Geometry

In this section we consider problems of Wasan geometry involving an arbelos. For a point O on the segment AB, let α, β, and γ be the semicircles of diameters AO, BO, and AB, respectively, constructed on the same side of AB (see Fig. 31). The area surrounded by the three semicircles is called an arbelos and denoted by (α, β, γ). We call the perpendicular to AB at O the axis. The axis divides the arbelos into two curvilinear triangles with congruent incircles. The two congruent circles are believed to be studied by Archimedes and called the twin circles of Archimedes. Circles congruent to the twin circles are said to be Archimedean. Today's research on the arbelos is mostly concerning with finding new Archimedean circles. However the third Archimedean circle was not found until the twentieth century. Meanwhile Leon Bankoff found an Archimedean circle, which is sometimes called Bankoff triplet circle (Bankoff, 1974). After the publication of the notable paper entitled "Those ubiquitous Archimedean circles" (Dodge et al., 1999), which presented dozens of Archimedean circles, many mathematicians were interested in the arbelos, and many papers on the arbelos have been published.

Since the arbelos was also considered in Wasan geometry, it is an very good example to see the different approaches to studying the same figure between the East and the West. Ordinarily the arbelos is described by three semicircles so that the axis is vertical as in Fig. 31. But in Wasan geometry, it is described by three mutually touching circles with collinear centers such that the line passing through the centers is vertical (see Fig. 32). However we describe figures of Wasan geometry in ordinary way to reduce the space here. As Fig. 32 shows, twin circles of Archimedes were also considered in Wasan geometry (Akabane, 1998; Fukushimaken Wasan Kenkyū Hozonkai, 1989; Hirayama and Matsuoka, 1966); however there are few problems

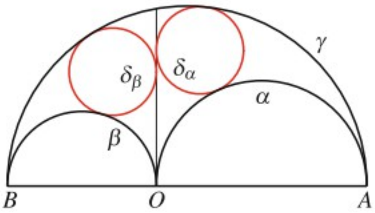

Fig. 31 (α, β, γ) and the twin circles

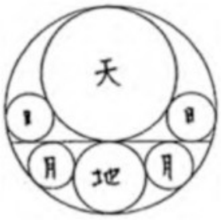

Fig. 32 Fujisawa (1874)

involving other Archimedean circles. We will see two sangaku problems involving such Archimedean circles at the end of this section. On the other hand, various kinds of non-Archimedean circles were considered. We generalize those problems or show that the figures of the problems have some interesting properties.

We assume $|AO| = 2a$, $|BO| = 2b$. The radius of Archimedean circles equals $r_\mathrm{A} = ab/(a+b)$. The twin circles of Archimedes touching α and β are denoted by δ_α and δ_β, respectively.

Two Sangaku Problems Involving a Circle of the Same Radius

We consider two sangaku problems involving a circle of the same radius. The part (i) of the next problem was proposed by Izumiya in 1866 (Saitama Prefectural Library, 1969) (see Fig. 33), and the part (ii) was proposed by Naitoh in 1983 (this sangaku seems to be made in modern days) (Fukushimaken Wasan Kenkyū Hozonkai, 1989) (see Fig. 34).

Problem 7. Assume that $a = b$ for (α, β, γ).
(i) The tangent of α from B meet γ again in a point D. Show that the inradius of the curvilinear triangle made by α, γ and the perpendicular from D to AB equals $a/9$.
(ii) Show that the radius of the circle touching the remaining external common tangent of α and δ_α and the minor arc of γ cut by the tangent at the midpoint equals $a/9$.

The next theorem shows that there are several congruent circles including the two circles in the problem even in the case $a \neq b$ (Okumura, 2019d) (see Fig. 35).

Theorem 12. *We assume that t is the external common tangent of α and β, u is the remaining external common tangent of α and δ_α, v is the tangent of α from B*

meeting γ again in a point D, and w is the perpendicular from D to AB. Then the following five circles are congruent and have radius

$$\frac{a^2b}{(a+2b)^2}.$$

ε_1*: the incircle of the curvilinear triangle made by* α, γ, *and* w
ε_2*: the circle touching* u *and the minor arc of* γ *cut by* u *at the point* D
ε_3*: the incircle of the curvilinear triangle made by* γ, δ_β, *and the axis*

ε_4*: the smallest circle touching* w *and passing through the point of intersection of* u *and* v

ε_5*: the smallest circle touching the axis and passing through the point of intersection of* β *and* v

The circle ε_1 also touches the line t, and D is the midpoint of the minor arc of γ cut by u in the theorem.

Two Congruent Circles Touching a Perpendicular to AB

We consider the next sangaku problem, which was proposed by Tamura in 1898 (Saitama Prefectural Library, 1969) (see Fig. 36).

Problem 8. Assume that h is a perpendicular to AB intersecting α and the incircle of the curvilinear triangle made by α, γ, and h is congruent to the circle touching α and β externally and h. Show that the common radius equals $|AB|/10$ in the case $a = b$.

For this problem, we are interested in a necessary and sufficient condition, in which the two congruent circles are obtained. The next theorem gives such a condition (Okumura, 2019e) (see Fig. 37).

Theorem 13. *Let* T *be the point of tangency of the incircle of* (α, β, γ) *and* α. *Let* h *be a perpendicular from* P *to* AB *for a point* P *on* α. *The incircle of the curvilinear triangle made by* α, γ, *and* h *is congruent to the circle touching* α *and* β *externally and* h *if and only if* P *coincides with* T. *In this event if* h *meets* AB *in a point* U,

Fig. 36 Tamura's problem

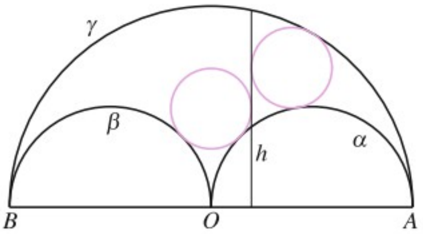

Fig. 37 Three congruent circles

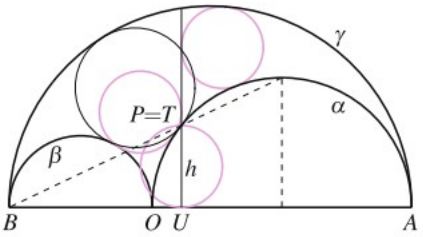

then the circle of diameter TU is also congruent to the two circles and the common radius equals

$$\frac{ab(a+b)}{b^2+(a+b)^2}.$$

Notice that the line BT meets α again in the farthest point on α from AB in the theorem.

Two Circles Touching a Perpendicular to AB at the Same Point

We consider two sangaku problems and assume that h is the perpendicular to AB at H for a point H on the segment AO, δ is the circle touching α and β externally and h, and ε is the incircle of the curvilinear triangle made by α, γ and h. The part (i) of the next problem was proposed by Satoh in 1883 (Fukushimaken Wasan Kenkyū Hozonkai, 1989) (see Fig. 38). The part (ii) was proposed by Chiba in 1880 (Yasutomi, 1987) (see Fig. 39).

Problem 9. (i) The circle ε is congruent to the circle of diameter OH and $a = b$. Show that the common radius is triple the inradius of the curvilinear triangle made by α, γ and the external common tangents of α and β.

(ii) The circle δ is congruent to the circle of diameter AH. Show that the radius of ε equals $ab/(a+2b)$.

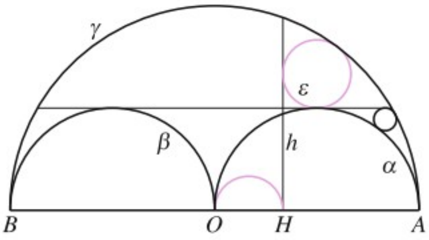

Fig. 38 Two congruent circles

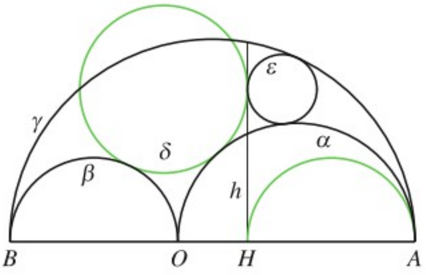

Fig. 39 Two congruent circles

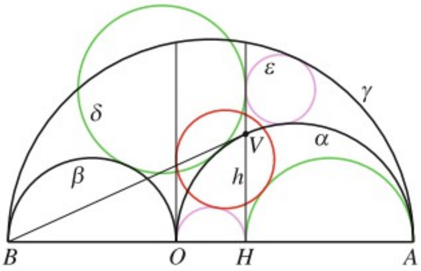

Fig. 40 Circles derived from the tangent of α from B touching α at V

The incircle of the curvilinear triangle made by α, γ, and the external common tangents of α and β in (i) is the circle ε_1 in Theorem 12, i.e., its radius equals $a^2b/(a+2b)^2$ in the case $a \neq b$. We also consider necessary and sufficient conditions, in which each of the pairs of congruent circles in the problem is obtained. The next theorem gives several such conditions (Okumura, 2019b,i) (see Fig. 40).

Theorem 14. *Let V be the point of tangency of α and its tangent from B. The following statements are equivalent.*

(i) *The line h passes through the point V.*
(ii) *The circle δ and the circle of diameter AH are congruent.*
(iii) *The circle ε and the circle of diameter HO are congruent.*
(iv) *The circles δ and ε touch.*
(v) *The two circles touching the two circles of diameters HO and AH externally and the axis are Archimedean.*

If h passes through the point V, then $|HO| = 2ab/(a+2b)$ and the radius of the circle δ equals $a(a+b)/(a+2b)$ in the theorem.

Two Congruent Circles Touching an Inclined Line to AB

We denote the point of intersection of γ and the axis by I. Let ρ be the reflection in the line AB. We assume that ε_1 is the incircle of the curvilinear triangle made by α, γ, and the line IP for a point P on the semicircle α^ρ and ε_2 is the circle touching the semicircles α^ρ, γ^ρ, and IP from the side opposite to A (see Fig. 41). We consider the next problem (Akita, 1833).

Problem 10. The circles ε_1 and ε_2 are congruent. Find the common radius in terms of a and $|IO|$.

Considering the power of the point O with respect to γ, we get $|IO| = 2\sqrt{ab}$. Therefore Problem 10 essentially demands to find the common radius of the two circles in terms of a and b. However b was not used in the problem because of the

absence of the semicircle β from the figure. Let J be the point of intersection of α and the segment AI. The next theorem gives a condition, in which the pair of congruent circles in the problem is obtained (Okumura, 2019a) (see Fig. 42).

Theorem 15. *The circles ε_1 and ε_2 are congruent if and only if the point P^ρ coincides with the point J. In this event the common radius equals*

$$\frac{4a^2b}{(2a+b)^2}.$$

The point J is one of the most notable points on α, because the external common tangent of α and β touches α at J, the distances from the center of β to I and J are the same, and the distance between J and the axis equals $2r_{\mathrm{A}}$, where recall that r_{A} is the radius of Archimedean circles.

Congruent Circles Touching a Circle Passing Through the Center of α

The next sangaku problem was proposed by Matsuda (no author's name, no dateb) (see Fig. 43).

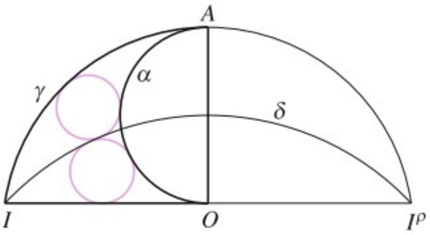

Fig. 43 Matsuda's problem

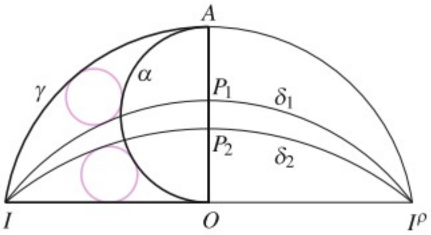

Fig. 44 A generalization

Problem 11. A circle δ passes through the points I and I^ρ and divides the curvilinear triangle made by α, γ, and IO into two curvilinear triangles with congruent incircles. Show that δ passes through the center of α.

The problem is generalized as follows (Okumura, 2019c) (see Fig. 44).

Theorem 16. *For a point P_i $(i = 1, 2)$ on the segment AO, let δ_i be the circle passing through the points I, I^ρ, and P_i. Then the incircle of the curvilinear triangle made by α, γ, and δ_1 is congruent to the incircle of the curvilinear triangle made by α, IO, and δ_2 if and only if the center of α coincides with the midpoint of P_1P_2.*

Reflection in the Axis

Let $'$ be the reflection in the axis. The next sangaku problem was proposed by Satoh in 1850 (Yasutomi, 1987) (see Fig. 45).

Problem 12. Show that the radius of the circle touching the semicircles β' externally, γ internally, and the axis from the side opposite to B equals $a/2$.

The problem is obtained if $n = 1$ in the next theorem (Okumura, 2019f) (see Fig. 46).

Theorem 17. *Let (n) be the composition of' and the homothety with center O and ratio n for a non-negative real number n, where we consider $X^{(0)} = O$ for any point X. If α_2 (resp. β_2) is the circle touching $\beta^{(n)}$ (resp. $\alpha^{(n)}$) externally, γ internally, and*

Fig. 45 Satoh's problem

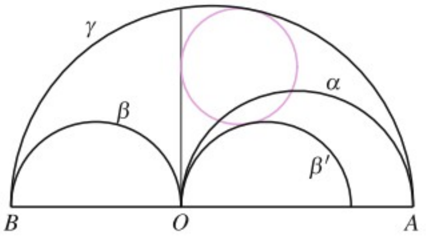

Fig. 46 $n = 0.8$

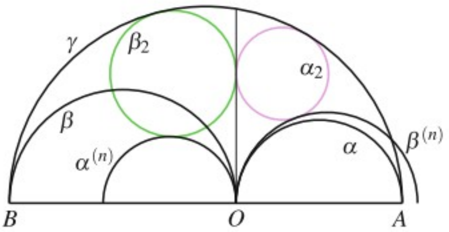

Fig. 47 C_1

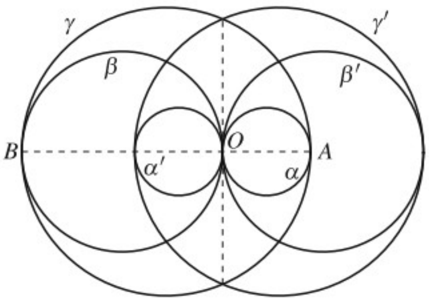

the axis from the side opposite to B (resp. A), then the circles α_2 *and* β_2 *touch and have radii* $a/(n+1)$ *and* $b/(n+1)$*, respectively.*

We construct a recursive circle configuration by Theorem 17. For this purpose we consider the arbelos together with its reflection in AB, i.e., we assume that α, β, and γ are the circles of diameters AO, BO, and AB, respectively, and denote the configuration consisting of the three circles by (α, β, γ). Let $C_1 = (\alpha, \beta, \gamma) \cup (\alpha, \beta, \gamma)'$ (see Fig. 47). We call C_1 a symmetric arbelos of diameter $|AB|$, where we assume $|AB| = 1$. Let α_2 (resp. β_2) be one of the circles touching β' (resp. α') externally, γ internally, and the axis from the side opposite to B (resp. A), where we assume that α_2 and β_2 lie on the same side of AB, i.e., they touch by Theorem 17. If γ_2 is the smallest circle touching the two circles internally, then the figure $(\alpha_2, \beta_2, \gamma_2) \cup (\alpha_2, \beta_2, \gamma_2)'$ is a symmetric arbelos of diameter $1/2$ similar to C_1. We call $(\alpha_2, \beta_2, \gamma_2) \cup (\alpha_2, \beta_2, \gamma_2)'$ with its reflection in AB the two small copies of C_1 (see Fig. 48). If the configuration C_k has been constructed, which consists of C_1, two symmetric arbeloi of diameter $1/2$ similar to C_1, four symmetric arbeloi

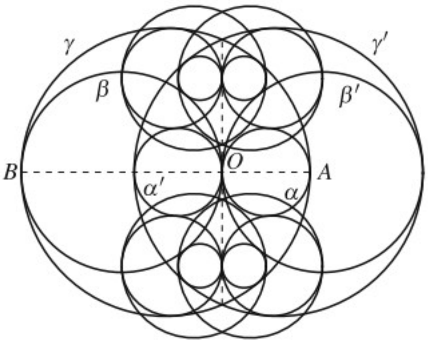

Fig. 48 C_1 with the two small copies $= C_2$

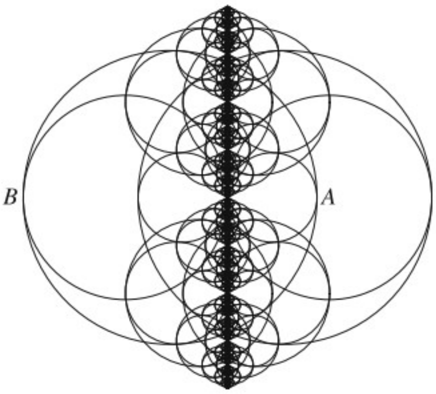

Fig. 49 C_0

of diameter $1/4$ similar to $C_1, \cdots$, and 2^{k-1} symmetric arbeloi of diameter $1/2^{k-1}$ similar to C_1, then we add the two small copies of each of the symmetric arbeloi of diameter $1/2^{k-1}$ and let C_{k+1} be the resulting configuration. The configuration C_n is now defined for any positive integer n. Then we define the configuration $C_0 = \bigcup_{i \geq 1} C_i$ (see Fig. 49).

Golden Arbelos

If $a/b = \phi^{\pm 1}$, then (α, β, γ) is called a golden arbelos, where $\phi = (1 + \sqrt{5})/2$. We consider a problem involving a golden arbelos. Let σ be the reflection in the perpendicular bisector of AB. Recall that the radius of Archimedean circles equals $r_{\mathrm{A}} = ab/(a+b)$. We consider the next problem (Ono, 1855) (see Fig. 50). The same sangaku problem can be found in Fukushimaken Wasan Kenkyū Hozonkai (1989).

Problem 13. Let ε be the circle touching the semicircles γ internally, α^{σ} externally, and the axis from the side opposite to A such that ε and α have the same radius. Find the radius of ε in terms of the radii of γ and δ_{α}.

Fig. 50 The case α^{σ} and ε being congruent

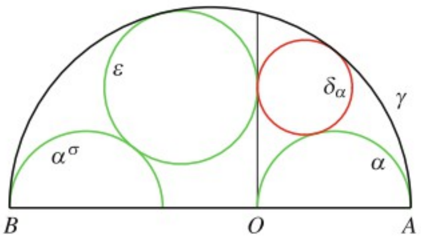

Fig. 51 A generalization

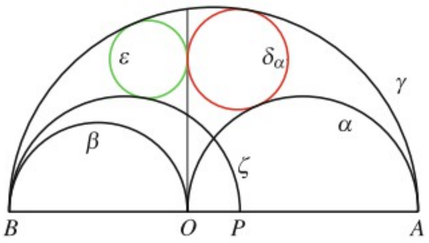

We show that the circles δ_{α} and ε touch in the problem. Let ζ be a semicircle of diameter BP for a point P on the segment AB constructed on the same side of AB as γ, and let ε be the circle touching γ internally, ζ externally, and the axis from the side opposite to A (see Fig. 51). The next theorem gives conditions in which the circles δ_{α} and ε touch (Okumura, 2019h).

Theorem 18. *The following statements are equivalent.*

(i) *The circles δ_{α} and ε touch.*
(ii) *The circle ε has radius $b - r_{\mathrm{A}}$.*
(iii) *The semicircle ζ coincides with α^{σ}.*

Assume that ζ and ε have radius a as in the problem. Then the circles δ_{α} and ε touch, and we get $a = b - r_{\mathrm{A}}$ by the theorem, which implies $2a = a + b - r_{\mathrm{A}}$. Hence we get the answer of the problem $a = (a + b - r_{\mathrm{A}})/2$. On the other hand, $a = b - r_{\mathrm{A}}$ is equivalent to $b = \phi a$. Therefore (α, β, γ) is a golden arbelos and $r_{\mathrm{A}}, a, b, a + b$ form a geometric progression with common ratio ϕ. Also $a = b - r_{\mathrm{A}}$ shows that the circle of diameter OO^{σ} is Archimedean. The circle also touches ε, since it is concentric to γ (see Fig. 52). The next theorem shows that the Archimedean circle can also be obtained in the case $b \neq \phi a$ and gives a characterization of the golden arbelos using the Archimedean circle (Okumura, 2019h) (see Fig. 53).

Theorem 19. *Let η be the circle touching the circle ε externally and the axis at O from the side opposite to A. Then η is Archimedean if and only if ζ and ε have the same radius. In this event, (α, β, γ) is a golden arbelos such that $b = \phi a$ if and only if ζ and η touch.*

$A^{\tau}{=}O^{\sigma}$
O
$B^{\tau}{=}A$

We assume $b = \phi a$ and construct a self-similar circle configuration. Let τ be the composition of σ and the homothety of center A and ratio $1/\phi$, where σ is applied at first. Then τ coincides with the homothety of center O and ratio $-1/\phi$ for a point on the line AB. Therefore the axis is fixed by τ. Also γ^{τ} passes through the point of tangency of δ_{α} and ε by Proposition 1, because $(2\sqrt{ar_{\mathrm{A}}})^2 = 2a \cdot 2\phi^{-1}a = |B^{\tau}O||A^{\tau}O|$ (see Fig. 54).

Let G be the figure consisting of α, α^{σ}, γ, δ_{α}, and ε, which is obtained by removing the axis and AB from Fig. 50. Let $G_i = G^{\tau^{i-1}}$ for $i = 1, 2, 3, \cdots$, and $G_0 = \bigcup_{i \geq 1} G_i$. Following to the custom of Wasan geometry, we describe G_0 so that AB is a vertical line with its reflection in AB (see Fig. 55).

Arbelos with Overhang

Aida (1747–1817) considered a deformed arbelos formed by a circle and two semicircles in the circle as in Fig. 56 and left several notable results, some of which are stated as follows (Aida, no date) (see Fig. 57).

Fig. 55 G_0 with its reflection in AB

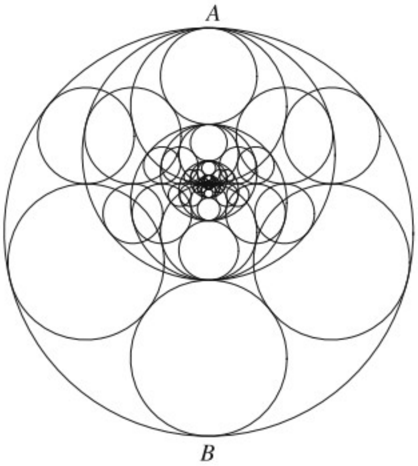

Fig. 56 Aida (no date)

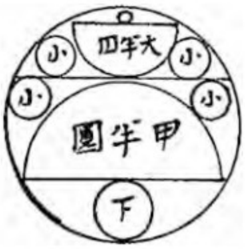

Fig. 57 Aida's deformed arbelos

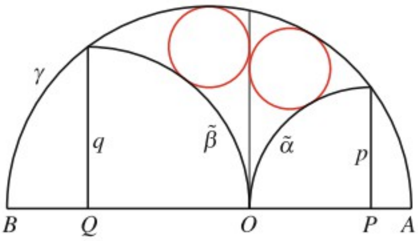

Problem 14. Assume that $\tilde{\alpha}$ (resp. $\tilde{\beta}$) is the quarter circle of radius p (resp. q) and center P (resp. Q) on the segment AO (resp. BO) such that one of the endpoints is O and the other lies on γ. Show that the following statements hold.

(i) The axis divides the curvilinear triangle made by $\tilde{\alpha}$, $\tilde{\beta}$, and γ into two curvilinear triangles with common inradius r satisfying $q = 2(p-r)r/(p-2r)$.
(ii) $c = |AP| + q = |BQ| + p$, where c is the radius of γ.
(iii) $p^2 + q^2 = c^2$.
(iv) If s is the inradius of the curvilinear triangle made by $\tilde{\alpha}$, $\tilde{\beta}$, and γ, then $2s = (p+q)^2/\sqrt{p^2+q^2} - (p+q)$.

Solving the equation in (i) for r, we get $r = (p+q-\sqrt{p^2+q^2})/2 = (p+q-c)/2$ by (iii). Therefore we have

$$2r + c = p + q.$$

By the last equation and (iv), we have $2s = (p+q)^2/c - (p+q) = 2(p+q)r/c$. Hence we get

$$\frac{s}{r} = \frac{p+q}{c}.$$

Essentially the same relation as (iii) was rediscovered (Jobbings, 2011). Aida's deformed arbelos is a special case of a generalized arbelos called the arbelos with overhang (Okumura, 2014). Let A_h (resp. B_h) be a point on the half line OA (resp. OB) with initial point O such that $|OA_h| = 2(a+h)$ (resp. $|OB_h| = 2(b+h)$) for a real number h satisfying $-\min(a,b) < h$. Let α_h (resp. β_h) be the semicircle of diameter A_hO (resp. B_hO) constructed on the same side of AB as γ. The configuration of three semicircles α_h, β_h, and γ is called an arbelos with overhang h and denoted by $(\alpha_h, \beta_h, \gamma)$ (see Figs. 58 and 59). The circle touching α_h (resp. β_h) externally, γ internally, and the axis from the side opposite to B (resp. A) has radius

$$\frac{ab}{a+b+h}.$$

Circles of the same radius are called Archimedean circles of $(\alpha_h, \beta_h, \gamma)$.

Let V (resp. W) be the point of intersection of α_h (resp. β_h) and γ in the case $h \geq 0$. Since

Fig. 58 $-\min(a,b) < h < 0$

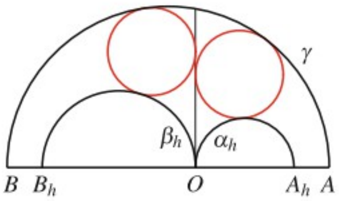

Fig. 59 $h \geq 0$

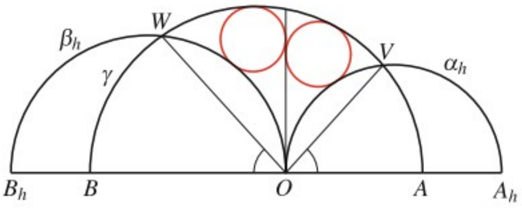

$$\cos \angle VOA = \cos \angle WOB = \sqrt{\frac{ab}{(a+h)(b+h)}},$$

Aida's deformed arbelos is obtained if $\cos \angle VOA = 1/\sqrt{2}$, which is equivalent to

$$h = \frac{f-a-b}{2}, \tag{3}$$

where $f = \sqrt{a^2+6ab+b^2}$. While we easily have $h = p-a = q-b$. Therefore

$$p = a+h = \frac{f+a-b}{2}, \quad q = b+h = \frac{f+b-a}{2}, \quad p+q = f.$$

The equation (3) is equivalent to $h = ab/(a+b+h)$. Therefore we get $r = h$, and the circles of diameters AA_h and BB_h are Archimedean circles of $(\alpha_h, \beta_h, \gamma)$.

Arbeloi Determined by a Chord

Let δ be a circle of radius s. A chord of δ determines two congruent arbeloi, if we consider two circles touching the chord at the midpoint and the circle δ (see Fig. 60). We denote the radius of Archimedean circles of the arbeloi by $\overline{p}$ if the length of the chord equals p. There is a simple relation between p and $\overline{p}$ (Okumura, 2019g):

$$p = 4\sqrt{s\overline{p}}. \tag{4}$$

The next sangaku problem was proposed by Kawada (or Kawata) in 1816 (no author's name, no datea) and cited in Saitama Prefectural Library (1969) (see Fig. 61).

Fig. 60 $p = |QR|$

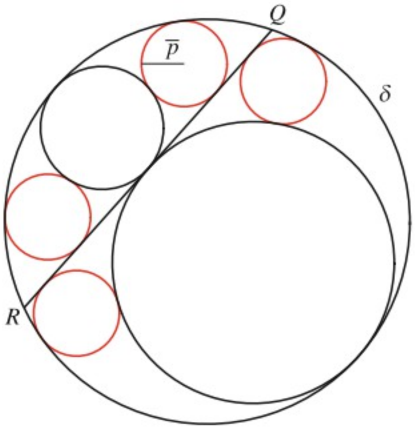

Fig. 61 $\overline{p} = \overline{q} + \overline{r}$

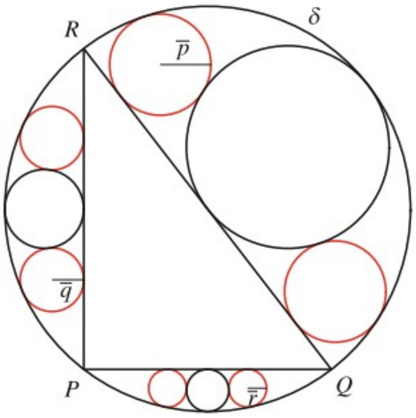

Problem 15. A triangle PQR with right angle at P is inscribed in the circle δ. Show that $\overline{p} = \overline{q} + \overline{r}$ holds, where $p = |QR|$, $q = |RP|$ and $r = |PQ|$.

The relation (4) gives a solution of the problem and shows that the converse is also true. A problem stating the relationship between s and $\overline{p}$, $\overline{q}$, $\overline{r}$ for a general triangle can be found in Aida (1788). Also a problem stating a relationship between s and the four radii of Archimedean circles of the arbeloi determined by four chords forming an inscribed quadrilateral in δ can be found in Aida (1788). Those relationships can also be derived by (4) from the relation between the lengths of the sides of a triangle or a cyclic quadrilateral and its circumradius.

A Sangaku Problem Involving an Archimedean Circle

We consider the next problem proposed by Ootoba, which can be found in the sangaku hung in 1853 at Takenobu Inari Shrine in Kyoto (Kinki Sūgakushigakukai, 1992) (see Fig. 62).

Problem 16. Let H be the point of intersection of the tangent of γ parallel to AB and the tangent of α at the point A. Show that the incircle of the triangle made by the tangent of γ parallel to AB, the axis, and the remaining tangent of α from H is Archimedean.

The circle corresponding to γ is not described in the original sangaku problem, but a square is described (see Fig. 63). As stated before, the twin circles of Archimedes were considered in Wasan geometry. But it is little to see the other Archimedean circles. Moreover there seems no other mathematicians who found the same circle as to Ootoba's Archimedean circle until today. Therefore this circle is very notable. As stated at the beginning of this section, it is believed that Bankoff's circle is the thirdly discovered Archimedean circle (Bankoff, 1974). But the date

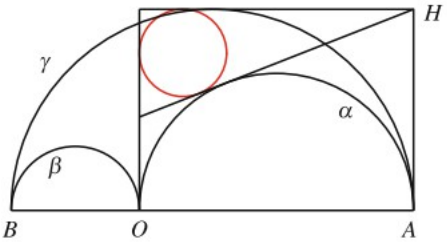

Fig. 62 Ootoba's Archimedean circle

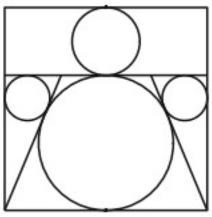

Fig. 63 Original figure

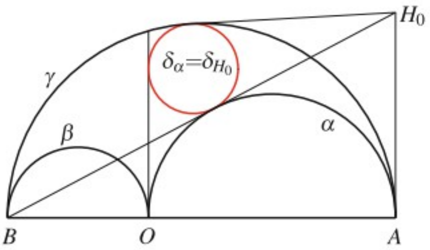

Fig. 64 Generalized Ootoba's Archimedean circle closest to the line AB

of the sangaku suggests that the history of studying Archimedean circles should be updated. The problem is generalized as follows (Okumura, 2019j) (see Figs. 64 and 65).

Theorem 20. *Let H_0 be the point of intersection of the tangent of α from B and the common tangent of α and γ at A. Let H_1 and H_2 be points different from A on the half line AH_0 with initial point A. If the incircle of the triangle made by the remaining tangents of α and γ from H_i and the axis is denoted by δ_{H_i} for $i = 0, 1, 2$, then the following statements hold.*

(i) *The circle δ_{H_i} is Archimedean.*
(ii) *The circle δ_{H_1} is closest to AB if and only if $H_1 = H_0$, where the circles δ_{H_0} and δ_α coincide.*
(iii) *The circles δ_{H_1} and δ_{H_2} coincide if and only if H_2 is the inverse of H_1 in the circle of center A passing through H_0*

Since there are infinitely many choices of the point H_1, we get infinitely many Archimedean circles touching the axis from the side opposite to B. Similar infinitely

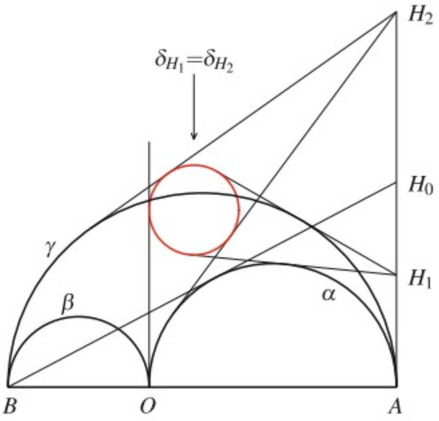

Fig. 65 A generalization

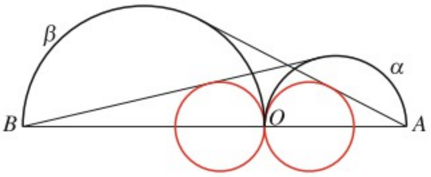

Fig. 66 Nagata's Archimedean circles

many Archimedean circles are also obtained from points on the common tangent of β and γ at B.

A Sangaku Problem Involving Two Archimedean Circles

We consider the next problem proposed by Nagata described in the sangaku hung in 1831 at Atsuta Shrine in Nagoya (Morishima, no date) (see Fig. 66).

Problem 17. Show that the circle touching α at O internally and the tangent of β from A is congruent to the circle touching β at O internally and the tangent of α from B.

The common radius of the two circles equals r_{A} in the problem. However the problem can be solved without expressing the radius of the two circles in terms of a and b. Therefore we cannot be sure that Nagata noticed that the radius of the two small circles equaled r_{A}. In any case, Nagata's Archimedean circles should also be noticed in the history of studying Archimedean circles. The problem is stated in a slightly generalized form in Fukagawa and Pedoe (1989), and a generalization of this can be found in Okumura (1995).

We give another generalization of the problem. For two points P and Q, we denote the circle of diameter PQ by (PQ). Let P and Q be points on the line AB lying in the order P, B, A, Q, or B, P, Q, A or B, Q, P, A such that O is the point

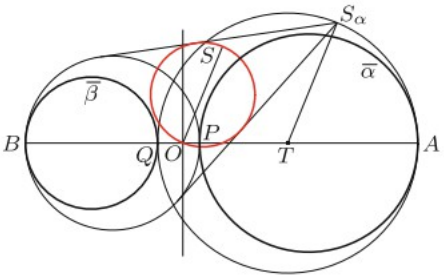

Fig. 67 A generalization

of intersection of AB and the radical axis of the circles (AP) and (BQ). In this case we call the configuration consisting of the three circles $\overline{\alpha} = (AP)$, $\overline{\beta} = (BQ)$, and $\gamma = (AB)$ a collinear arbelos and denote by $(\overline{\alpha}, \overline{\beta}, \gamma)$. Let s and t be the radii of the circles (AQ) and (BP), respectively. Circles of radius $st/(s+t)$ are called Archimedean circles of $(\overline{\alpha}, \overline{\beta}, \gamma)$. The collinear arbelos and its Archimedean circles coincide with the ordinary arbelos and its Archimedean circles if $P = Q = O$. The problem is generalized as follows (Okumura, 2013) (see Fig. 67).

Theorem 21. *For a collinear arbelos $(\overline{\alpha}, \overline{\beta}, \gamma)$ and a point $S \neq O$, let S_α be the external center of similitude of the circles (OS) and (BP), where (OS) does not touch the circle β internally in the case $P = Q = O$. Then (OS) is an Archimedean circle of $(\overline{\alpha}, \overline{\beta}, \gamma)$ if and only if the point S_α lies on the circle (AQ) and the vectors $\overrightarrow{OS}$ and $\overrightarrow{TS_\alpha}$ are parallel with the same direction, where T is the center of (AQ).*

Since there are infinitely many choices of the point S_α, we get infinitely many Archimedean circles of $(\overline{\alpha}, \overline{\beta}, \gamma)$. Similar infinitely many Archimedean circles can also be obtained from points on the circle (BP). Another generalization of Problem 17 to a generalized arbelos called a skewed arbelos can also be found in Okumura (2013).

Wasan Geometry and Division by Zero

In this section we consider applications of recently made definition of division by zero (Kuroda et al., 2014) to Wasan geometry. The definition is stated as follows:

Definition 1.

$$\frac{z}{0} = 0 \text{ for any real number } z. \tag{5}$$

In other words, division is stated by

$$z \div x = z \cdot x^{-1} \quad (x \neq 0), \quad z \div x = z \cdot x \quad (x = 0),$$

which can also be considered in any field. Since the definition is very primitive, we have to check whether it is meaningful or not to our mathematics. The definition should be discarded if it can conclude less meaningful results. Hence we have to consider what the definition implies carefully. While Saburou Saitoh, who advocated the definition more than five years ago, has got more than a thousand meaningful results derived by the definition at the present time of writing. Meanwhile a recent study using the proof assistant Isabelle/HOL also derived (5) (Nipkow et al., 2015). In this section we will show two simple applications of the definition to Wasan geometry. For an extensive introduction of division by zero, see Okumura and Saitoh (2018b), and its application to Wasan geometry, see Kanai and Okumura (2017), Matsuura et al. (2019), Okumura (2018f, 2019h), Okumura and Saitoh (2018a).

The Configuration $A(1)$

In Theorem 1, we did not consider the case $n = 1$ for the configuration $A(n)$ consisting of a circle α of radius a with a tangent t and the other tangent parallel to t, because the radius of a line could not be considered (see Fig. 12). Circles and lines are represented by the equation $e(x^2 + y^2) + 2fx + 2gy + h = 0$. If $e \neq 0$, it represents a circle of radius

$$\sqrt{\frac{f^2 + g^2 - eh}{e^2}}.$$

Hence we can consider that *the radius of a line equals* 0 by (5), since the equation expresses a line if $e = 0$. Hence if $n = 1$, the left side of (1) equals $a/0 = 0$ by (5). Therefore (1) still holds for $A(1)$.

A Three-Circle Problem

We consider the following problem (Aida, 1788; Okumura, 2018c) (see Fig. 68).

Problem 18. Assume that t and u are parallel tangents of a circle β of radius b, α is a circle of radius a touching β externally and t from the same side as β, and γ is the circle of radius c touching α and β externally and u from the same side as β. Show that the following relation holds:

$$c = \frac{b^2}{4a}. \tag{6}$$

We consider the case $a = 0$ for the problem, where notice that the assumption $b > a$ stated in Fukagawa and Pedoe (1989) is unnecessary. Let O be the point of

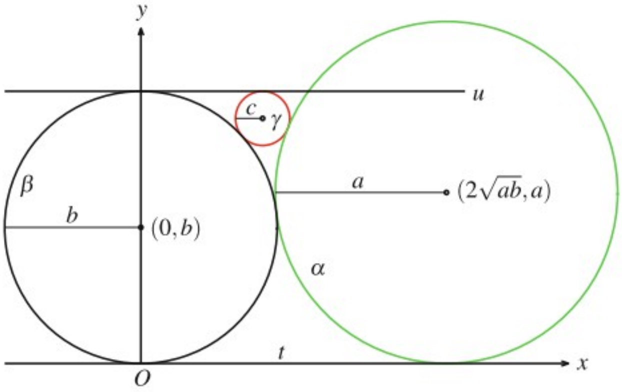

Fig. 68 A three-circle problem

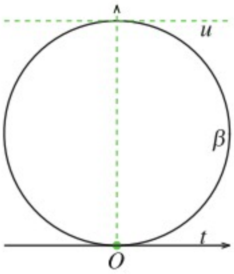
Fig. 69 The circle α (dotted lines and the point)



tangency of β and t. We use a rectangular coordinate system with origin O such that the center of β has coordinates $(0, b)$. We may assume that the circle α has an equation

$$\left(x - 2\sqrt{ab}\right)^2 + (y - a)^2 - a^2 = 0 \tag{7}$$

by Proposition 1. The equation can be arranged as

$$\frac{x^2 + y^2}{\sqrt{a}} - 4x\sqrt{b} - 2\sqrt{a}(y - 2b) = 0,$$
$$\frac{x^2 + y^2}{a} - 4x\sqrt{\frac{b}{a}} - 2(y - 2b) = 0.$$

Therefore if $a = 0$, we have $x^2 + y^2 = 0$, $x = 0$, and $y - 2b = 0$, respectively, by (5). The three equations express the origin, the y-axis, and the line $y = 2b$ (the line u), respectively (see Fig. 69). We can consider that the origin and the line u have radius 0 and touch β and t, i.e., they satisfy the assumption of the problem. But the y-axis is perpendicular to β and t, though it has radius 0. However we can still consider that *a line perpendicular to a circle and a line touches them*, because (5) implies $\tan(\pi/2) = 0$. Therefore we can consider that the y-axis has radius 0 and touches β and t, i.e., it also satisfies the assumption of the problem.

The circle γ has an equation $(x - 2\sqrt{bc})^2 + (y - 2b + c)^2 = c^2$. Substituting $c = b^2/(4a)$ in this equation and rearranging, we get the following three equations.

$$a(x^2 + (y - 2b)^2) - 2bx\sqrt{ab} + \frac{b^2 y}{2} = 0, \tag{8}$$

$$\sqrt{a}(x^2 + (y - 2b)^2) - 2bx\sqrt{b} + \frac{b^2 y}{2\sqrt{a}} = 0,$$

$$x^2 + (y - 2b)^2 - 2bx\sqrt{\frac{b}{a}} + \frac{b^2 y}{2a} = 0.$$

Hence if $a = 0$, we get $y = 0$, $x = 0$, and $x^2 + (y - 2b)^2 = 0$. The last three equations express the x-axis (the line t), the y-axis, and the point of coordinates $(0, 2b)$, respectively (see Fig. 70).

When α approaches to the origin, γ approaches to the line t. Hence we consider that if α coincides with the origin, then γ coincides with the line t (see Fig. 71). Symmetrically we also consider that if α coincides with the line u, γ coincides with the point of coordinates $(0, 2b)$ (see Fig. 72). Therefore we can consider if α coincides with the y-axis, γ also coincides with the y-axis as the remaining case (see Fig. 73). In all the cases, α and γ satisfy the assumption of the problem. Moreover (6) still holds by (5), since $a = 0$ implies $c = 0$.

Notice that the three cases described in Figs. 71, 72, and 73 are obtained if we consider the left sides of (7) and (8) as polynomials of $\sqrt{a}$ and assume that the constant terms, the coefficients of a, and the coefficients of $\sqrt{a}$ equal 0, respectively. Also notice that the case described in Fig. 73 could not be obtained without (5) before.

The first example for $A(n)$ shows that the definition enables us to include some cases which have been excluded before. The second example shows that the definition still enables us to see some unexpected but meaningful phenomena which cannot be seen without the definition. It seems that studies on such unexpected phenomena using (5) will open the door to the new mathematics in the near feature.

Practical Side

In this section we show several examples of application of Wasan and Wasan geometry. As stated before, many Wasan mathematician also studied astronomy, surveying, and the art of divination. They published many books on such areas. On the other hand, a popular book Jinkōki was published in early time of Edo era, which was a manual for the calculating tool called soroban. It also included other topics such as recreational mathematics and applications of mathematics in daily life (see Fig. 74) (Yoshida, 1632).

Figures 75 and 76 are taken from a book for surveying (Okumura, 1836). Figure 75 shows a frequently used diagram to get values of the six trigonometric functions. If the side length of the square equals 1, then the values of the six trigonometric functions of the angle between the horizontal side of the square and the oblique segment are obtained as the lengths of certain segments in the diagram. For example, the tangent equals the length of the oblique segment.

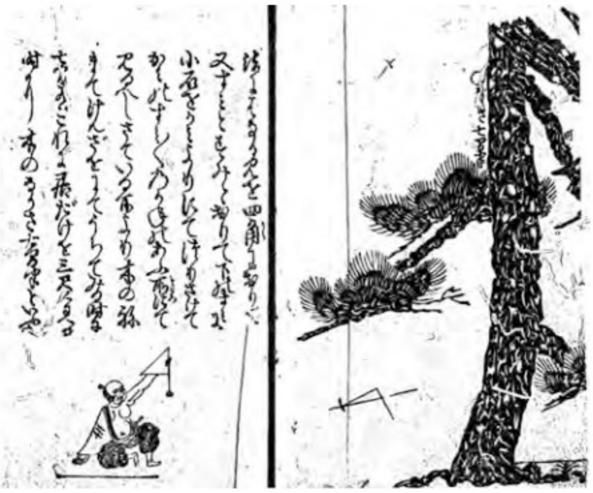

Fig. 74 (Yoshida, 1632)

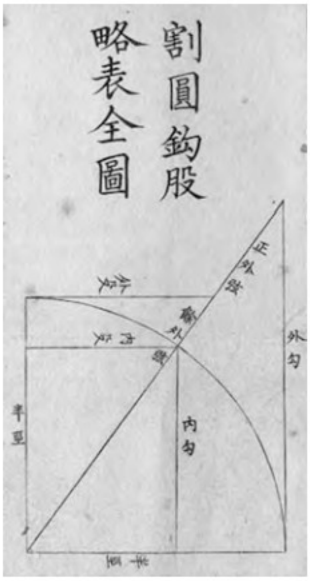

Fig. 75 (Okumura, 1836)

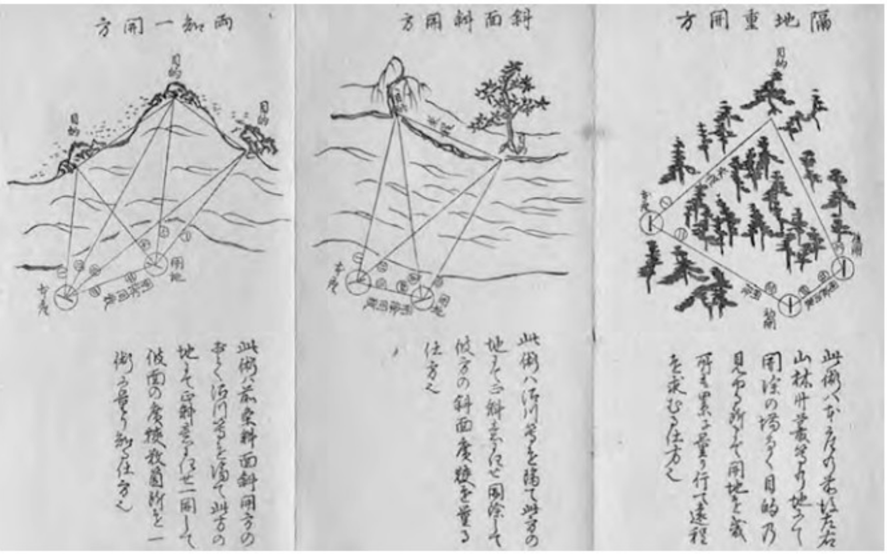
Trigonometric tables were imported in the eighteenth century and used in surveying and astronomy. Figure 77 shows an example of trigonometric table used for surveying written on a fan.

Wasan mathematician also published books for sailing the oceans. Ishiguro published a book of celestial navigation (Ishiguro, 1835). It explains how to use quadrant (see Fig. 78). It also explains how to determine the altitude of the celestial north pole using Triones (see Fig. 79). As we have just seen, the concept of angles was frequently used in surveying and astronomy, but it was not used in Wasan geometry.



隔地重用方
斜面斜用方
両斜一用方

Fig. 76 (Okumura, 1836)

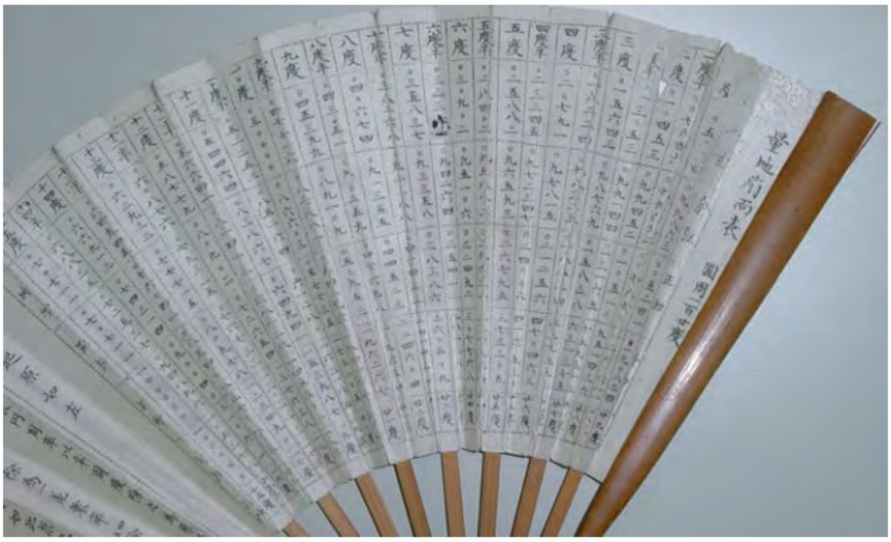


Fig. 77 Trigonometric table written on a fan (Nakasone, 1864)

On December 9 in 1872, Meiji Government declared that the old calendar system would be abolished and new Gregorian calendar system was used from the January first in 1873. Hanai published the book explaining the new calendar system in January in the same year (Hanai, 1873) (see Fig. 80). It seems that the publication was made with remarkably short preparation time.

Fig. 78 (Ishiguro, 1835)

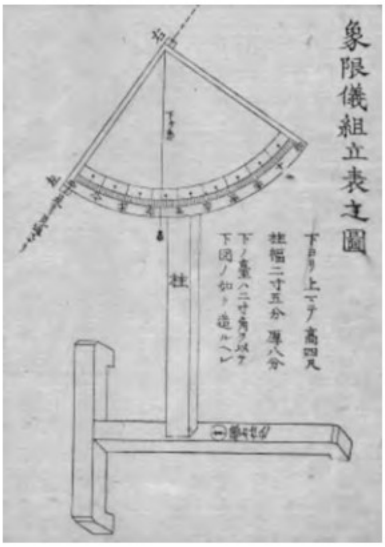

Fig. 79 (Ishiguro, 1835)

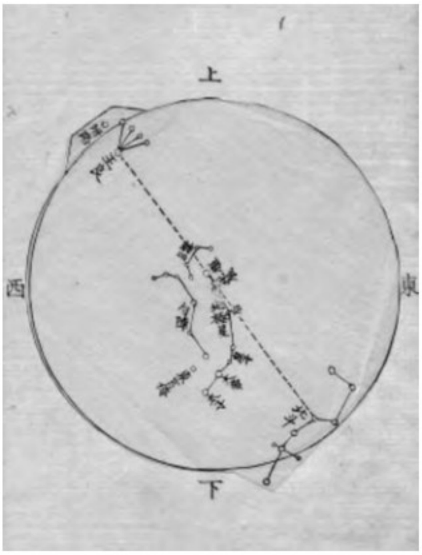

The change of the social system in Japan at the beginning of the Meiji era was so drastic and urgent as this example shows, but Wasan mathematicians supported it well. Surveying was done in all over the country due to the land-tax reformation in the same year 1873 with the aid of many Wasan mathematicians in each of the local areas.

Japanese traditional buildings were made of wood. Figure 81 is taken from a pattern book for carpenters (Suzuki, 1721), in which the lengths of several parts are indicated. Figure 82 is also taken from the same book, which shows architectural

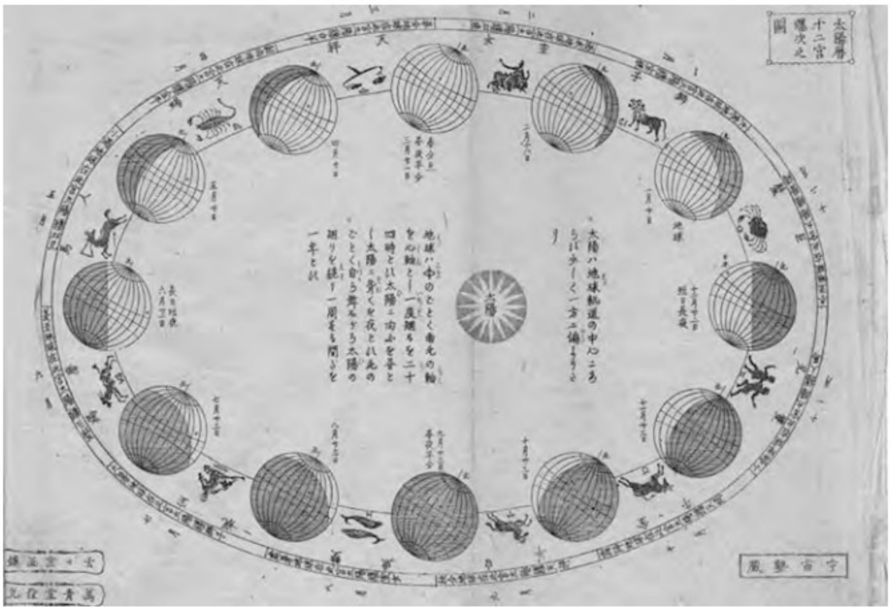

Fig. 80 (Hanai, 1873)

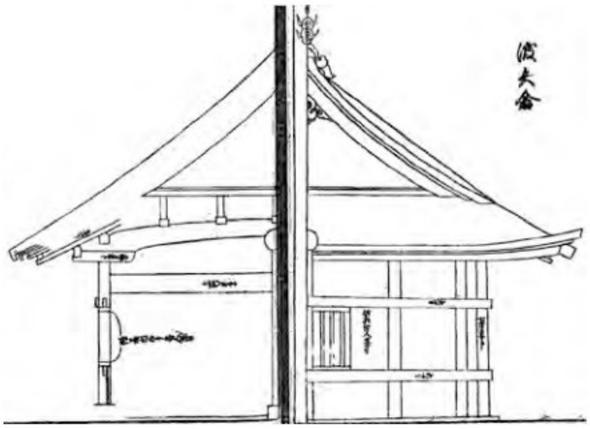
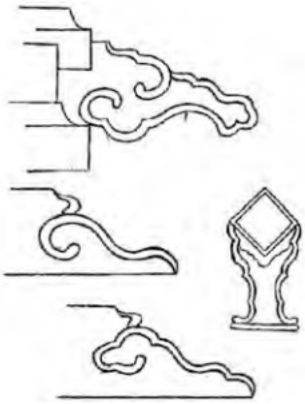
Fig. 81 (Suzuki, 1721)



ornaments. L-shaped carpenter's square were used as the main tool to design each of the architectural elements. Its basic principle has been supposed to be the similarity of right triangles, but the contents were not disclosed as secret methods used in each of the families of carpenters. Meanwhile Heinouchi published two books explaining how to use the carpenter's square in terms of Wasan geometry (Heinouchi, 1848, 1833). He gave a mathematical foundation of the methods and made them accessible. Figure 83 is taken from his 1833 book.

Fig. 82 (Suzuki, 1721)



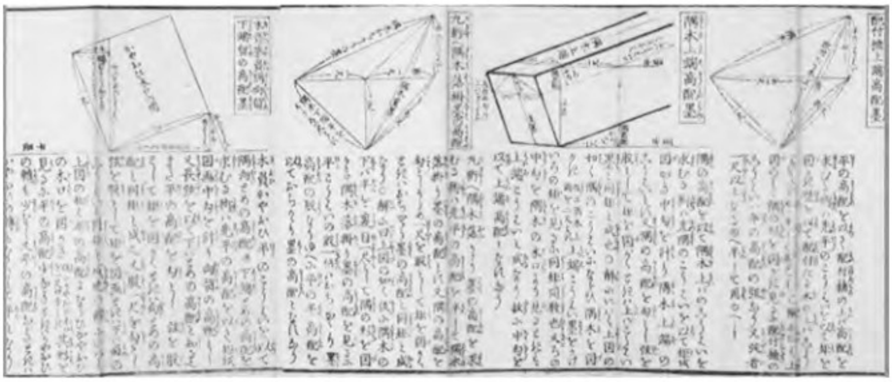


Fig. 83 (Heinouchi, 1833)

Study of Wasan Geometry: Past and Present

Wasan was in decline through Meiji era, and several attempts to gain perspective on Wasan were made. Tsuruichi Hayashi studied Wasan mathematically and published many papers including many geometric ones. Seki's famous work on determinant was discovered by him. Hayashi's works were collected and published as a book in two volumes consisting of about two thousands of total number of pages (Hayashi, 1937).

One of the most important works on Wasan geometry in the second half of the twentieth century was made by the geometer Shikō Iwata, who published a dictionary of geometry in six volumes with two supplement volumes (Iwata, 1993, 1988, 1982, 1980, 1978, 1976, 1974, 1971). It is a collection of results in plane and solid geometry including a huge number of results in Wasan geometry together with their modern proofs and references. The total number of pages of the 8 volumes is more than 4000 pages.

The works of notable Wasan mathematicians such as Seki were collected and published and studied by modern mathematicians and historians. However Wasan geometry were contributed by a lot of mathematicians and amateurs. The results were neither collected nor classified. As if this isn't bad enough, there were some difficulties to access Wasan books and manuscripts because of their preciousness. Thereby it had been difficult to access and check enough number of results of Wasan geometry till the end of the twentieth century. The opening of the several digital libraries at the beginning of the twenty-first century mentioned in the section of Wasan is one of the most noticeable changes for those who want to study Wasan and Wasan geometry, because it makes an immense amount of Wasan materials accessible to all the people. It seems that the physical environment to study Wasan geometry is made up for all the people in the world today.

Chapter 13

Arithmetic of Elliptic Curves

Christophe Doche and Tanja Lange

Contents in Brief

13.1 Summary of background on elliptic curves 268
First properties and group law • Scalar multiplication • Rational points • Torsion points • Isomorphisms • Isogenies • Endomorphisms • Cardinality

13.2 Arithmetic of elliptic curves defined over $\mathbb{F}_p$ 280
Choice of the coordinates • Mixed coordinates • Montgomery scalar multiplication • Parallel implementations • Compression of points

13.3 Arithmetic of elliptic curves defined over $\mathbb{F}_{2^d}$ 289
Choice of the coordinates • Faster doublings in affine coordinates • Mixed coordinates • Montgomery scalar multiplication • Point halving and applications • Parallel implementation • Compression of points

Elliptic curves constitute one of the main topics of this book. They have been proposed for applications in cryptography due to their fast group law and because so far no subexponential attack on their discrete logarithm problem (cf. Section 1.5) is known. We deal with security issues in later chapters and concentrate on the *group* arithmetic here. In an actual implementation this needs to be built on an efficient implementation of finite field arithmetic (cf. Chapter 11).

In the sequel we first review the background on elliptic curves to the extent needed here. For a more general presentation of elliptic curves, see Chapter 4. Then we address the question of efficient implementation in large odd and in even characteristics. We refer mainly to [HaMe$^+$ 2003] for these sections.

Note that there are several softwares packages or libraries able to work on elliptic curves, for example `PARI/GP` [Pari] and **apecs** [Apecs]. The former is a linkable library that also comes with an interactive shell, whereas the latter is a `Maple` package. Both come with full sources. The computer algebra systems `Magma` [Magma] and `SIMATH` [Simath] can deal with elliptic curves, too.

Elliptic curves have received a lot of attention throughout the past almost 20 years and many papers report experiments and timings for various field sizes and coordinates. We do not want to repeat the results but refer to [Ava 2004a, CoMi$^+$ 1998] and Section 14.7 for odd characteristic and [HaLó$^+$ 2000, LóDa 1998, LóDa 1999] for even characteristic. Another excellent and comprehensive reference comparing point multiplication costs and implementation results is [HaMe$^+$ 2003, Tables 3.12, 3.13 and 3.14 and Chap. 5].

13.1 Summary of background on elliptic curves

13.1.1 First properties and group law

We start with a practical definition of the concept of an elliptic curve.

Definition 13.1 An *elliptic curve* E *over a field* K denoted by E/K is given by the *Weierstraß equation*

$$E : y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6 \tag{13.1}$$

where the coefficients $a_1, a_2, a_3, a_4, a_6 \in K$ are such that for each point (x_1, y_1) with coordinates in $\overline{K}$ satisfying (13.1), the partial derivatives $2y_1 + a_1x_1 + a_3$ and $3x_1^2 + 2a_2x_1 + a_4 - a_1y_1$ do not vanish simultaneously.

The last condition says that an elliptic curve is *nonsingular* or *smooth*. A point on a curve is called *singular* if both partial derivatives vanish (cf. the Jacobi criterion 4.94). For shorter reference we group the coefficients in (13.1) to the equation

$$E : y^2 + h(x)y = f(x), \quad h(x), f(x) \in K[x], \quad \deg(h) \leqslant 1, \deg(f) = 3 \text{ with } f \text{ monic.}$$

The smoothness condition can also be expressed more intrinsically. Indeed, let

$$\begin{aligned} &b_2 = a_1^2 + 4a_2, \;\; b_4 = a_1a_3 + 2a_4,\\ &b_6 = a_3^2 + 4a_6, \;\; b_8 = a_1^2a_6 - a_1a_3a_4 + 4a_2a_6 + a_2a_3^2 - a_4^2. \end{aligned}$$

In odd characteristic, the transformation $y \mapsto y - (a_1x + a_3)/2$ leads to an isomorphic curve given by

$$y^2 = x^3 + \frac{b_2}{4}x^2 + \frac{b_4}{2}x + \frac{b_6}{4}\cdot \tag{13.2}$$

The cubic polynomial above has only simple roots over the algebraic closure $\overline{K}$ if and only if its discriminant is nonzero. The equation of the discriminant is therefore useful to determine if (13.2) is an elliptic curve or not. In addition, it is relevant for characteristic 2 fields as well.

Definition 13.2 Let E be a curve defined over K by (13.1) and let b_2, b_4, b_6 and b_8 as above. The *discriminant of the curve* E denoted by Δ satisfies

$$\Delta = -b_2^2b_8 - 8b_4^3 - 27b_6^2 + 9b_2b_4b_6.$$

The curve E is nonsingular, and thus is an elliptic curve, if and only if Δ is nonzero. In this case, we introduce the j-*invariant* of E, that is $j(E) = (b_2^2 - 24b_4)^3/\Delta$.

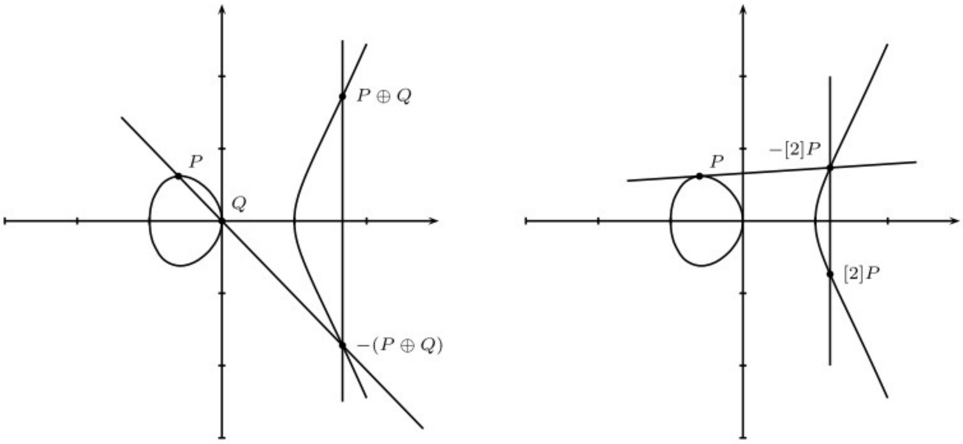
Example 13.3 In $\mathbb{F}_p$ with $p = 2003$, an elliptic curve is given by

$$E_1 : y^2 + 2xy + 8y = x^3 + 5x^2 + 1136x + 531. \tag{13.3}$$

Indeed, we have $b_2 = 24, b_4 = 285, b_6 = 185, \Delta = 1707 \neq 0$ and $j = 171$.

We now show how to turn the set of points of E into a group with group operation denoted by $\oplus$. For this we visualize it over the reals as in Figure 13.1 and assume $h(x) = 0$.

Figure 13.1 Group law on elliptic curve $y^2 = f(x)$ over $\mathbb{R}$.



To add two points $P = (x_1, y_1)$ and $Q = (x_2, y_2)$ in general position one draws a line connecting them. There is a third point of intersection. Mirroring this point at the x-axis gives the sum $P \oplus Q$. The same construction can be applied to double a point where the connecting line is replaced by the tangent at P.

Furthermore, we need to define the sum of two points with the same x-coordinate since for them the group operation cannot be performed as stated. As $y^2 = f(x)$ there are at most 2 such points (x_1, y_1) and $(x_1, -y_1)$. Furthermore, we have to find the neutral element of the group.

The way out is to include a further point P_∞ called the *point at infinity*. It can be visualized as lying far out on the y-axis such that any line $x = c$, for some constant c, parallel to the y-axis passes through it. This point is the neutral element of the group. Hence, the line connecting (x_1, y_1) and $(x_1, -y_1)$ passes through P_∞. As it serves as the neutral element, the inflection process leaves it unchanged such that $(x_1, y_1) \oplus (x_1, -y_1) = P_\infty$, i.e., $(x_1, -y_1) = -P$.

This explanation might sound a little like hand-waving and only applicable to $\mathbb{R}$. We now derive the addition formulas for an arbitrary field K, which hold universally. For a proof we refer to Chapter 4.

Take $P \neq Q$ with $x_1 \neq x_2$ as above and let us compute the coordinates of $R = P \oplus Q = (x_3, y_3)$. The intersecting line has slope

$$\lambda = \frac{y_1 - y_2}{x_1 - x_2}$$

and passes through P. Its equation is thus given by

$$y = \lambda x + \frac{x_1 y_2 - x_2 y_1}{x_1 - x_2}.$$

We denote the constant term by μ and remark $\mu = y_1 - \lambda x_1$. The intersection points with the curve are obtained by equating the line and E

$$(\lambda x + \mu)^2 + (a_1 x + a_3)(\lambda x + \mu) = x^3 + a_2 x^2 + a_4 x + a_6.$$

This leads to the equation $r(x) = 0$ where

$$r(x) = x^3 + (a_2 - \lambda^2 - a_1\lambda)x^2 + (a_4 - 2\lambda\mu - a_3\lambda - a_1\mu)x + a_6 - \mu^2 - a_3\mu.$$

We already know two roots of $r(x)$, namely the x-coordinates of the other two points. Since

$$r(x) = (x - x_1)(x - x_2)(x - x_3)$$

one has $\lambda^2 + a_1\lambda - a_2 = x_1 + x_2 + x_3$. As x_1, x_2 are defined over K so is x_3 and $\tilde{y}_3 = \lambda x_3 + \mu$. The inflection at the x-axis has to be translated to the condition that the second point has the same x-coordinate and also satisfies the curve equation. We observe that if $P = (x_1, y_1)$ is on the curve then so is $(x_1, -y_1 - a_1x_1 - a_3)$, which corresponds to $-P$ since the point at infinity is the neutral element for this law. Accordingly, we find $y_3 = -\lambda x_3 - \mu - a_1 x_3 - a_3$.

Doubling $P = (x_1, y_1)$ works just the same with the slope obtained by implicit derivating. Thus we have $P \oplus Q = (x_3, y_3)$ and

$$\begin{aligned} -P &= (x_1, -y_1 - a_1x_1 - a_3), \\ P \oplus Q &= (\lambda^2 + a_1\lambda - a_2 - x_1 - x_2, \lambda(x_1 - x_3) - y_1 - a_1x_3 - a_3), \text{ where} \\ \lambda &= \begin{cases} \dfrac{y_1 - y_2}{x_1 - x_2} & \text{if } P \neq \pm Q, \\ \dfrac{3x_1^2 + 2a_2x_1 + a_4 - a_1y_1}{2y_1 + a_1x_1 + a_3} & \text{if } P = Q. \end{cases} \end{aligned}$$

It is immediate from the pictorial description that this law is commutative, has the point at infinity as neutral element, and that the inverse of (x_1, y_1) is given by $(x_1, -y_1 - a_1x_1 - a_3)$. The associativity can be shown to hold by simply applying the group law and comparing elements. We leave the lengthy computation to the reader. Note that Chapter 4 gives extensive background showing in an abstract way the group of points on E to form a group. For a more geometrical proof, relying on Bezout's theorem, see e.g., [CAS 1991].

Example 13.4 One can easily check that the points $P_1 = (1118, 269)$ and $Q_1 = (892, 529)$ lie on the curve $E_1/\mathbb{F}_p$ as defined by (13.3). Then

$$\begin{aligned} -P_1 &= (1118, 1493), \\ P_1 \oplus Q_1 &= (1681, 1706), \\ [2]P_1 &= (1465, 677) \end{aligned}$$

are also on E_1.

The point at infinity can be motivated by giving an alternative description of elliptic curves. Equation (13.1) expresses the curve in *affine coordinates*. The same elliptic curve E in *projective coordinates* is then given by the equation

$$E : Y^2Z + a_1XYZ + a_3YZ^2 = X^3 + a_2X^2Z + a_4XZ^2 + a_6Z^3.$$

Let us denote by $(X_1 : Y_1 : Z_1)$ an element of the *projective* 2*-space* $\mathbb{P}^2/K$, i.e., a class of $\overline{K}^3 \setminus \{(0,0,0)\}$ modulo the relation

$$(X_1 : Y_1 : Z_1) \sim (X_2 : Y_2 : Z_2) \iff \text{there is } \lambda \in \overline{K}^* \mid X_2 = \lambda X_1,\ Y_2 = \lambda Y_1 \text{ and } Z_2 = \lambda Z_1.$$

By abuse of notation, we identify a class with any of its representatives and call $(X_1 : Y_1 : Z_1)$ a *projective point*. We remark that only a single point of E satisfies $Z_1 = 0$, namely the *point at infinity*, which is in this case $P_\infty = (0 : 1 : 0)$. When $Z_1 \neq 0$, there is a simple correspondence between the projective point $(X_1 : Y_1 : Z_1)$ and the affine point (x_1, y_1) using the formula

$$(x_1, y_1) = (X_1/Z_1, Y_1/Z_1) \tag{13.4}$$

As the representation $(X_1 : Y_1 : Z_1)$ is not normalized, one can perform arithmetic in projective coordinates without any inversion. Note also that *generalized projective coordinates* involving suitable powers of Z_1 in (13.4) are commonly used, cf. Sections 13.2.1 and 13.3.1.

Example 13.5 The point $P_1' = (917 : 527 : 687)$ lies on the curve E_1 of equation (13.3) expressed in projective coordinates, i.e.,

$$E_1 : Y^2Z + 2XYZ + 8YZ^2 = X^3 + 5X^2Z + 1136XZ^2 + 531Z^3.$$

In fact, P_1' is in the same class as $(1118 : 269 : 1)$ and thus corresponds to the affine point $P_1 = (1118, 269)$.

13.1.2 Scalar multiplication

Take $n \in \mathbb{N} \setminus \{0\}$ and let us denote the *scalar multiplication by n on E* by $[n]$, or $[n]_E$ to avoid confusion. Namely,

$$\begin{aligned} [n] : E &\to E \\ P &\mapsto [n]P = \underbrace{P \oplus P \oplus \cdots \oplus P}_{n \text{ times}}. \end{aligned}$$

This definition extends trivially to all $n \in \mathbb{Z}$, setting $[0]P = P_\infty$ and $[n]P = [-n](-P)$ for $n < 0$. Chapter 9 deals with exponentiation, i.e., the computation of x to some power n. In the context of elliptic curves, this corresponds to $[n]P$. Thus multiplications, squarings, and divisions are replaced by additions, doublings, and subtractions on E.

As an example, we give the analogue of Algorithm 9.10 with additive notation.

Algorithm 13.6 Sliding window scalar multiplication on elliptic curves

INPUT: A point P on an elliptic curve E, a nonnegative integer $n = (n_{l-1} \dots n_0)_2$, a parameter $k \geqslant 1$ and the precomputed points $[3]P, [5]P, \dots, [(2^k - 1)]P$.
OUTPUT: The point $[n]P$.

```
$Q \leftarrow P_\infty$ and $i \leftarrow l - 1$
while $i \geqslant 0$ do
    if $n_i = 0$ then $Q \leftarrow [2]Q$ and $i \leftarrow i - 1$
    else
        $s \leftarrow \max(i - k + 1, 0)$
        while $n_s = 0$ do $s \leftarrow s + 1$
        for $h = 1$ to $i - s + 1$ do $Q \leftarrow [2]Q$
        $u \leftarrow (n_i \dots n_s)_2$                [$n_i = n_s = 1$ and $i - s + 1 \leqslant k$]
        $Q \leftarrow Q \oplus [u]P$              [$u$ is odd so that $[u]P$ is precomputed]
```

```
            $i \leftarrow s - 1$
    return $Q$
```

Remark 13.7 Since subtractions can be obtained in a straightforward way, signed-digit representations of n are well suited to compute $[n]P$, cf. Section 9.1.4.

Example 13.8 With the settings of Example 13.4, let us compute $[763]P_1$ with Algorithm 13.6 and a window of size 3. We precompute $[3]P_1 = (1081, 1674)$, $[5]P_1 = (851, 77)$, $[7]P_1 = (663, 1787)$ and since $763 = (\underset{5}{\underline{101}}\,\underset{7}{\underline{111}}\,\underset{5}{\underline{101}}\,\underset{1}{\underline{1}})_2$, the intermediate values of Q are

$$\begin{aligned}
[5]P_1 &= (851, 77), & [10]P_1 &= (4, 640), & [20]P_1 &= (836, 807),\\
[40]P_1 &= (1378, 1696), & [47]P_1 &= (1534, 747), & [94]P_1 &= (1998, 1094),\\
[188]P_1 &= (1602, 1812), & [376]P_1 &= (478, 1356), & [381]P_1 &= (1454, 981),\\
[762]P_1 &= (1970, 823), & [763]P_1 &= (1453, 1428).
\end{aligned}$$

Using the NAF expansion of $763 = (\underset{3}{\underline{10\bar{1}}}\,00000\,\underset{-5}{\underline{\bar{1}0\bar{1}}})_s$ instead, one obtains

$$\begin{aligned}
[3]P_1 &= (1081, 1674), & [6]P_1 &= (255, 1499), & [12]P_1 &= (459, 1270),\\
[24]P_1 &= (41, 1867), & [48]P_1 &= (1461, 904), & [96]P_1 &= (1966, 1808),\\
[192]P_1 &= (892, 529), & [384]P_1 &= (1928, 1803), & [768]P_1 &= (799, 1182),\\
[763]P_1 &= (1453, 1428).
\end{aligned}$$

The last step, namely $[763]P_1 = [768]P_1 \oplus [-5]P_1$, needs $[-5]P_1 = (851, 216)$ which is obtained directly from $[5]P_1$.

13.1.3 Rational points

When we consider a point P on an elliptic curve E/K, it is implicit that P has its coordinates in $\overline{K}$. To stress that P has its coordinates in K, we introduce a new concept.

Definition 13.9 Let E be an elliptic curve defined over K. The points lying on E with coordinates in K form the set of *K-rational points of E* denoted by $E(K)$. We have

$$E(K) = \{(x_1, y_1) \in K^2 \mid y_1^2 + a_1x_1y_1 + a_3y_1 = x_1^3 + a_2x_1^2 + a_4x_1 + a_6\} \cup \{P_\infty\}.$$

The structure of the group of $\mathbb{F}_q$-rational points is easy to describe. Indeed, by Corollary 5.77, $E(\mathbb{F}_q)$ is either cyclic or isomorphic to a product of two cyclic groups, namely $E(\mathbb{F}_q) \simeq \mathbb{Z}/d_1\mathbb{Z} \times \mathbb{Z}/d_2\mathbb{Z}$ where $d_1 \mid d_2$ and $d_1 \mid q - 1$.

For cryptographic applications one usually works in a subgroup of prime order ℓ. Hence, one is interested in curves and finite fields such that $|E(\mathbb{F}_q)| = c\ell$ for some small *cofactor* c. See [GAMC 2000] for conjectural probabilities that the number of points is a prime or has a small cofactor.

Finding a random $\mathbb{F}_q$-rational point P on an elliptic curve $E/\mathbb{F}_q$ is quite easy. See Sections 13.2 and 13.3 for examples. If the curve has a cofactor $c > 1$ then this random point needs not lie inside the group of order ℓ. However, the point $Q = [c]P$ either equals P_∞, in which case one has to try with a different random point P, or is a point in the prime order subgroup.

Example 13.10 Let us consider the curve E_1 as defined by (13.3). One can check that $|E_1(\mathbb{F}_p)| = 1956 = 12 \times 163$. So, there are 1955 affine points with coordinates in $\mathbb{F}_p$ and the point at infinity P_∞ lying on E_1. The point $P_1 = (1118, 269)$ is of order 1956 which implies that the group $E_1(\mathbb{F}_p)$ is cyclic generated by P_1. The point $Q_1 = (892, 529)$ is of prime order 163.

Gauss as Scientific Mediator Between Mathematics and Geodesy from the Past to the Present

Willi Freeden, Thomas Sonar, and Bertold Witte

Abstract. The objective of the paper is to document the pioneer dimension of Gauss's ideas, concepts, and methods in a twofold direction based on selected case examples, namely to demonstrate his mediation function between mathematics and geodesy to explain the historic development over the past centuries from the initial Gaussian ignition to modern characteristics and tendencies.

Keywords. Gauss, geometric number theory, numerical integration, integral theorems and boundary value problems, least squares adjustment.

1. Introduction

1.1. C.F. Gauss (1777–1855): A brief look at his life

Carl Friedrich Gauss, born on 30 April 1777 in Brunswick (Braunschweig), came from a humble background whose parents were only able to enroll him in a basic writing and counting school. His mathematics teacher discovered his exceptional arithmetic skills and became an advocate for the talented student to facilitate the placement in a grammar school. At the age of fourteen the young Gauss was introduced to the Duke of Brunswick who pledged to finance the education of the extraordinarily talented boy. At the age of 15, Gauss had the genial idea to transfer the principles of logarithm tables to the prime number theory. It was the first time in the history of prime number research that prime number probability became object of research for increasing number ranges. However, he was not able to prove his prime number assumption that the number $\pi(x)$ smaller than x behaves asymptomatically as the quotient from x and $\log(x)$. Still this became the starting point for a variety of number theoretical examinations of renowned mathematicians until present. In the year 1795 Gauss started his studies at the University of Göttingen. After a brief period of time he decided to study mathematics. In

1796 Gauss discovered the solution to an old geometric problem, namely the answer to the question "which straight lines, regular polygons can be exclusively constructed by compass and straightedge". The evidence for the constructability of the regular hexadecagon led Gauss to continue groundbreaking research work, the results of which he compiled to a significant number theoretical work already during his study period which, alas, was only published in 1801 because it had to be translated into Latin as it was customary at that time. This opus published under the title "Disquisitiones arithmeticae" (cf. Figure 2.1) assured Gauss the recognition, in particular, amongst the leading French mathematicians of the era (Cauchy, Laplace, d'Alembert, Laguerre). He was attributed to the best mathematicians of his time due to his number theory. The "Disquisitiones arithmeticae" contain many significant research results such as, e.g., the celebrated Fundamental Theorem of Gauss, or the Law of Quadratic Reciprocity of Legendre. The crowning result of his contributions was the complete solution of binomial equations, and a most unexpected achievement in placing the imaginary unit on a firm basis. He actually was the first to use the imaginary symbol "i", giving it the interpretation of a geometric mean (see [27] for more details). After having graduated from Göttingen – upon the Duke's request who continued to grant him financial support – he switched to the University of Helmstedt where he studied under Prof. Pfaff and finished his thesis in 1799 in which he provided the exact evidence of the "Fundamental Theorem of Algebra" (Latin title: "Demonstratio nova theorematis, omnem functionem algebraicam rationalem integram unius variabilis in factores reales primi vel secundi gradus resolvi posse"). In the following time Gauss almost exclusively dealt with strictly mathematic or geometric questions. Applications were secondary during this epoch although he had already been working on the least squares method since 1794 with a multitude of practical studies. The deeper he penetrated into mathematics, the more fully he was persuaded that its true meaning lies in its application to practical life and natural science (cf. [27]). On January 1st, 1801 the astronomer Piazzi from Palermo discovered a small planet named Ceres. He could only track it for a time period of 41 days. Due to the low number of measuring values, the known methods at that time did not allow to calculate the precise orbit of Ceres in order to locate this planetoid again. The interest in the new planet caused Gauss to temporarily lay aside his purely mathematical researches. Now he created applicable methods for orbit determinations. He sought the orbit which would fit the observations as good as possible using an ellipse by applying his method of least squares. In doing so, his way resulted in the solution of two different problems: first, to find an approximate orbit; second, to correct this orbit in such a way that it "satisfies" the observations as well as possible (for more details the reader is referred to [27]). At the turn of the year 1801/1802 von Zach in Gotha and Olbers in Bremen rediscovered the planetoid, its location agreeing exactly with the ephemeris computed by Gauss. The discovery of Ceres introduced him to the world as an astronomer of the highest order (cf. [27]).

Gauss received a lot of praise and recognition for his scientific achievements; in January 1802 the Petersburg Academy of Sciences nominated him Correspond-

FIGURE 1.1. Medal (headside (left), backside (right)) of the 150th anniversary of the death of C.F. Gauss, 2005 (from [122]).

ing Member and in September 1802 he was invited to teach at the Academy which he declined as other offers later. In 1807 he accepted the call to Göttingen to become a professor for astronomy and the director of the observatory. In the years to follow Gauss mainly worked on astronomic topics but still on the theory of numbers. In the meantime he refocused his research works on application-related topics of mathematics which he found in astronomy as well as in geodesy. From 1818 until approximately 1830 geodesy became the center of his activities. Gauss made many geodetic observations during the arc measurements and the land surveying (1821–1844) in the Kingdom of Hanover in which he personally participated. As a matter of fact, Gauss alone managed the comprehensive calculations for this surveying project. Geodesy derived large direct and indirect profits from this practical activity which, for instance, was lamented by Bessel because of the entailing large time commitment and physical strain. During these works of arc measurements and geodetic surveying Gauss also proved to be a gifted practitioner: Particular mention should be made to the heliotrope (cf. Figure 6.5) invented by him which significantly facilitated and accelerated surveying works. The fundamental studies in classical differential geometry, in particular on the theory of surfaces, and his contributions to potential theory and the further development of the least squares method can be attributed to his practical activity as geodesist and astronomer. The fundamental surface studies, the so-called "Disquisitiones generales circa superficies curvas" (Gauss's Works, Vol. IV), due to their content, cannot be allocated to the actual geodetic works (see [141]) but more to the mathematical fundus. However, they are closely related to geodesy. The significance for geodesy constitutes in the detailed elaboration on the theory of geodetic lines for which preparatory studies had been done by Bernoulli, Euler, and Clairaut, but not with the strong comprehensiveness and thoroughness Gauss applied. The "Disquisitiones" laid the grounds for suitable arithmetic formulas and coordinate systems on the geodetically relevant rotation ellipsoid. Gauss published practical applications for geodetic questions in his "Studies on Topics of Higher Geodesy" in

1843 and 1846 (see Gauss's Works, Vol. IV). Their importance for geodesy can be concisely expressed by the following words: Gauss is the founder of higher geodesy.

Since the collaboration with the Göttingen physicist Weber in the year 1831, Gauss published contributions to classical mechanics, Earth's magnetism, geometric optics, and electrodynamics. In mechanics, for example, he developed the principle of least constraint which was named after him and which has the advantage in comparison to other approaches that it can be demonstratively construed. The theory of optical systems of Gauss for the first time shows the exact principles of the passage of one light beam through a coaxial lens system when it is slightly tilted to the axis. The Gauss ocular is still used for autocollimation nowadays, e.g., for specific tasks in engineering surveying. Gauss's magnetic studies are recognized as his most significant contributions to physics. Gauss and Weber jointly developed the first electromagnetic telegraph.

The three areas of geomagnetism in which Gauss made great contributions were those related to the absolute measurement of the field, the analysis in terms of spherical harmonics, and the organization and equipping of magnetic observatories. Because of the insufficiency of observations over the globe at the time he worked, many of the investigations which he proposed on the basis of the spherical harmonic analysis had in spite of their tremendous significance to await later workers. These include the quantitative separation of internal and external sources, the effect of the Earth's ellipsoidal shape, the possible non-vanishing of the constant term in the expression for the potential and the possible existence of a non-potential portion of the field (see, e.g., [70, 179] and the references therein).
Following W.K. Bühler [17], Gauss did not venture deeply into electrodynamics. In this field he is an outsider fascinated by interesting ideas and phenomena. His legacy contains several interesting recordings, however, no reasonably rounded theory. In fragments regarding the nature of the electromagnetic field, Gauss attempts to describe the theory of long-distance effects – a theory which was then further developed by Weber and Neumann and finally superseded by Maxwell's theory of electromagnetism.

Measured by his rich mathematic knowledge, Gauss published a relatively small number of papers. After his death on 23 February 1855, large amount of unpublished mathematic ideas was detected in his legacy, among others, recordings on non-Euclidean geometry. Gauss supposedly asked himself the question in view of the different geometries, which geometry correctly depicts the physical reality. The experience taught that if the dimensions are sufficiently small, the Euclidean geometry applied regarding the measuring precision, based on which Gauss assumed that the Euclidean geometry also applies to the "infinite small", but that deviations occur with larger dimensions. Gauss wished to know whether our space is curved, i.e., non-Euclidean. For this purpose he measured the inner angles in a large triangle (cf. Figure 6.1). More concretely, Gauss took measurements from three mountains in Germany, Hohenhagen, near Göttingen, Brocken in the Harz Mountains and Inselsberg in the Thüringer Wald to the south. The three lines joining these locations form a great triangle, the angle at Hohenhagen is close to a right angle, so the area of the triangle is close to half the product of the two short sides. Gauss assumed that light propagates along geodesics. During his high-precision measurement campaign he was not able to detect deviations from the Euclidean internal angle amount, implying that the Euclidean geometry can be applied for relatively large distances in the physical space. This result was negative for Gauss which may have been the reason for his decision not to publish his studies on non-Euclidean geometry. It is doubtful whether this interpretation is correct; Gauss presumably knew that potential deviations would only become obvious in triangles of astronomic dimensions (see [240] for more details). At a later time, Riemann, who was inspired by Gauss, created the Riemann geometry, the basis on which Einstein was able to build up his relativity theory which also finds its application, e.g., in satellite geodesy (see also [224]).

In conclusion, it has to be stated that it was extremely fortunate for geodesy that the world-renowned mathematician (*"Princeps Mathematicorum"*), Carl Friedrich Gauss (cf. Figure 1.2), had been so much fascinated by geodesy from early on in his mathematical career to which he dedicated a significant part of this work time over his life. In a letter to the astronomer Olbers in January 1802 he expressed it as follows: *"The most refined geometer and the perfect astronomer these are two separate titles which I highly esteem with all my heart, and which I worship with passionate warmth whenever they are united"* (see [27, 141] for more details).

1.2. Scientific bridge between mathematics and geodesy

Evidently, a contribution concerned with Gauss as scientific mediator between mathematics and geodesy (as intended by this publication) has to follow an obligatory line, namely to provide an appropriate platform within which mathematically/geodetically interrelated features can be better motivated and understood, thereby canonically leading to an interdisciplinary palette of solution procedures in diverse areas of application. In accordance with this intention, criteria must be found relative to which the scope and limitations of the various methods can be assessed. This is important both in theory and practice since there generally is no cure-all method for most of the problems in reality; it is imperative to be able to clarify why a certain method works in some context as well as when not to use that method.

The authors of this work are convinced that Gauss's suggestions and ideas as exemplary work is still helpful to understand the intuitive principles and interrelations that underlie the various methods and procedures to be needed for the solution of problems and desiderata. So, in summary, the present article may be regarded as an attempt to justify this basic assertion.

1.3. Mathematical circuit: abstraction and concretization

What is it exactly that enables mathematicians to build a bridge between geodesy and their discipline? What is exactly that enables the mathematicians to provide the transfer from concrete geodetic measurements and observables to abstract

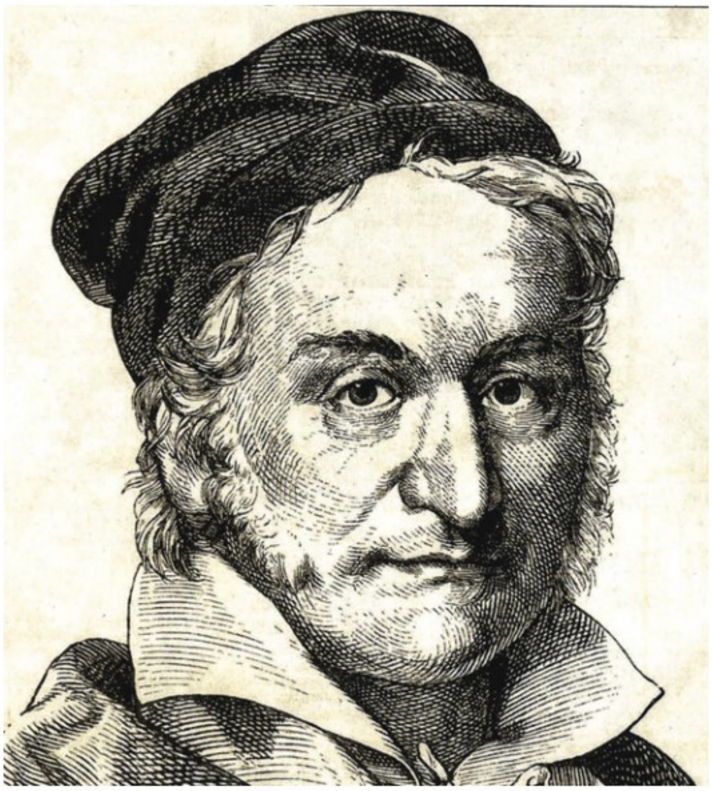

FIGURE 1.2. Johann Carl Friedrich Gauss, born, 30 April 1777 Brunswick, Duchy of Brunswick-Wolfenbüttel, Holy Roman Empire, died, 23 February 1855 (aged 77) Göttingen, Kingdom of Hanover.

mathematical formalisms and models? What is exactly that enables the mathematicians to bridge the time gap from historic nomenclature to modern notation? Some answers should be given already at this early stage: The mathematics world of numbers and structures contains efficient tokens by which the rule-like aspect of geodetic problems can be described appropriately. In fact, this description includes as essential step a simplification by abstraction. Essential properties of the problem are separated from unimportant ones, further specified, and afterwards included into a solution scheme. The "eye for similarities" often enables mathematicians to recognize a posteriori that an adequately reduced problem may also arise from very different situations in various application areas, so that the resulting solutions may be applicable to multiple cases after an adequate adaptation or concretization. Without this ingredient, the abstraction remains essentially useless. The interaction between abstraction and concretization characterizes the history of mathematics and its current development as a common language and independent standards in a unified setup. A problem reduced by abstraction has to be considered as a new "concrete" problem to be solved within a general framework, that determines the validity of a possible solution, not only in geodesy, but also in quite different sciences. The more examples and facets one knows, the more one recognizes the causality between the abstractness of mathematical concepts and their impact and cross-sectional significance.

As an immediate consequence, two important questions arise in a work making the attempt to pursue geodetic ideas and concepts from Gaussian time up to resulting mathematical settings in our days.

(i) What can be specified as mathematical structures and settings by a process of abstraction, i.e., a reduction to essential features?
(ii) What can be achieved from the reduced context obtained by abstraction as a new field of scientific interest, e.g., in geodesy or other sciences?

The purpose of this contribution is to discuss these questions for a selected collection of case studies. The interplay between abstraction and concretization will be explained for each of the problems, thereby offering new perspectives for future challenges. Dilemmas and methodologies will be indicated during the resolution process.

1.4. Specific strategies imposed on our work

The purpose of our work is not to describe the entire opus of the "science titan" Gauss in all its facets from the past until today. Such an approach would be doomed to fail in view of the enormous significance and the immense amount of ideas and works of Gauss. The objective of the authors is rather to document the pioneer dimension of Gauss's ideas, concepts, and methods in a twofold direction based on selected case examples, to demonstrate his mediation function between mathematics and geodesy firstly and secondly the historic development over the past centuries from the initial ignition by Gauss to the modern characteristics and tendencies in mathematics and/or geodesy. The authors consciously limited themselves to special topics in which they feel competent to focus on based on their scientific formation. It includes lattice point number theory with its basics for the development of modern sampling methods, Gauss integration with its impacts on modern fast algorithms for global modeling of geodetically and geophysically relevant quantities, the potential theory with the Gauss law as the initial point for geodetic boundary value problems to determine the physically defined Earth's figure and finally the least squares method in its canonic continuation into the issues of present ill-posed and inverse problems, e.g., in terms of pseudodifferential equations. Due to the reference of this contribution to mathematical geodesy, Gauss's contributions to geomagnetics were not reflected here (in this conjunction, reference is made to, e.g., publications of G.D. Garland [70], K. Reich, E. Roussanova [179] and their cross-references). In addition, a difficulty arose with translating Gauss terms into modern mindsets. The mathematic/geodetic language and forms of expression have developed and changed over the past two centuries. The authors, alas, were not able to convey and suitably illustrate the development process of the notation. For reasons of legibility, a standardized unified notation was selected (except quotes) adjusted to the requirements of modern times as the last link of the term-defining process.

2. From Gaussian circle problem to geosampling

There is no doubt that the theory of numbers was Gauss's favourite subject. In a much quoted dictum, he asserted that

> *"Mathematics is the Queen of the Sciences and the Theory of Numbers is the Queen of Mathematics".*

Moreover, in the introduction to "Eisenstein's Mathematische Abhandlungen" Gauss wrote:

> *"The Higher Arithmetic presents us with an inexhaustible storehouse of interesting truths – of truths, too, which are not isolated but stand in the closest relation to one another, and between which, with each successive advance of the science, we continually discover new and sometimes wholly unexpected points of contact. A great part of the theories of Arithmetic derive an additional charm from the peculiarity that we easily arrive by induction at important propositions which have the stamp of simplicity upon them but the demonstration of which lies so deep as not to be discovered until after many fruitless efforts; and even then it is obtained by some tedious and artificial process while the simpler methods of proof long remain hidden from us."*

All this is well illustrated by what is perhaps Gauss's most profound publication, namely his "Disquisitiones arithmeticae"(cf. Figure 2.1). It has been described, quite justifiably, as the "Magna Carta of Number Theory", and the depth and originality of thoughts to be manifested in this work are particularly remarkable considering that they were written when Gauss was only about eighteen years of age. In view of the great impact Gauss had on large areas of modern number theory, anything even approaching a comprehensive representation of their influence seems untenable. It is not surprising that there is a huge amount of literature concerned with Gauss's number theoretical results, and his influence on modern mathematics is enormous. However, the obvious problem for our purposes here is the question if the "Queen of Mathematics" is actually able to show impacts to modern mathematical geodesy.

2.1. Lattice points inside circles

We start our bridge from Gaussian concepts of number theory to modern geodetically relevant sampling with a recapitulation of some results on the number of lattice points inside circles

$$\mathbb{S}^1_N = \{x \in \mathbb{R}^2 : |x| = N\} \tag{2.1}$$

FIGURE 2.1. Title-page of **"Disquisitiones arithmeticae"**, original latin edition by Gerhard Fleischer, Lipsiae (Leipzig) 1801 (668 pages), first reprint as first issue of "Gesamtausgabe Carl Friedrich Gauss: Werke. Band 1, Dieterich, Göttingen 1863", reprint by Springer-Verlag, New York Heidelberg 1986, ISBN 0-387 96254-9 (English translation by Arthur A. Clarke, 1986, in revised form by William C. Waterhouse).

of radii $N > \frac{\sqrt{2}}{2}$ around the origin 0; more accurately, we deal with closed disks

$$\overline{\mathbb{B}_N^2} = \{x \in \mathbb{R}^2 : |x| \leq N\} \tag{2.2}$$

of radii $N > \frac{\sqrt{2}}{2}$ (for more background material and deeper number theoretical concepts the reader is referred, e.g., to the monographs [47, 66]).

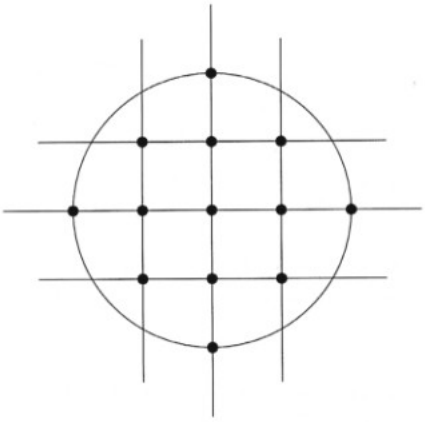

FIGURE 2.2. Lattice points inside a circle.

The problem of determining the total number of lattice points of $\mathbb{Z}^2$ inside and on a circle with radius N, i.e., the determination of the quantity

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_N}\right) = \sharp\left\{(n_1,n_2)^T \in \mathbb{Z}^2 : n_1^2+n_2^2 \leq N^2\right\} \tag{2.3}$$

reaches back to L. Euler [33]. In today's nomenclature it can be equivalently expressed as a sum in the form

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_N}\right) = \sum_{\substack{n_1^2+n_2^2\leq N^2;\\ (n_1,n_2)^T\in\mathbb{Z}^2}} 1. \tag{2.4}$$

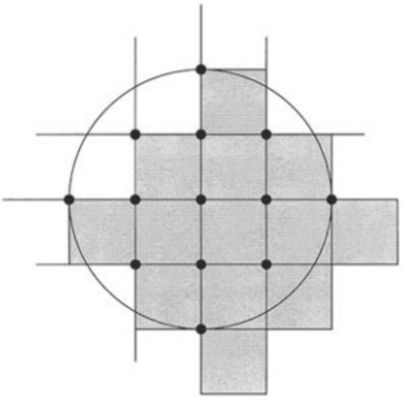

FIGURE 2.3. The polyhedral set $\mathbb{P}^2_N$.

Gauss [1801] found a simple, but efficient method for its estimation (cf. Figures 2.2 and 2.3): associate to every square the Northwest edge as lattice point. The union of all squares with lattice points inside $\overline{\mathbb{B}_N^2}$ defines a polyhedral set $\mathbb{P}_N^2$ with area

$$\|\mathbb{P}_N^2\| = \sharp_{\mathbb{Z}^2}(\overline{\mathbb{B}_N^2}) \tag{2.5}$$

(cf. Figure 2.3). Since the diagonal of each square is $\sqrt{2}$, the geometry of Figure 2.3 tells us that

$$\pi\left(N - \frac{\sqrt{2}}{2}\right)^2 \leq \sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_N^2}\right) \leq \pi\left(N + \frac{\sqrt{2}}{2}\right)^2. \tag{2.6}$$

Therefore, $\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_N^2}\right) - \pi N^2$ after division by N is bounded for $N \to \infty$, which is usually written with Landau's O-symbol as

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_N^2}\right) = \pi N^2 + O(N). \tag{2.7}$$

In other words, the number of lattice points in $\overline{\mathbb{B}_N^2}$ is equal to the area of that circle plus a remainder of the order of the boundary. In particular,

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_N^2}\right) \sim \pi N^2 \tag{2.8}$$

so that a method of determining the irrational, transcendent number π becomes obvious (for alternative approaches to π within the history of analysis the reader is referred to [204]):

$$\lim_{N\to\infty} \frac{\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_N^2}\right)}{N^2} = \pi. \tag{2.9}$$

C.F. Gauss [71] illustrated his result by taking $N^2 = 100\,000$. In this case he calculated

$$\sum_{\substack{|g|^2 \leq 100\,000;\\ g \in \mathbb{Z}^2}} 1 = 314\ 197. \tag{2.10}$$

This calculation determines the number π up to three decimals after the comma.

2.2. Circle problem and Hardy's conjecture

The formula (2.7) due to C.F. Gauss [71] allows the following representation in the nomenclature of Landau's O-symbols:

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_N^2}\right) = \pi N^2 + O(N). \tag{2.11}$$

The so-called *circle problem* is concerned with the question of determining the bound

$$\alpha_2 = \inf\left\{\gamma : \sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}_{\sqrt{N}}^2}\right) = \pi N + O(N^\gamma)\right\}. \tag{2.12}$$

Until now, we knew from (2.11) that $\alpha_2 \leq \frac{1}{2}$. An improvement of the Gaussian result, however, turns out to be very laborious, in fact, requiring a great effort.

A first remarkable result is due to W. Sierpinski [201], who proved by use of a method of his teacher G. Voronoi [220] that

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) \quad = \pi N + O\left(N^{\frac{1}{3}}\right), \tag{2.13}$$

i.e., $\alpha_2 \leq \frac{1}{3}$. The proof of Sierpinski is elementary (see, e.g., [47, 66] for more details); it is a link between geometry and number theory.

By use of advanced methods on exponential sums (based on the work by, e.g., H. Weyl [228], H.R. Chen [18], and many others) the estimate $\frac{1}{3}$ could be strengthened to some extent. It culminated in the publication by G. Kolesnik [128], who had as his sharpest result with these techniques

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) \quad - \pi N = O\left(N^{\frac{139}{429}}\right). \tag{2.14}$$

M.N. Huxley [117] devised a substantially new approach (not discussed here); his strongest result was the estimate

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) \quad - \pi N = O\left(N^{\frac{131}{416}}\right). \tag{2.15}$$

(note that $\frac{139}{429} = 0.324009\ldots$, while $\frac{131}{416} = 0.315068\ldots$).

Hardy's conjecture claims

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) - \pi N = O\left(N^{\frac{1}{4}+\varepsilon}\right) \tag{2.16}$$

for every $\varepsilon > 0$. This conjecture seems to be still a challenge for future work. However, in the year 2007, S. Cappell and J. Shaneson deposited a paper entitled "Some Problems in Number Theory I: The Circle Problem" in the arXiv:math/0702613 claiming to prove the bound of $O(N^{\frac{1}{4}+\varepsilon})$ for $\varepsilon > 0$.

TABLE 1. Incremental improvements for the value ε_2 in the estimate (2.17).

Table 1 lists incomplete incremental improvements for the quantity ε_2 of the upper limit for the circle problem

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) - \pi N = O\left(N^{\frac{1}{4}+\varepsilon_2}\right) \; . \tag{2.17}$$

For all recent improvements, the proofs became rather long and made use of some of the more heavy machinery in hard analysis.

Summarizing our results about lattice points inside circles (cf. [47]) we are confronted with the following situation:

$$\frac{1}{4} \;\leq\; \alpha_2 \;\leq\; \frac{1}{4} + \varepsilon_2 \tag{2.18}$$

and

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) - \pi N \neq O\left(N^{\frac{1}{4}}\right), \tag{2.19}$$

$$\sharp_{\mathbb{Z}^2}\left(\overline{\mathbb{B}^2_{\sqrt{N}}}\right) - \pi N = O\left(N^{\frac{1}{4}+\varepsilon_2}\right), \tag{2.20}$$

where $0 < \varepsilon_2 \leq \frac{1}{4}$ (for example, Huxley's bound $\varepsilon_2 = 0.064903\ldots$).

2.3. Variants of the circle problem

There are many perspectives to formulate variants of the Gaussian lattice point problem for the circle. It already was the merit of E. Landau [135] to point out particularly interesting areas, such as

- *General two-dimensional lattices*

$$\Lambda = \{g = ng_1 + mg_2 \;:\; n, m \in \mathbb{Z}\} \tag{2.21}$$

with $g_1, g_2 \in \mathbb{R}^2$ linearly independent (see Figure 2.4) can be used instead of the unit lattice $\mathbb{Z}^2$.

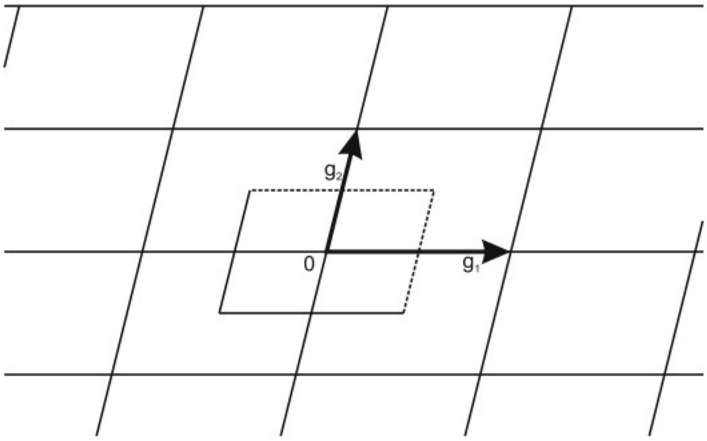

FIGURE 2.4. Two-dimensional lattice Λ generated by $g_1, g_2 \in \mathbb{R}^2$.

- The *remainder term* can be represented as alternating series, called *Hardy–Landau series* in terms of the Bessel function J_1 of order 1 (for the different facets of the proof see [103, 134, 160])

$$\sum_{\substack{|g|\leq N\\ g\in\Lambda}}{}' \, 1 = \frac{\pi N^2}{\|\mathcal{F}_\Lambda\|} + \lim_{R\to\infty} \frac{\pi N^2}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{0<|h|\leq R\\ h\in\Lambda^{-1}}} \frac{J_1(2\pi|h|N)}{\pi|h|N}, \tag{2.22}$$

where Λ is an arbitrary lattice in $\mathbb{R}^2$ and

$$\mathcal{F}_\Lambda = \left\{ x = x_1 g_1 + x_2 g_2 \in \mathbb{R}^2 : -\frac{1}{2} \leq x_i < \frac{1}{2},\ i = 1,2 \right\} \tag{2.23}$$

is the *fundamental cell of* $\Lambda \subset \mathbb{R}^2$ with

$$\|\mathcal{F}_\Lambda\| = \sqrt{\det\left((g_i \cdot g_j)_{i,j=1,2}\right)} \tag{2.24}$$

as the area $\|\mathcal{F}_\Lambda\|$ *of* $\mathcal{F}_\Lambda$. Moreover, the following convention

$$\sum_{\substack{|g| \leq N \\ g \in \Lambda}}{}' 1 = \sum_{\substack{|g| < N \\ g \in \Lambda}} 1 + \frac{1}{2} \sum_{\substack{|g| = N \\ g \in \Lambda}} 1 \tag{2.25}$$

is used in lattice point theory (note that the last sum only occurs if there is a lattice point $g \in \Lambda$ with $|g| = N$).

- Lattice points can be affected by non-constant weights (see [35])

$$\begin{aligned} &\sum_{\substack{|a+g| \leq N \\ g \in \Lambda}}{}' e^{2\pi i y \cdot (a+g)} F(a+g) \\ &\quad = \lim_{R \to \infty} \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{|h-y| \leq R \\ h \in \Lambda^{-1}}} e^{2\pi i a \cdot h} \int_{\substack{|x| \leq N \\ x \in \mathbb{R}^2}} F(x)\, e^{-2\pi i x \cdot (h-y)}\, dx, \end{aligned} \tag{2.26}$$

where dx is the volume element, $a, y \in \mathbb{R}^2$, F is twice continuously differentiable in $\overline{\mathbb{B}^2_N}$, $N > 0$, and the following convention has been used analogously to (2.25)

$$\sum_{\substack{|a+g| \leq N \\ g \in \Lambda}}{}' \cdots = \sum_{\substack{|a+g| < N \\ g \in \Lambda}} \cdots + \frac{1}{2} \sum_{\substack{|a+g| = N \\ g \in \Lambda}} \cdots . \tag{2.27}$$

Note that, for $F = 1$, this formula leads back to

$$e^{2\pi i a \cdot y} \sum_{\substack{|g+a| \leq N \\ g \in \Lambda}}{}' e^{2\pi i g \cdot y} = \lim_{R \to \infty} \frac{\pi N^2}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{|h-y| \leq R \\ h \in \Lambda^{-1}}} e^{2\pi i a \cdot h} \frac{J_1(2\pi |h-y| N)}{\pi |h-y| N}. \tag{2.28}$$

For $a = y = 0$ we obtain the *classical Hardy–Landau identity*, i.e., the identity

$$\sum_{\substack{|g| \leq N \\ g \in \Lambda}}{}' 1 = \lim_{R \to \infty} \frac{\pi N^2}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{|h| \leq R \\ h \in \Lambda^{-1}}} \frac{J_1(2\pi |h| N)}{\pi |h| N}. \tag{2.29}$$

holds true. Observe that J_1 satisfies the asymptotic relation $J_1(r) = \frac{r}{2} + \cdots$, so that

$$\sum_{\substack{|g| \leq N \\ g \in \Lambda}}{}' 1 = \frac{\pi N^2}{\|\mathcal{F}_\Lambda\|} + \lim_{R \to \infty} \frac{\pi N^2}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{0 < |h| \leq R \\ h \in \Lambda^{-1}}} \frac{J_1(2\pi |h| N)}{\pi |h| N}. \tag{2.30}$$

- Generalizations to lattices $\Lambda \subset \mathbb{R}^q$ and regular regions $\mathcal{G} \subset \mathbb{R}^q, q \geq 2$, and continuous functions on $\overline{\mathcal{G}} = \mathcal{G} \cup \partial\mathcal{G}$ can be formulated in Gaussian summability (see [47] for the proof and a more detailed study)

  $$\sum_{\substack{a+g\in\overline{\mathcal{G}}\\ g\in\Lambda}}{}' e^{2\pi i y\cdot(a+g)} F(a+g) = \lim_{\substack{\tau\to 0\\ \tau>0}} \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{h\in\Lambda^{-1}} e^{-\tau\pi^2 h^2} e^{2\pi i h\cdot a} \int_{\mathcal{G}} F(x) e^{-2\pi i x\cdot(h-y)}\, dx, \ \ a, y \in \mathbb{R}^q, \quad (2.31)$$

  where a *regular region* $\mathcal{G}$ *in* $\mathbb{R}^q$ is understood to be an open and connected set $\mathcal{G} \subset \mathbb{R}^q$, $q \geq 2$, for which
  (i) its boundary $\partial\mathcal{G}$ constitutes an orientable, piecewise smooth Lipschitzian manifold of dimension $q-1$,
  (ii) the origin is contained in $\mathcal{G}$,
  (iii) $\mathcal{G}$ divides $\mathbb{R}^q$ into the "inner space" $\mathcal{G}$ and the "outer space" $\mathbb{R}^q \backslash \overline{\mathcal{G}}$, $\overline{\mathcal{G}} = \mathcal{G} \cup \partial\mathcal{G}$.

  Clearly,

  $$\sum_{\substack{a+g\in\overline{\mathcal{G}}\\ g\in\Lambda}}{}' e^{2\pi i y\cdot(a+g)} F(a+g) = \frac{1}{\|\mathcal{F}_\Lambda\|} \int_{\mathcal{G}} F(x) e^{2\pi i x\cdot y}\, dx + \lim_{\substack{\tau\to 0\\ \tau>0}} \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{0<|h|\leq R\\ h\in\Lambda^{-1}}} e^{-\tau\pi^2 h^2} e^{2\pi i h\cdot a} \int_{\mathcal{G}} F(x) e^{-2\pi i x\cdot(h-y)}\, dx, \ \ a, y \in \mathbb{R}^q. \quad (2.32)$$

  The following abbreviation has been used consistently

  $$\sum_{\substack{a+g\in\overline{\mathcal{G}}\\ g\in\Lambda}}{}' \cdots = \sum_{\substack{a+g\in\mathcal{G}\\ g\in\Lambda}} \cdots + \sum_{\substack{a+g\in\partial\mathcal{G}\\ g\in\Lambda}} \alpha(a+g) \cdots \quad (2.33)$$

  with $\alpha(a+g)$ denoting the *solid angle* subtended by $\partial\mathcal{G}$ at $a+g$ (note that, as geoscientifically relevant regular regions, we may choose the interior of the (actual) Earth's body or parts of it, the interior of geoscientifically relevant surfaces such as the geoid, telluroid, etc., but also ball, ellipsoid, cube, polyhedral bodies, etc. are included in accordance with the above definition; in potential-theoretic jargon, the solid angle will be explained by Definition 4.1 in a more detailed way).

2.4. Multivariate Shannon sampling

Let us continue with the observation that, for every $y \in \mathbb{R}^q$, the (for dimensions $q \geq 3$ formally understood) series

$$a \mapsto \lim_{N\to\infty} \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{\substack{|h-y|\le N \\ h\in\Lambda^{-1}}} e^{2\pi i a\cdot h} \underbrace{\int_{\mathcal{G}} F(x) e^{-2\pi i x\cdot(h-y)}\,dx}_{F_{\mathcal{G}}^{\wedge}(h-y)},\ a\in\mathbb{R}^q, \tag{2.34}$$

as well as the finite sum

$$a \mapsto \sum_{\substack{a+g\in\overline{\mathcal{G}} \\ g\in\Lambda}}{}' e^{2\pi i y\cdot(a+g)} F(a+g),\ a\in\mathbb{R}^q, \tag{2.35}$$

show Λ-periodicity, i.e., as functions of the variable $a\in\mathbb{R}^q$ they are periodic with respect to the lattice $\Lambda\subset\mathbb{R}^q$. As a consequence (see [57] for the details), Shannon-type sampling procedures can be obtained by formal integration of the lattice point identity (2.31) over a regular region $\mathcal{H}$ that is not necessarily equal to $\mathcal{G}$

$$\begin{aligned}
&\int_{\mathcal{H}} \sum_{\substack{a+g\in\overline{\mathcal{G}} \\ g\in\Lambda}}{}' e^{-2\pi i y\cdot(a+g)} F(a+g)\,da \\
&\quad = \sum_{\substack{(\mathcal{F}_\Lambda+\{g'\})\cap\overline{\mathcal{H}}\neq\emptyset \\ g'\in\Lambda}} \underbrace{\int_{\mathcal{G}\cap\bigcup_{g\in\Lambda}(((\overline{\mathcal{H}}\cap(\mathcal{F}_\Lambda+\{g'\}))-\{g'\})+\{g\})} F(x)e^{-2\pi i y\cdot x}\,dx}_{=F^{\wedge}_{\mathcal{G}\cap\bigcup_{g\in\Lambda}(((\overline{\mathcal{H}}\cap(\mathcal{F}_\Lambda+\{g'\}))-\{g'\})+\{g\})}(y)} \\
&\quad = \lim_{\substack{\tau\to0 \\ \tau>0}} \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{h\in\Lambda^{-1}} e^{-\tau\pi^2h^2} \underbrace{\int_{\mathcal{G}} F(x)e^{-2\pi i h\cdot x}\,dx}_{=F_{\mathcal{G}}^{\wedge}(h)}\ \underbrace{\int_{\mathcal{H}} e^{2\pi i a\cdot(h-y)}\,da}_{=K_{\mathcal{H}}(h-y)}.
\end{aligned} \tag{2.36}$$

The identity (2.36) has many interesting properties. For example, by virtue of the Gaussian summability, the convergence of the cardinal-type series on the right-hand side of (2.36) may be exponentially accelerated. All manifestations of over- and undersampling can be explicitly analyzed by the finite sum of Fourier transforms on the left side of the identity (see [57]), dependent on the geometric configurations of the chosen regular regions $\mathcal{G},\mathcal{H}$ (note that the identity (2.36) also seems to be unknown for the uni-variate case in this generality).

The Gaussian summability of the cardinal series on the right-hand side of (2.36) is of great importance from numerical point of view; it enables a fast computation of the series. Nonetheless, W. Freeden, M.Z. Nashed [57]) show that the identity (2.36) additionally holds true in ordinary sense, i.e., we have

$$\begin{aligned}
&\int_{\mathcal{H}} \sum_{\substack{a+g\in\overline{\mathcal{G}} \\ g\in\Lambda}}{}' e^{-2\pi i y\cdot(a+g)} F(a+g)\,da \\
&\quad = \sum_{\substack{(\mathcal{F}_\Lambda+\{g'\})\cap\overline{\mathcal{H}}\neq\emptyset \\ g'\in\Lambda}} \underbrace{\int_{\mathcal{G}\cap\bigcup_{g\in\Lambda}(((\overline{\mathcal{H}}\cap(\mathcal{F}_\Lambda+\{g'\}))-\{g'\})+\{g\})} F(x)e^{-2\pi i y\cdot x}\,dx}_{=F^{\wedge}_{\mathcal{G}\cap\bigcup_{g\in\Lambda}(((\overline{\mathcal{H}}\cap(\mathcal{F}_\Lambda+\{g'\}))-\{g'\})+\{g\})}(y)}
\end{aligned}$$

$$= \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{h \in \Lambda^{-1}} \underbrace{\int_{\mathcal{G}} F(x) e^{-2\pi i h \cdot x} \, dx}_{= F^\wedge_{\mathcal{G}}(h)} \; \underbrace{\int_{\mathcal{H}} e^{2\pi i a \cdot (h-y)} \, da}_{= K_{\mathcal{H}}(h-y)}. \tag{2.37}$$

A simple, but significant case of (2.37) in Euclidean space $\mathbb{R}^q$ showing no phenomenon of aliasing is obtained under the special choice $\overline{\mathcal{G}} = \overline{\mathcal{H}} \subset \overline{\mathcal{F}_\Lambda}$ leading to the Shannon-type identity

$$F^\wedge_{\mathcal{G}}(y) = \frac{1}{\|\mathcal{F}_\Lambda\|} \sum_{h \in \Lambda^{-1}} F^\wedge_{\mathcal{G}}(h) \;\; K_{\mathcal{G}}(h-y). \tag{2.38}$$

In fact, the identity (2.38) is a multi-variate variant of the Shannon sampling theorem (cf. [198]), but now for (geoscientifically relevant) regions $\mathcal{G}$. The principal impact of Shannon sampling on information theory is that it allows the replacement of a bandlimited signal $F^\wedge_{\mathcal{G}}$ related to $\mathcal{G}$ by a discrete sequence of its samples without loss of any information. Also it specifies the lowest rate, i.e., the Nyquist rate (cf. [57]), that it enables to reproduce the original signal. In other words, Shannon sampling provides the bridge between continuous and discrete versions of a bandlimited function.

The Shannon sampling theorem has many applications in engineering and physics, for example, in signal processing, data transmission, cryptography, constructive approximation such as spectral analysis by Slepian functions (see, e.g., [202, 203]), partial differential equations such as Boltzmann equation (see, e.g., [171] and the references therein), and inverse problems such as the multi-variate discussion of a Fourier transform over a (geodetically relevant) regular region (see, e.g., [164] and the references therein for the uni-variate study of the antenna problem).

Finally, it should be remarked that sampling theory (in the sense of the representation of an analog signal in terms of its samples) has attracted considerable interest in the past three decades. Major advances in the theory and applications of sampling expansion in different function spaces have been made by mathematicians and engineers. There are several journals on signal processing and computational harmonic analysis that publish papers on sampling theory and its applications. The field also sports its own journal "Sampling Theory in Signal and Image Processing" and has its own "professional society". We quote from Wikipedia:

> *"SampTA (Sampling Theory and Applications) is a biennial interdisciplinary conference for mathematicians, engineers, and applied scientists. The main purpose of SampTA is to exchange recent advances in sampling theory and to explore new trends and directions in related areas of applications. The SampTA conference series began as a small workshop in* 1995 *in Riga, Latvia, but the meetings grew into full-fledged conferences attracting an even mix of mathematicians and engineers as the interest in sampling theory blossomed."*

Pág. 28(43) Gaussian Quadrature

where

$$G_{0,\ldots,m}((\mathrm{L}+\lambda)^p;x,t) = \sum_{\substack{k=0\\ \lambda\neq \mathrm{L}^\wedge(k)}}^{m} \frac{1}{(\lambda-\mathrm{L}^\wedge(k))^p} P_k^*(x)P_k^*(t). \tag{3.49}$$

$G^{\perp}_{0,\ldots,m}((\mathrm{L}+\lambda)^p;\cdot,\cdot)$ is called *mth truncated Legendre (Green) function with respect to the operator* $(\mathrm{L}+\lambda)^p$. These functions admit an easy reformulation of Theorem 3.2 after application of partial integration.

Theorem 3.3. *Suppose that $p\in\mathbb{N}$, $m\in\mathbb{N}_0$. Assume that $\lambda\in\mathbb{R}$ with*

$$\lambda\neq \mathrm{L}^\wedge(m+1), \mathrm{L}^\wedge(m+2),\ldots.$$

Then, for all $x\in(-1,1)$ and $F\in C^{(2p)}([-1,1])$,

$$\begin{aligned} F(x) &= \sum_{n=0}^{m}\int_{-1}^{+1} F(t)P_n^*(t)\;dt\;P_n^*(x)\\ &\quad+\int_{-1}^{1} G^{\perp}_{0,\ldots,m}((\mathrm{L}+\lambda)^p;x,t)\;(\mathrm{L}_t+\lambda)^p F^{\perp}_{0,\ldots,m}(t)\;dt, \end{aligned}\tag{3.50}$$

where we have used the abbreviation

$$F^{\perp}_{0,\ldots,m} = F - \underbrace{\sum_{n=0}^{m}\int_{-1}^{1} F(t)P_n^*(t)\;dt\;P_n^*}_{=F_{0,\ldots,m}}. \tag{3.51}$$

Theorem 3.3 enables a comparison between the functional value $F(x)$ at the point x and the mth truncated orthogonal expansion of F in terms of Legendre polynomials at x with explicit representation of the remainder term in integral form.

Later on, this formula will be used to formulate adaptive estimates of the remainder terms in Gaussian numerical integration.

Gaussian Quadrature. Let $x_{1,n},\ldots,x_{n,n}$ with $x_{1,n}<\cdots<x_{n,n}$ be the zeros of the Legendre polynomial P_n of degree n. Then it is well known that there is precisely one zero of the polynomial P_{n+1} in each interval $(-1,x_{1,n}),\ldots,(x_{n,n},1)$.

For later use we want to prove the following preparatory result.

Lemma 3.5. *The matrix*

$$A=\Big(P_k^*(x_{j,n})\Big)_{\substack{k=0,\ldots,n-1\\ j=1,\ldots,n}} \tag{3.52}$$

is non-singular.

Proof. Assume that the matrix is singular. Then there exist coefficients $C_0,\ldots,C_{n-1}$ with $c=(C_0,\ldots,C_{n-1})^T\neq(0,\ldots,0)^T$ such that $c^TA=0$, i.e., the following polynomial of degree $\leq n-1$

$$Q(x)=\sum_{l=0}^{n-1} C_l P_l^*(x) \tag{3.53}$$

has as zeros $x_{1,n}, \ldots, x_{n,n}$. Hence, $Q = 0$. Now, for $k = 0, \ldots, n-1$,

$$0 = \int_{-1}^{1} Q(x) P_k^*(x)\ dx = C_k. \tag{3.54}$$

But this is a contradiction. Thus, Lemma 3.5 must be true. □

We are now interested in the *"Gaussian integration formula"* involving the "*Gaussian n-point formula*" $\mathcal{G}_n$

$$\mathcal{I}(F) = \int_{-1}^{1} F(t)\ dt \simeq \mathcal{G}_n(F) = \sum_{i=1}^{n} w_{i,n} F(x_{i,n}), \tag{3.55}$$

where the knots $x_{i,n}$, $i = 1, \ldots, n$, are the zeros of the Legendre polynomial P_n and the weights $w_{i,n}, i = 1, \ldots, n$, are determined by the linear system

$$\begin{aligned}
\sum_{i=1}^{n} w_{i,n} P_0^*(x_{i,n}) &= \int_{-1}^{1} P_0(t) P_0^*(t)\ dt &&= \sqrt{2},\\
\sum_{i=1}^{n} w_{i,n} P_1^*(x_{i,n}) &= \int_{-1}^{1} P_1(t) P_0^*(t) dt &&= 0,\\
&\ \ \vdots && \ \ \vdots\\
\sum_{i=1}^{n} w_{i,n} P_{n-1}^*(x_{i,n}) &= \int_{-1}^{1} P_{n-1}(t) P_0^*(t)\ dt = 0.
\end{aligned} \tag{3.56}$$

From Lemma 3.5 it is clear that the system (3.56) is uniquely solvable in the unknown weights $w_{1,n}, \ldots, w_{n,n}$.

Central for our considerations is the following well-known theorem (see, e.g., [206, 226]).

Theorem 3.4. *Let $x_{1,n}, \ldots, x_{n,n}$ be the zeros of the Legendre polynomial P_n. Furthermore, let $w_{1,n}, \ldots, w_{n,n}$ be the (unique) solution of the linear system* (3.56).

(i) *Then, the weights are positive, i.e., $w_{i,n} > 0$ for $i = 1, \ldots, n$, and we have*

$$\int_{-1}^{+1} P(t)\ dt = \sum_{i=1}^{n} w_{i,n} P(x_{i,n}) \tag{3.57}$$

for all $P \in \mathrm{Pol}_{0,\ldots,2n-1}$, i.e., for all algebraic polynomials of degrees $\leq 2n-1$,

(ii) *Conversely, if* (3.57) *is valid for real numbers $w_{i,n}, x_{i,n}$, $i = 1, \ldots, n$, then the knots $x_{i,n}$, $i = 1, \ldots, n$, are the zeros of the Legendre polynomial P_n and the weights $w_{i,n}, i = 1, \ldots, n$, satisfy the linear equations* (3.56).

(iii) *Finally, there exist no real numbers $x_{i,n}, w_{i,n}, i = 1, \ldots, n$, such that* (3.57) *holds true for all $P \in \mathrm{Pol}_{2n}$.*

Proof. Consider a polynomial $P \in \mathrm{Pol}_{0,\ldots,2n-1}$. Then there exist $Q, R \in Pol_{n-1}$ with

$$Q = \sum_{r=0}^{n-1} A_r P_r^* \tag{3.58}$$

and

$$R = \sum_{r=0}^{n-1} B_r P_r^* \tag{3.59}$$

such that

$$P = P_n^* Q + R. \tag{3.60}$$

Because of the orthogonality of the Legendre polynomials it is clear that

$$\begin{aligned}\int_{-1}^{+1} P(t)\, dt &= \int_{-1}^{1} P(t) \underbrace{P_0(t)}_{=1}\, dt \\ &= \int_{-1}^{1} Q(t) P_n^*(t)\, dt + \int_{-1}^{1} R(t) P_0(t)\, dt \\ &= \int_{-1}^{1} R(t) P_0(t)\, dt. \end{aligned}\tag{3.61}$$

In connection with (3.59) this implies

$$\int_{-1}^{1} P(t)\, dt = \sqrt{2}\, B_0. \tag{3.62}$$

Moreover, because of $P_n^*(x_{i,n}) = 0$, $i = 1, \ldots, n$, we obtain

$$\begin{aligned}\sum_{i=1}^{n} w_{i,n} P(x_{i,n}) &= \sum_{i=1}^{n} w_{i,n} \underbrace{P_n^*(x_{i,n})}_{=0} Q(x_{i,n}) + \sum_{i=1}^{n} w_{i,n} R(x_{i,n}) \\ &= \sum_{i=1}^{n} w_{i,n} \sum_{k=0}^{n-1} B_r P_r^*(x_{i,n}) \\ &= \sqrt{2}\, B_0. \end{aligned}\tag{3.63}$$

This shows us that (3.57) holds true.

Inserting the polynomials $\tilde{T}_k \in \mathrm{Pol}_{0,\ldots,2n-1}$, $k = 1, \ldots, n$, given by

$$\tilde{T}_k(x) = \prod_{\substack{j=1 \\ j \neq k}}^{n} (x - x_{j,n})^2, \quad x \in [-1, 1], \tag{3.64}$$

into (3.57) we get for $k = 1, \ldots, n$

$$0 < \int_{-1}^{+1} \tilde{T}_k(t)\, dt = \sum_{i=1}^{n} w_{i,n} \tilde{T}_k(x_{i,n}) = \sum_{i=1}^{n} w_{i,n} \prod_{\substack{j=1 \\ j \neq k}}^{n} (x_{i,n} - x_{j,n})^2, \tag{3.65}$$

hence, it is clear that

$$w_{i,n} > 0, \quad i = 1, \ldots, n. \tag{3.66}$$

This proves (i).

Next we verify (iii). Suppose that $w_{i,n}, x_{i,n}$, $i = 1, \ldots, n$, are given in such a way that (3.57) is valid for all $P \in \mathrm{Pol}_{0,\ldots,2n}$. Choose $H \in \mathrm{Pol}_{0,\ldots,2n}$ of the form

$$H(x) = \prod_{j=1}^{n} (x - x_{j,n})^2. \tag{3.67}$$

Then

$$0 < \int_{-1}^{1} H(x)\ dx = \sum_{i=1}^{n} w_{i,n} H(x_{i,n}) = 0. \tag{3.68}$$

This is a contradiction.

In order to guarantee (ii) we apply the Gauss rule (3.57) especially to the Legendre polynomials P_k^*, $k = 0, \ldots, n-1$, such that

$$\sum_{i=1}^{n} w_{i,n} P_k^*(x_{i,n}) = \int_{-1}^{1} P_k^*(x)\ dx = \int_{-1}^{1} P_k^*(x) \underbrace{P_0(x)}_{=1}\ dx. \tag{3.69}$$

In other words, the weights have to satisfy (3.56), i.e.,

$$\sum_{i=1}^{n} w_{i,n} P_k^*(x_{i,n}) = \left\{ \begin{array}{rl} \sqrt{2}, & k = 0, \\ 0, & k = 1, \ldots, n-1. \end{array} \right. \tag{3.70}$$

We now consider $P = P_k^* P_n^*$ for $k = 0, \ldots, n-1$, and apply (3.57). This gives

$$0 = \int_{-1}^{1} P_k^*(t) P_n^*(t)\ dt = \sum_{i=1}^{n} w_{i,n}\ P_k^*(x_{i,n})\ P_n^*(x_{i,n}) \tag{3.71}$$

for $k = 0, \ldots, n-1$. Consequently, the vector $a = (A_1, \ldots, A_n)^T$ given by

$$(A_1, \ldots, A_n)^T = (w_{1,n} P_n^*(x_{1,n}), \ldots, w_{n,n} P_n^*(x_{n,n}))^T \tag{3.72}$$

satisfies the linear system

$$0 = \sum_{i=1}^{n} A_i P_k^*(x_{i,n}), \quad k = 0, \ldots, n-1, \tag{3.73}$$

where the coefficient matrix is non-singular. But this means that $A_i = 0$, $i = 1, \ldots, n$, hence, $P_n(x_{i,n}) = 0$, $i = 1, \ldots, n$, as required. □

Remainder Terms Involving Green's Function. Now, the integral formula (Theorem 3.3) comes into play. For all values $\lambda \in \mathbb{R} \backslash \{\mathrm{L}\hat{}(2n), \mathrm{L}\hat{}(2n+1), \ldots\}$ and for functions $F \in C^{(2p)}([-1,+1])$, $p \in \mathbb{N}$, we have

$$\begin{aligned} \sum_{i=1}^{n} w_{i,n} F(x_{i,n}) = & \int_{-1}^{1} F(t)\ dt \\ & + \sum_{i=1}^{n} w_{i,n} \int_{-1}^{1} G^{\perp}_{0,\ldots,2n}((\mathrm{L}+\lambda)^p; x_{i,n}, t)\ (\mathrm{L}_t + \lambda)^p F(t)\ dt. \end{aligned} \tag{3.74}$$

In other words, the remainder

$$\mathcal{E}_n(F) = \mathcal{I}(F) - \mathcal{G}_n(F), \tag{3.75}$$

when the integral

$$\mathcal{I}(F) = \int_{-1}^{1} F(t)\ dt, \quad F \in C^{(2p)}([-1,1]), \tag{3.76}$$

is replaced by the "*Gaussian n-point formula*"

$$\mathcal{G}_n(F) = \sum_{i=1}^{n} w_{i,n} F(x_{i,n}), \tag{3.77}$$

is expressible by means of the $2n$th truncated Legendre (Green) function in integral form

$$\mathcal{E}_n(F) = -\sum_{i=1}^{n} w_{i,n} \int_{-1}^{1} G^{\perp}_{0,\ldots,2n}((\mathrm{L}+\lambda)^p; x_{i,n}, t)\ (\mathrm{L}_t+\lambda)^p F(t)\ dt \tag{3.78}$$

for all $\lambda \in \mathbb{R}\backslash\{\mathrm{L}^\wedge(2n), \mathrm{L}^\wedge(2n+1), \ldots\}$.

Applying the Cauchy–Schwarz inequality to (3.78) we obtain

$$|\mathcal{E}_n(F)| \le \sqrt{A^{(p)}_{\lambda}(n)} \sqrt{\int_{-1}^{1} |(\mathrm{L}_t+\lambda)^p F(t)|^2\ dt}, \tag{3.79}$$

for $\lambda \in \mathbb{R}\backslash\{\mathrm{L}^\wedge(2n), \mathrm{L}^\wedge(2n+1), \ldots\}$, where we have used the abbreviation

$$A^{(p)}_{\lambda}(n) = \sum_{i=1}^{n}\sum_{j=1}^{n} w_{i,n} w_{j,n} G^{\perp}_{0,\ldots,2n}((\mathrm{L}+\lambda)^{2p}; x_{i,n}, x_{j,n}) \tag{3.80}$$

with

$$\begin{aligned} &G^{\perp}_{0,\ldots,2n}((\mathrm{L}+\lambda)^{2p}; x_{i,n}, x_{j,n}) \\ &\quad = \int_{-1}^{1} G^{\perp}_{0,\ldots,2n}((\mathrm{L}+\lambda)^p; x_{i,n}, t) G^{\perp}_{0,\ldots,2n}((\mathrm{L}+\lambda)^p; t, x_{j,n})\ dt. \end{aligned} \tag{3.81}$$

Summarizing our results we obtain the following remainder estimate.

Theorem 3.5. *Let $x_{i,n}, i = 1, \ldots, n$, be the zeros of the Legendre polynomial P_n, $n \ge 1$, and let $w_{i,n}, i = 1, \ldots, n$, be the unique solution of the linear system*

$$\sum_{i=1}^{n} w_{i,n} P_k(x_{i,n}) = \int_{-1}^{1} P_0(t) P_k(t)\ dt, \tag{3.82}$$

$k = 0, \ldots, n-1$.

Then, for values $\lambda \in \mathbb{R}\backslash\{\mathrm{L}^\wedge(2n), \mathrm{L}^\wedge(2n+1), \ldots\}$ and for functions $F \in C^{(2p)}[-1,1]$, we have

$$\left| \int_{-1}^{1} F(t)\ dt - \sum_{i=1}^{n} w_{i,n} F(x_{i,n}) \right| \le \sqrt{A^{(p)}_{\lambda}(n)} \sqrt{\int_{-1}^{1} \left|(\mathrm{L}_t+\lambda)^p F(t)\right|^2\ dt}, \tag{3.83}$$

where

$$A_\lambda^{(p)}(n) = \sum_{i=1}^{n}\sum_{j=1}^{n} w_{i,n}w_{j,n} \sum_{k=2n}^{\infty} \frac{1}{(\lambda - \mathrm{L}^\wedge(k))^{2p}} P_k^*(x_{i,n})P_k^*(x_{j,n}). \tag{3.84}$$

Remainder Term Estimation. From (3.78), we get the estimate

$$|\mathcal{E}_n(F)| \le \sqrt{A_\lambda^{(p)}(n)}\sqrt{\int_{-1}^{1} \left|(\mathrm{L}_t + \lambda)F_{0,\dots,2n-1}^{\perp}(t)\right|^2 \, dt}, \tag{3.85}$$

where

$$F_{0,\dots,2n-1}^{\perp}(t) = F(t) - \underbrace{\sum_{n=0}^{2n-1} \int_{-1}^{1} F(u)P_n^*(u)\, du\; P_n^*(t)}_{=F_{0,\dots,2n-1}}, \tag{3.86}$$

$t \in [-1,1]$.

Observing the estimate $|P_n(t)| \le 1$ for all $n \in \mathbb{N}_0$ and $t \in [-1,1]$ and the properties of the Gaussian weights we get

$$|A_\lambda^p(n)| \le \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} w_{i,n}w_{j,n} \sum_{k=2n}^{\infty} \frac{2k+1}{(\lambda - \mathrm{L}^\wedge(k))^{2p}} = 2\sum_{k=2n}^{\infty} \frac{2k+1}{(\lambda - \mathrm{L}^\wedge(k))^{2p}} \tag{3.87}$$

for all $\lambda \in \mathbb{R}\backslash\{\mathrm{L}^\wedge(2n), \mathrm{L}^\wedge(2n+1), \dots\}$.

Theorem 3.6. *For* $F \in C^{(2n)}([-1,1])$,

$$\begin{aligned}\int_{-1}^{1} F(t)\, dt - \sum_{i=1}^{n} w_{i,n}F(x_{i,n}) \\ = \sum_{i=1}^{n} w_{i,n} \int_{-1}^{1} G_{2n}^{\perp}\big((L+\lambda)^n; x_{i,n}, t\big)(\mathrm{L}_t + \lambda)^n F_{0,\dots,2n-1}^{\perp}(t)\, dt,\end{aligned} \tag{3.88}$$

where $F_{0,\dots,2n-1}^{\perp}(t)$ *is defined by* (3.86).

Convergence of Gaussian Quadrature. From Theorem 3.5 we obtain

$$\left|\int_{-1}^{1} F(t)\, dt - \sum_{i=1}^{n} w_{i,n}F(x_{i,n})\right| \le \sqrt{A_0^{(p)}(n)}\sqrt{\int_{-1}^{1} (\mathrm{L}_t F(t))^2\, dt}, \tag{3.89}$$

where

$$A_0^{(p)}(n) = \sum_{i=1}^{n}\sum_{j=1}^{n} w_{i,n}w_{j,n} \sum_{k=2n}^{\infty} \frac{1}{(k(k+1))^{2p}} P_k^*(x_{i,n})P_k^*(x_{j,n}). \tag{3.90}$$

The sequence

$$\left\{2\sum_{k=2n}^{\infty} \frac{2k+1}{(k(k+1))^{2p}}\right\}_{n\in\mathbb{N}} \tag{3.91}$$

is (strictly) monotonously decreasing and positive. Furthermore, we have the rough estimate

$$0 \leq A_0^{(p)}(n) \leq 2 \sum_{k=2n}^{\infty} \frac{2k+1}{(k(k+1))^{2p}}. \tag{3.92}$$

Therefore, we come to the conclusion.

Theorem 3.7. *The sequence* $\{A_o^{(p)}(n)\}_{n\in\mathbb{N}}$ *has the limit*

$$\lim_{n\to\infty} A_0^p(n) = 0 \tag{3.93}$$

such that, for all $F \in C^{(2p)}([-1,1])$,

$$\lim_{n\to\infty} \mathcal{E}_n(F) = 0, \tag{3.94}$$

i.e., the Gaussian quadrature rule is convergent:

$$\lim_{n\to\infty} \sum_{i=1}^{n} w_i F(x_{i,n}) = \int_{-1}^{1} F(t)\ dt. \tag{3.95}$$

Comparing different numerical integration techniques with the Gaussian method we see that the last method assures the highest degree of polynomial precision. The critical point of the estimate (3.85), however, is to find an estimate for $(\mathrm{L}+\lambda)^{2p}F(t)$ with $(L+\lambda)^{2p}$ being appropriately adapted to the specific properties of the function such that the bound of $|\mathcal{E}_n(F)|$ becomes small. Moreover, it should be critically mentioned that the pointsets $\{x_{1,n},\ldots,x_{n,n}\}_{n\in\mathbb{N}}$ are not hierarchically distributed.

Gauss's work was simplified by Jacobi and further developed by F.G. Mehler [149], E.B. Christoffel [19], and others through much of the 19th century. Eventually, there emerged a coherent theory which received its first systematic expositions by E.B. Christoffel [19], R. Radau [177], and E. Heine [106] in his book on spherical functions. An outline of the developments in numerical quadrature that took place in a period of approximately 200 years from Newton via Gauss to early developments in the 20th century can be found in [188], and a German edition of the four principal memoirs (of Newton, Cotes, Gauss, and Jacobi) is due to A. Kowalewski [129]. A more detailed survey on developments up to the second half of the 20th century is given by W. Gautschi [85], culminating in the following comment:

> *"Gauss's discovery must be rated as one of the most significant events of the* 19*th century in the field of numerical integration and perhaps in all of numerical analysis. The result not only has great beauty and power, but also influenced many later developments in computing and approximation. It soon inspired contemporaries, such as Jacobi and Christoffel, to perfect Gauss's method and to develop it into new directions. Towards the end of the century, it inspired K. Heun* [109] *to generalize Gauss's idea to ordinary differential equations, which in turn led to significant developments in the numerical solution of differential equations, notably the discovery of the Runge–Kutta method* (*cf.* [133])*. Gauss's influence continues into the* 20*th century and is still felt today, ..."*

Whether or not the Gauss method had actually been widely used in practice up to the seventieth of the last century is a matter of some doubt, since the method requires the evaluation of functions at irrational arguments, hence, tedious interpolation. All this changed when powerful digital computers entered the scene, which generated a phase of renewed interest in Gaussian quadrature. The formulas began to be routinely applied, and increased usage, in turn, led to important new theoretical developments.

3.2. Periodic approximate integration

Next we are interested in trapezoidal sums based on Euler-type summation formulas for approximate integration of one-dimensional periodic functions.

To this end we first list some obvious results on *"τ-dilated lattices"*

$$\tau\mathbb{Z} = \{\tau g : g \in \mathbb{Z}, \tau > 0\}. \tag{3.96}$$

The *fundamental cell* $\mathcal{F}_{\tau\mathbb{Z}}$ of the lattice $\tau\mathbb{Z}$ is given by

$$\mathcal{F}_{\tau\mathbb{Z}} = \left\{ x \in \mathbb{R} : -\frac{1}{2}\tau \le x < \frac{1}{2}\tau \right\}. \tag{3.97}$$

A function $F : \mathbb{R} \to \mathbb{C}$ is called *$\tau\mathbb{Z}$-periodical* if $F(x+g) = F(x)$ holds for all $x \in \mathcal{F}_{\tau\mathbb{Z}}$ and $g \in \tau\mathbb{Z}$. The function $\Phi_h : \mathbb{R} \to \mathbb{C},\ h \in \frac{1}{\tau}\mathbb{Z}$, given by

$$x \mapsto \Phi_h(x) = \frac{1}{\sqrt{\tau}} e^{2\pi i h x} \tag{3.98}$$

is $\tau\mathbb{Z}$-periodical and satisfies the identity

$$\int_{\mathcal{F}_{\tau\mathbb{Z}}} \Phi_h(x) \Phi_{h'}(x)\ dx = \left\{ \begin{array}{ll} 1, & h = h' \\ 0, & h \ne h'. \end{array} \right. \tag{3.99}$$

The space of all $F \in C^{(m)}(\mathbb{R})$ that are $\tau\mathbb{Z}$-periodical is denoted by $C^{(m)}_{\tau\mathbb{Z}}(\mathbb{R})$, $0 \le m \le \infty$. Clearly, the space $L^2_{\tau\mathbb{Z}}(\mathbb{R})$ is the completion of $C^{(0)}_{\tau\mathbb{Z}}(\mathbb{R})$ with respect to the norm $\|\cdot\|_{L^2_{\tau\mathbb{Z}}(\mathbb{R})}$. The system $\{\Phi_h\}_{h \in \frac{1}{\tau}\mathbb{Z}}$ is orthonormal with respect to the $L^2_{\tau\mathbb{Z}}(\mathbb{R})$-inner product. By convention, we say that λ is an *eigenvalue of the lattice $\tau\mathbb{Z}$ with respect to the operator* Δ of the second-order derivative (i.e., the one-dimensional Laplace operator), if there is a non-trivial solution U of the differential equation $(\Delta + \lambda)U = 0$ satisfying the "boundary condition" of periodicity $U(x+g) = U(x)$ for all $x \in \mathcal{F}_{\tau\mathbb{Z}}$ and $g \in \tau\mathbb{Z}$. From classical Fourier analysis we know that the operator Δ has a half-bounded and discrete eigenspectrum $\{\Delta^\wedge(h)\}_{h \in \frac{1}{\tau}\mathbb{Z}} \subset \mathbb{R}$ such that $(\Delta_x + \Delta^\wedge(h))\,\Phi_h(x) = 0, x \in \mathcal{F}_{\tau\mathbb{Z}}$, with eigenvalues $\Delta^\wedge(h)$ given by $\Delta^\wedge(h) = 4\pi^2 h^2, h \in \frac{1}{\tau}\mathbb{Z}$, and eigenfunctions $\Phi_h(x) = \tau^{-\frac{1}{2}} e^{2\pi i h x}, h \in \frac{1}{\tau}\mathbb{Z}, x \in \mathcal{F}_{\tau\mathbb{Z}}$.

Consequently, the *eigenspectrum of the operator* Δ (with respect to $\tau\mathbb{Z}$) is given by

$$\mathrm{Spect}_\Delta(\tau\mathbb{Z}) = \left\{ \Delta^\wedge(h) : \Delta^\wedge(h) = 4\pi^2 h^2,\ h \in \frac{1}{\tau}\mathbb{Z} \right\}. \tag{3.100}$$

Trapezoidal Integration Rule. For purposes of *numerical integration of one-dimensional periodic functions* we introduce the *definition of the $\tau\mathbb{Z}$-lattice Green* both points Gauss's idea proved to be very fertile. His formulas are distinguished from other solutions due to their superior convergence, but also because Gauss had proven their accuracy and the size of the neglected terms. Gauss derived these formulas in two different ways: through a conformal mapping of the ellipsoid to the sphere and through power series expansions stemming from the differential equations of the geodesic on the ellipsoid of rotation. Gauss, however, did not present the formulas. This was done by F.R. Helmert [108] based on Gauss's formulas of the mean width (cf. [141]). A disadvantage of the series ansatz using arguments of means lies in the fact that the coefficients of the series have to be newly computed for each new pair of points, while the coefficients of the Legendre series have to be computed only once if the coordinates of multiple points have to be determined with respect to the same pole.

Approximately since 1965 the possibilities of numerical methods to solve the main tasks of geodesy, provided by standard methods of numerical mathematics, can be exploited due to the beginning development of electronic data processing computers. The variety of potential solutions can be divided roughly in four categories (according to B. Heck [105]):

(i) The first kind of approach rests on classical solutions of O. Schreiber [196] and H. Boltz [12]. Since poles are singular points of the geographical coordinate system Legendre's series cannot be used in the vicinity of poles. Moreover, these series show slow convergence in case of large distances so that this approach makes sense only in case of a short geodesic up to 150 km and up to 400 km if Gauss's formulas are used.

(ii) The second category rests on Bessel's approach (cf. [6]) of exploiting elliptic integrals which are today directly computed by numerical quadrature rules (see, e.g., [193]). This approach can also be used in the vicinity of poles and is accurate and advisable even in case of large distances of > 500 km.

(iii) The solution approaches in the third category are based on Gauss's conformal mapping of the ellipsoid to the sphere or the plane (cf. [84]) which are considered as auxiliary surfaces on which the main tasks of geodesy can be accomplished by means of closed formulas from spherical and plane trigonometry, respectively. Subsequently, the inverse mapping may be used to transfer back to the ellipsoid.

(vi) In the fourth category we find methods which were already used by A.M. Legendre [139] in a special case, namely that a given geodetic line is replaced by another line connecting start and end point of the geodesic. This other line may be a spatial chord, for example. Due to geodetic use of Earth satellites this three-dimensional ansatz has grown in importance.

6.2. Gaussian conformal mapping of the Earth's surface

For quite some time Gauss had dealt with the question of the method best suited to coordinate triangulation points because the knowledge of geographical coordinates is not sufficient. It seemed most convenient to him to exploit the coordinates with which every point could be represented in a plane (Gauss Werke, Vol. V, p. 367).

About 1815 he recognized the conformal mapping of the triangular points onto the plane as being the most appropriate solution to the problem. The term "konform" was used by him since 1843. The task formulated by Gauss, to project a given surface onto another one in a fairly general manner so that the image becomes similar to the preimage in its smallest parts was formulated as a contest question for the year 1821 by the Scientific Society in Copenhagen and reformulated the next year. Gauss submitted his solution (cf. [78]) on the 11, December 1822 and won the prize. His solution was distinguished from other known work in that it was valid in case of arbitrary surfaces and that he had fully laid open the conditions of conformity, the constancy of the augmenting relation in a certain point, and the equal angle condition (cf. [141]). Gauss applied his general solution to the following particular cases:

- *Conformal mapping between two planes.* As Gauss himself remarked (cf. Art. 8 in [78]), this is a useful method for the geodetic praxis, in order "to transform a map based on mediocre measurements which may be good in small details but is generally somehow distorted into a better one, if one knows the correct loci of a number of points."
- Conformal mapping of the sphere by transversal Mercator's projection or other mappings, e.g., the *conforming Lambert mapping.*
- *Conformal mappings of the ellipsoid of rotation onto the sphere.* In this mapping one can choose a suitable radius of the sphere to keep the differences between the ellipsoidal and spherical geometries relatively small. Hence, for practical applications spherical relations can be used which allow closed form solution. In case of local computations reasonable accuracy can be gained by letting the radius of the sphere depend on the geographic latitude. To this end two "replacement spheres" have proved their worth, namely the image sphere of Soldner, formerly used in Bavarian land surveying, and the Gaussian osculating sphere. The latter was used by Gauss (see [84]) with the radius M_0N_0 with regard to a point P_0, M_0 being the radius of curvature of the meridian and N_0 being the oblique radius of curvature.

  Since the ellipsoid shows the same measure of curvature in the central point P_0 in this mapping the differences in scale between ellipsoid and sphere stay small for regions not too large. As Gauss has shown the metric on a surface is determined by the Gaussian curvature. Hence, line segments and angles agree on two surfaces with the same Gaussian curvature. The surface of an ellipsoid, however, shows a variable Gaussian curvature so that the relationship of curvatures are only equivalent in the small (cf. Figures 6.2 and 6.3).

Under all mappings associated with Gauss's name the so-called *Gauss–Krüger projection* (and similar ones) have enjoyed wide distribution. In this projection the main meridian is mapped length-preserving to a straight line and is the abscissa of the plane system. Gauss had chosen this projection for the land surveying of Hanover (1828–1844) (cf. [141]). The size of the distortion depends only on the

distance between the points and the main meridian and is independent from the north-south dilatation. Today one follows the idea that meridian strips of 6° width with a difference in longitude of 3° from the main meridian to the boundary meridians suffice for tolerable distortions (this is today's UTM-coordinate system).

Gauss's work on surface theory was important for the later nineteenth century in the sense of Sophus Lie, while until his time in geometry only finite groups of transformations had been considered. Gauss paved the way for the general theory

FIGURE 6.4. A detail of the triangulation of Hanover carried out under Gauss's supervision 1821–1825 (Collected Works, Vol. 9, p. 347). Note that the three lines joining the locations Hohenhagen, Brocken, and Inselsberg (this point does not appear here, only a part of the connecting lines is displayed) form a great triangle, the angle at Hohenhagen is close to a right angle, so that the area of the triangle is close to half the product of the two short sides.

The Hanover surveying work also stimulated Gauss's interest in the study of curves and surfaces in three-dimensional differential geometry in Euclidean space (today usually called *Gaussian geometry*). Gauss also was led to the Gaussian curvature (an intrinsic measure of curvature, dependent only on how distances are measured on the surface, not on the way it is embedded in space).

6.3. Claims and perspectives

All in all, while engaged on a surveying task for the Royal House of Hanover in the years after 1818, Gauss was also concerned with the shape of the Earth. He started to formulate revolutionary ideas, like the concept of the geoid. He questioned one of the central tenets of the whole of mathematics, Euclidean geometry, which was clearly premised on a flat, and not a curved, universe. He later claimed to have considered a non-Euclidean geometry, which was internally consistent and free of contradiction. Unwilling to court controversy, however, Gauss decided not to pursue or publish any of his far-reaching concepts in non-Euclidean geometry. János Bolyai independently discovered non-Euclidean geometry in 1829; his work was published in 1832. After seeing it, Gauss wrote to Farkas Bolyai, the father of János Bolyai:

> *"To praise it would amount to praising myself. For, the entire content of the work ... coincides almost exactly with my own meditations which have occupied my mind for the past thirty or thirty-five years."*

The long history of the discussion of the parallel postulate started probably sooner than Euclid published his *Elements* about 300 BC as his fifth postulate [32], p. 155:

> *"That, if a straight line falling on two straight lines make the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which are the angles less than the two right angles."*

Many modern authors have commented on the meaning of this postulate; we mention only R. Bonola [13], J. Gray [90], B.A. Rosenfeld [184]. In fact, even in our time the fifth Euclidean postulate seems odd and we may understand why so many authors after Euclid tried to prove the fifth postulate (and thus making it a theorem) from the other axioms and postulates. Already Proclus (412–485), who wrote a Commentary on the First Book of Euclid's Elements, tried to prove the fifth postulate exploiting an argument given by Aristoteles to show the finiteness of the universe [176], p. 291, and failed, cf. [90], p. 39. Proclus informs us, that the first of the Ptolemies under whose reign Euclid lived, wrote himself a book on the fifth postulate and proved it, but Proclus points out the fallacy of this attempt. John Playfair (1748–1819) gave an alternative formulation of the fifth postulate in 1795 which is now known as *Playfair's Axiom* but which he himself attributed to William Ludlam (1717–1788). This formulation is the one which most people refer to nowadays when speaking of the "axiom of parallels" [239, p. 16]:

> *"Given a line a and a point A not lying on a, then there exists, in the plane determined by a and A, one and only one line which contains A but not any point of a."*

Or, even shorter,

> *"Through a given point can be drawn only one parallel to a given line."*

Many mathematicians tried to get hold of a proof of the fifth postulate; famous names over the centuries being Nasir al-Din al-Tusi (1201–1274) in Persia, John Wallis (1616–1703) in England, Giovanni Girolamo Saccheri (1667–1733) in Italy, the Swiss mathematician Johann Heinrich Lambert (1728–1777) in Germany, and Adrien-Marie Legendre (1752–1833) in France. At the beginning of the 19th century the invention of a Non-Euclidean Geometry seemed to have been in the air. If so many and different attempts to prove the fifth postulate a mere conclusion of other axions had failed the question whether there exists a geometry in which the fifth postulate was wrong became sensible. This may explain why it was not only Gauss who found the key to this new geometry but also Nikolai Lobachevsky (1792–1856) and János Bolyai (1802–1860) independently. However, Gauss was the first, although he did not publish his results. It is now known that it was he who coined the denotation "Non-Euclidean" for the new geometries which emerge out of a neglect of the fifth postulate. Already in 1804 Gauss received a letter of his friend Farkas Bolyai (1775–1856), father of János Bolyai, in which Bolyai presented a proof that the fifth postulate could be deduced from other axioms of geometry. Gauss praised the work of his friend, but found a flaw in the argument. He wrote (cf. [16, p. 100]):

> *"You want to know my sincere and frank opinion. And this is that your method does not satisfy me. I will try to make the critical point* (*which belongs to the same kind of obstacles which made my own efforts so futile*) *as clear as I can. I still hope that these cliffs will be navigated eventually, and this, before I die. For now, I am, however, extremely busy with other things…"*

Although Gauss remarked in 1846 that he knew about the existence of Non-Euclidean geometries for the last fifty years it is not before 1816 that we see written evidence. In that year Gauss reflected on different attempts to prove the fifth postulate in a book review. Although he was too careful to express his own opinion we can be sure that the reason why he reviewed these attempts can be seen in the fact that Gauss was already convinced in 1816 that Non-Euclidean geometries existed.

Perhaps the Non-Euclidean geometry which can be most easily understood is the spherical geometry. The navigators, map makers, and naval mathematicians of the 16th century were very well aware of this type of geometry in which every triangle (build from parts of three great circles on the sphere) shows a sum of inner angles of larger than 180° and is thus today seen as a simple model of elliptic geometry. The Non-Euclidean geometries by Gauss, Lobachevsky, and Bolyai are nowadays classified as being hyperbolic geometries, in which a triangle shows an angular sum of less than 180°.

Spherical geometry was Gauss's bread-and-butter occupation as early as 1803 when he started to survey the Duchy of Brunswieck by means of a triangulation and met his wife to be, Johanna Osthoff. After Heinrich Christian Schumacher (1780–1850), astronomer and geodesist, informed Gauss of the Danish arc measurement and stimulated a surveying of the Hanoverian lands to fit the Danish measurements in the north, Gauss became enthusiastic. Eventually, Schumacher succeeded in persuading the English king Georg IV, who was head of the house of Hanover, to authorize Gauss with the surveying work, and Gauss started field work in 1821 (see Figures 6.1 and 6.4) concerned with measurements from three mountains in Germany, Hohenhagen, near Göttingen, Brocken in the Harz Mountains and Inselberg in the Thüringer Wald to the south. The three lines joining these locations form a great triangle, the angle at Hohenhagen is close to a right angle, so the area of the triangle is close to half the product of the two short sides). Gauss made the important invention of the heliotrope (cf. Figure 6.5) to ensure measurements of hitherto unknown accuracy. In fact, heliotropes were used

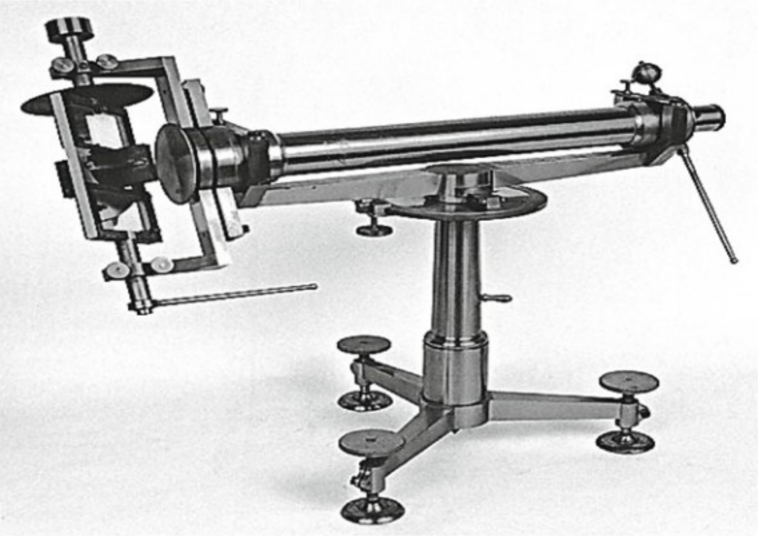

FIGURE 6.5. Heliotrope (Geophysical Institute of Göttingen University).

in surveys from Gauss's survey in Germany in 1821 through the late 1980s, when GPS measurements replaced the use of the heliotrope in long distance surveys. Surveying field work lasted until 1825 when Gauss withdraw from working in the countryside. However, he oversaw the further surveying work going on in 1828 and lasting until 1844 and did all the number crunching necessary. Friends, including Friedrich Wilhelm Bessel (1784–1846), criticized him for wasting his time in these computations instead of creating new theorems, but Gauss saw deeper. In a letter to Bessel dated March 14, 1824, he wrote (cf. [8]):

> *"... you accused me of loosing my time and wished me luck that the loss of time might be over soon. Great God, how wrong you judge me. ... Certainly, I also think like you in that matter. All measurements in the world do not outweigh a single theorem, with which the science of eternal truths will be truly advanced. But you should not judge over the absolute, but over the relative worth* [of measurements]. ... *And however small you estimate this worth, in my eyes it is higher than those concerns which are interrupted by them."*

Surveying problems also motivated Gauss to develop his thoughts on least squares and more general problems of what is now called mathematical statistics. The result was the definitive exposition of his mature concepts in the note "Theoria combinationis observationum erroribus minimis obnoxiae" (1823, with supplement in 1826). In "Bestimmung des Breitenunterschiedes zwischen den Sternwarten von Göttingen and Altona durch Beobachtungen am Ramsdenschen Zenithsector" of the year 1828 he summed up his ideas on the figure of the Earth, instrumental errors, and the calculus of observations. Furthermore, his publication "Disquisitiones generales circa superficies curvas" (1828), which grew out of his meditations in surveying and geodesy of three decades, represented the seed of more than a century of work on differential geometry.

Finally it should be mentioned that resulting research led to, among other things, Einstein's theory of general relativity, which describes the universe as non-Euclidean.

Poincaré who is certainly the major founder of the modern field of topology

First letter by Betti, dated October 6, 1863.

Betti then writes:

"What gave Riemann the idea of the cuts was that Gauss defined them to him, talking about other matters, in a private conversation.

In his writings one finds that analysis situs, that is, the consideration of quantities independently from their measure, is " wichtig"..."

of the mind." On Kant, Gauss had the advantage of being a mathematician. In a letter to his friend Bessel, dated April 9, 1830, Gauss writes (translation from [30] p. 13):

> We must confess in all humility that a number is *solely* a product of our mind. Space, on the other hand, possesses also a reality outside of our minds, the laws of which we cannot fully prescribe a priori.

In another letter, sent to Wolfgang Bolyai on March 6, 1832 and published in his *Collected Works*, Gauss writes, concerning the two hypotheses on the angle sum in a triangle, that it is precisely in the difficulty of this decision that "lies the clearest proof that Kant was wrong in asserting that space is just a form of our perception."

Gauss was also very critical of Kant's argument based on symmetries in the text we quoted above ("There being in perfectly similar and equal but incongruous solids, such as the right and the left hand, conceived of solely as to extent,…it is patent that only by pure intuition can the difference, namely, incongruity, be noticed"). We further discuss this in Chap. 6 of the present volume [190].

It is not surprising that Riemann declares, in his habilitation lecture, that, concerning his ideas on space, he is influenced by Gauss.

Riemann's ideas on space were discussed by Clifford, the first mathematician who translated into English Riemann's habilitation text, cf. [46].

8 Topology

Poincaré, who is certainly the major founder of the modern field of topology,[64] declares in his "Analysis of his own works" (*Analyse des travaux scientifiques de Henri Poincaré faite par lui-même*), [202] p. 100, that he has two predecessors in the field, namely, Riemann and Betti. The latter, in his correspondence with his friend and colleague Placido Tardy reports on several conversations he had with Riemann on topology. Two letters from Betti to Tardy on this subject are reproduced and translated in the book [206] by Pont, in the article [257] by Weil, and prior to them, by Loria in his obituary on Tardy [178].

The first of these two letters by Betti, dated October 6, 1863, starts with the following (Weil's translation): "I have newly talked with Riemann about the connectivity of spaces, and have formed an accurate idea of the matter," and he goes on explaining to his friend the notion of connectivity and that of the order of connectivity. Betti then writes:

> What gave Riemann the idea of the cuts was that Gauss defined them to him, talking about other matters, in a private conversation. In his writings one finds that analysis situs, that is, this consideration of quantities independently from their measure, is "wichtig"; in the last

---

[64] We may quote P. S. Alexandrov, who declared in a talk he gave at a celebration of the centenary of Poincaré's birth [9]: "To the question of what is Poincaré's relationship to topology, one can reply in a single sentence: he created it." On Poincaré and Riemann, Alexandrov, in the same talk, says the following: "The close connection of the theory of functions of a complex variable, which Riemann has observed in embryonic form, was first understood in all its depth by Poincaré."

> years of his life he has been much concerned with a problem in analysis situs, namely: given a winding thread and knowing, at every one of its self-intersections, which part is above and which below, to find whether it can be unwound without making knots; this problem he did not succeed in solving except in special cases ...

The second letter, dated October 16, 1863, starts with: "Riemann proves quite easily that every space can be reduced to an SC space by means of 1-cuts and SC 2-cuts." In the same letter, Betti elaborates on this subject, giving many examples in n dimensions. He concludes the letter by noting that the number of line sections is equal to the number of periodicity moduli of an $(n-1)$-integral, the number of simply connected surface sections to the number of periodicity moduli of an $(n-2)$-integral, and so on.

This should make clear the parentage, for what concerns topology, from Riemann to Poincaré, potentially including Betti. In this section, we go further back in the history of topological ideas, and we review some of the important works done before Riemann in this field.

René Thom considers that topology was born in ancient Greece. He expanded on this idea in several articles, cf. [246, 247]. This is a perfectly reasonable theory. In fact, the question depends on what sense we give to the word "topology." If the matter concerns the notions of limit and convergence, then the roots of this field are indeed in Greek antiquity, and more especially, in the writings of Zeno, which do not survive, but which were quoted by his critics and commentators, including Plato, Aristotle and Simplicius. Likewise, if the question concerns the notion of space, and the related notion of place, then the roots also are in Greek science. We already alluded to this fact in the previous section. The Greeks made a distinction between space and place and the notion of place (situs) is at the basis of topology. The three words place, situs and $\tau\acute{o}\pi o\varsigma$ are synonyms. To the best of our knowledge, a systematic investigation of the origin of topology in Greek antiquity has never been conducted. A whole book may be written on that subject. Failing to do this now, we shall start our exposition of the roots of topology with Leibniz, as it is usually done. Indeed, it is commonly accepted that the first explicit mention of topology as a mathematical field was made by him.

Even though no purely topological result can be attributed to Leibniz, he had the privilege to express for the first time, back in the seventeenth century, the need for a new branch of mathematics, which would be "a geometry that is more general than the rigid Euclidean geometry and the analytic geometry of Descartes." Leibniz describes his geometry as purely qualitative and concerned with the study of figures independently of their metrical properties. In a letter to Christiaan Huygens, sent on September 8, 1679 (cf. [176] pp. 578–569 and [144] vol. VIII n$^{\text{o}}$ 2192), he writes:

> After all the progress I have made in these matters, I am still not happy with Algebra, because it provides neither the shortest ways nor the most beautiful constructions of Geometry. This is why when it comes to that, I think that we need another analysis which is properly geometric or linear, which expresses to us directly *situm*, in the same way as algebra expresses *magnitudinem*. And I think that I have the tools for that, and that we might represent figures

> and even engines and motion in character, in the same way as algebra represents numbers in magnitude.[65]

In the same letter ([176] p. 570), Leibniz adds:

> I found the elements of a new characteristic, completely different from Algebra and which will have great advantages for the exact and natural mental representation, although without figures, of everything that depends on the imagination. Algebra is nothing but the characteristic of undetermined numbers or magnitudes. But it does not directly express the place, angles and motions, from which it follows that it is often difficult to reduce, in a computation, what is in a figure, and that it is even more difficult to find geometrical proofs and constructions which are enough practical even when the Algebraic calculus is all done.[66]

Together with his letter to Huygens, Leibniz included the manuscript of an essay he wrote on the new subject. He writes, in the same letter ([176] p. 571):

> But since I don't see that anybody else has ever had the same thought, which makes me fear that it might be lost if I do not get enough time to complete it, I will add here an essay which seems to me important, and which will suffice at least to rendre my aim more credible and easier to conceive, so that if something prevents its realization now, it will serve as a monument for posterity and give the possibility to somebody else to finish it.[67]

He then explains in more detail his vision of this new domain of mathematics, and where it stands with respect to algebra and geometry, giving several examples of a formalism to denote loci, showing how this formalism expresses statements such that the intersection of two spherical surfaces is a circle, and the intersection of two planes is a line.

Leibniz' letter ends with the words ([174] p. 25):

---

[65] Après tous les progrès que j'ai faits en ces matières, je ne suis pas encore content de l'Algèbre, en ce qu'elle ne donne ni les plus courtes voies, ni les plus belles constructions de Géométrie. C'est pourquoi lorsqu'il s'agit de cela, je crois qu'il nous faut encore une autre analyse proprement géométrique ou linéaire, qui nous exprime directement *situm*, comme l'algèbre exprime *magnitudinem*. Et je crois d'en avoir le moyen, et qu'on pourrait représenter des figures et même des machines et mouvements en caractères, comme l'algèbre représente les nombres en grandeurs. [We have modernized the French.].

[66] J'ai trouvé quelques éléments d'une nouvelle caractéristique, tout à fait différente de l'Algèbre, et qui aura de grands avantages pour représenter à l'esprit exactement et au naturel, quoique sans figures, tout ce qui dépend de l'imagination. L'Algèbre n'est autre chose que la caractéristique des nombres indéterminés ou des grandeurs. Mais elle n'exprime pas directement la situation, les angles et les mouvements, d'où vient qu'il est souvent difficile de réduire dans un calcul ce qui est dans la figure, et qu'il est encore plus difficile de trouver des démonstrations et des constructions géométriques assez commodes lors même que le calcul d'Algèbre est tout fait.

[67] Mais comme je ne remarque pas que quelqu'autre ait jamais eu la même pensée, ce qui me fait craindre qu'elle ne se perde, si je n'y ai pas le temps de l'achever, j'ajouterai ici un essai qui me paraît considérable, et qui suffira au moins à rendre mon dessein plus croyable et plus aisé à concevoir, afin que si quelque hasard en empêche la perfection à présent, ceci serve de monument à la postérité, et donne lieu à quelque autre d'en venir à bout.

> I have only one remark to add, namely, that I see that it is possible to extend the characteristic to things which are not subject to imagination. But this is too important and it would lead us too far for me to be able to explain myself on that in a few words.[68]

When Leibniz started his correspondence with Huygens, the latter was already a well established scientist whose achievements were behind him, and it was not easy to convince him of the usefulness of a new theory. Huygens thought that the theory was too abstract and he remained skeptical about it. He was above all a geometer working on concrete geometrical problems.

One may recall that when Leibniz sent him the above letter, Huygens was considered as a world authority in geometry and physics. He was settled in Paris since 15 years, and he was a leading member of the *Académie Royale des Sciences*. Leibniz had studied mathematics with Huygens, who was seventeen years older than him, and he considered him as his mentor. Huygens responded to Leibniz in a letter dated November 22, 1679 ([176] p. 577):

> I have examined carefully what you are asking me regarding your new characteristic, and to be frank with you, I cannot not conceive the fact that you have so much expectations from what you spread on me. Because your example of places concerns only realities which were already perfectly known, and the proposition saying that the intersection of a plane and a spherical surface makes the circumference of a circle does not follow clearly. Finally, I cannot see in what way you can apply your characteristic to which you seem you want to reduce all these different matters, like the quadratures, the invention of curves by the properties of tangents, the irrational roots of equations, Diophantus' problems, the shortest and the most beautiful constructions of the geometric problems. And what still appears to me stranger than anything else, the invention and the explanation of machines. I say it to you unsuspiciously, in my opinion this is only wishful thinking, and I need other proofs in order to believe that there could be some reality in what you present. I would nevertheless restrain myself from saying that you are mistaken, knowing the subtlety and the deepness of your mind. I only beg you that the magnificence of the things you are searching won't let you postpone from giving us those which you already found, like this Arithmetic Quadrature you discovered, concerning the roots of the equations beyond the cubical, if you are still satisfied with it.[69]

---

[68] Je n'ai qu'une remarque à ajouter, c'est que je vois qu'il est possible d'étendre la caractéristique jusqu'aux choses, qui ne sont pas sujettes à l'imagination ; mais cela est trop important et va trop loin pour que je me puisse expliquer là-dessus en peu de paroles.

[69] J'ai examiné attentivement ce que vous me demandez touchant votre nouvelle caractéristique, mais pour vous l'avouer franchement, je ne conçois pas parce que vous m'en étalez, que vous y puissiez fonder de si grandes espérances. Car votre exemple des Lieux ne regarde que des vérités qui nous étaient déjà fort connues, et la proposition de ce que l'intersection d'un plan et d'une surface sphérique fait la circonférence d'un cercle, s'y conclut assez obscurément. Enfin, je ne vois point de quel biais vous pourriez appliquer votre caractéristique à toutes ces choses différentes qu'il semble que vous y vouliez réduire, comme les quadratures, l'invention des courbes par la propriétés des tangentes, les racines irrationnelles des Équations, les problèmes de Diophante, les plus courtes et plus belles constructions des problèmes géométriques. Et ce qui me paraît encore le plus étrange, l'invention et l'explication des machines. Je vous le dis ingénument, ce ne sont là à mon avis que de beaux souhaits, et il me faudrait d'autres preuves pour croire qu'il y eût de la réalité dans ce que vous avancez. Je n'ai pourtant garde de dire que vous vous abusiez, connaissant d'ailleurs la subtilité et profondeur de votre esprit. Je vous prie seulement que la grandeur des choses que vous cherchez ne vous fasse point différer de nous donner celles que vous avez déjà trouvées, comme est

In another letter dated January 11, 1680 ([176] p. 584) Huygens writes:

> For what concerns the effects of your characteristic, I see that you insist on being persuaded of them, but as you say yourself, the examples will be more important than reasonings. This is why I am asking you much simpler examples, but capable of overcoming my incredulity, because that of the places, I confess, does not seem to me of that sort.[70]

The essay that Leibniz sent did not obtain Huygens' backing and it remained hidden among other manuscripts in Huygens' estate. It was published for the first time in 1833, and drew the attention of several nineteenth-century mathematicians, including Grassmann (1809–1877), the founder of the theory of vector spaces, who realized its importance for the new field of topology. There are two recent editions of this text, both included in doctoral dissertations, by J. Acheverría [175] (1995), in France, and by de Risi, [234] (2007), in Germany. The two dissertations contain other texts by Leibniz on the same subject.

Leibniz used several names for the new field, including *analysis situs, geometria situs, characteristica situs, characteristica geometrica, analysis geometrica, speciosa situs*, etc.

The first mathematician who worked consciously on topological questions is Euler. These questions include the definition and the invariance of the Euler characteristic of a convex polyheron, the problem known as that of the Königsberg seven bridges, another question related to the Knight's tour on the chessboard, and a musical question concerning a graph known as the *speculum musicum*. This graph was introduced in Euler's *Tentamen novae theoriae musicae ex certissimis harmoniae principiis dilucide expositae* (A attempt at a new theory of music, exposed in all clearness according to the most well-founded principles of harmony) [71]. Its vertices are the twelve notes of the chromatic scale, and the edges connect two elements which differ by a fifth or a major third with the property that one may traverse all the edges of the graph passing exactly once by each note. The article [189] is a detailed survey of the work of Euler on these questions. In the present section, we start by reviewing the work of Euler on the question of the seven bridges of Königsberg. This work shows that Euler considered himself as the direct heir of Leibniz for what concerns the field of topology. We shall then describe in detail the works of Euler and Descartes on the Euler characteristic, a question which is directly related to the topological classification of surfaces, which was one of Riemann's major achievements in topology. We recall that Euler formulated this result for a surface which is the boundary of a convex polyhedron having F faces, A edges and S vertices; the formula is then:

$$F - A + S = 2.$$

(Footnote 69 continued)
cette Quadrature Arithmétique et que vous avez découvert pour les racines des équations au-delà du cube, si vous en êtes content vous-même.

[70] Pour ce qui est des effets de votre caractéristique, je vois que vous persistez à en être persuadé, mais, comme vous dites vous-même, les exemples toucheront plus que les raisonnements. C'est pourquoi je vous en demande des plus simples, mais propres à convaincre mon incrédulité, car celui des lieux, je l'avoue, ne me paraît pas de cette sorte.

We start with the problem of the Königsberg bridges.

In the eighteenth century, the city of Königsberg[71] consisted of four quarters separated by branches of the river Pregel and related by seven bridges. The famous "problem of the seven bridges of Königsberg" asks for a path in that city that starts at a given point and returns to the same point after crossing once and only once each of the seven bridges. At the time of Euler, this was a popular question among the inhabitants of Königsberg.

Euler showed that such a path does not exist. He presented his solution to the Saint Petersburg Academy of Sciences on August 26, 1735, and in the same year he wrote a memoir on the solution of a more general problem entitled *Solutio problematis ad geometriam situs pertinentis* (Solution of a problem relative to the geometry of position) [74]. Euler learned about the problem from a letter, dated March 7, 1736, sent to him by Carl Leonhard Gottlieb Ehler, one of his friends who was the mayor of Danzig[72] and who had worked as an astronomer in Berlin. Euler solved the problem just after he received the letter. In a letter dated March 13, 1736, written to Giovanni Marioni, an Italian astronomer working at the court of Vienna, Euler declares that he became interested in this question because he realized that the problem could not be solved using geometry, algebra or combinatorics, and that therefore he wondered whether "it belonged to the 'geometry of position,' (*geometria situs*) which Leibniz has so much sought for." In the same letter, Euler announced to Marioni that after some thought, he found a proof which applies not only to that case, but to all similar problems.

In the introduction of his paper, Euler writes (translation from [29]):

> In addition to that branch of geometry which is concerned with magnitudes, and which has always received the greatest attention, there is another branch, previously almost unknown, which Leibniz first mentioned, calling it the geometry of position. This branch is concerned only with the determination of position and its properties; it does not involve measurements, nor calculations made with them. It has not yet been satisfactorily determined what kind of problems are relevant to this geometry of position, or what methods should be used in solving them. Hence, when a problem was recently mentioned, which seemed geometrical but was so constructed that it did not require the measurement of distances, nor did calculation help at all, I had no doubt that it was concerned with the geometry of position, especially as its solution involved only position, and no calculation was of any use. I have therefore decided to give here the method which I have found for solving this kind of problem, as an example of the geometry of position.

Euler's work on this problem is commented in several articles and books.

We now come to Euler's polyhedron formula, and we start with Descartes.

Long before Euler came out with his formula $F - A + S = 2$ relating the faces (F), edges (A) and vertices (S) of a convex polyhedron, Descartes obtained an equivalent result, with a geometric proof, involving the solid angles and the dihedral angles between the faces. Described in modern terms, Descartes' proof consists in computing in two different manners the total curvature of the boundary of the polyhedron.

---

[71] Today, the city of Königsberg, called Kaliningrad, is part of a Russian exclave between Poland and Lithuania on the Baltic Sea.

[72] Today, Danzig is the city of Gdansk, in Poland.

Descartes wrote that proof at the age of 25, but did not publish it. The story of Descartes' manuscript is interesting and we recall it now.

Descartes' manuscript was discovered in Hanover, among Leibniz's estate. The latter had copied Descartes' proof during a stay in Paris, in 1675 or 1676, presumably with the intention of publishing it. The original manuscript of Descartes, which carries the title *Progymnasmata de solidorum elementis* (Preparatory exercises to the elements of solids) [47] is mentioned in an inventory of papers which Descartes left in some chests in Stockholm, the city where he died. The copy, made by Leibniz, carries the same title, with the additional mention *excerpta ex manuscripto Cartesii* (Excerpt from a manuscript of Descartes). After the manuscript was discovered, a French translation was published by Foucher de Careil in 1859, in a volume of unpublished works of Descartes. This publication contained errors, because Foucher, who did it, was not a mathematician. The edition is nevertheless interesting, and in the introduction to the volume [114], Foucher recalls the story of the discovery. The story is also told by Adam in the commentaries of the volume of the Adam-Tannery edition of Descartes' works containing this theorem ([51] tome X, pp. 257–263).

In 1890, Jonquières presented to the Paris Académie des Sciences two Comptes Rendus notes entitled *Sur un point fondamental de la théorie des polyèdres* (On a fundamental property of the theory of polyhedra) [148] and *Note sur le théorème d'Euler dans la théorie des polyèdres* (Note on the theorem of Euler on the theory of polyhedra) [149], without being aware of the work of Descartes on this subject. After Jordan pointed out the existence of the work of Descartes in Foucher's edition, Jonquières published other Comptes Rendus notes on the work of Descartes, cf. [150–152]. Poincaré, in his celebrated first memoir on *Analysis situs* [200] attributes to Jonquières the generalization of Euler's theorem to non-necessarily convex polyhedral surfaces.

There is a relatively recent (1987) critical edition of Descartes' *Progymnasmata* with a French translation, with notes and commentaries, by P. Costabel [47].

Euler reported on his work on polyhedra in his correspondence with Goldbach. In a letter dated November 14, 1750, Euler informs his friend of the following two results which he refers to as Theorems 6 and 11 respectively:

> 6. In any solid enclosed by plane surfaces the sum of the number of faces and the number of solid angles is greater by 2 than the number of edges.
>
> 11. The sum if all planar angles equals four times as many right angles as the number of solid angles, decreased by 8.

The term "solid enclosed by plane surfaces" refers to a convex polyhedron. The first result is the Euler characteristic formula, and the second one is a form of the Gauss-Bonnet theorem for the sphere. Euler writes:

> I am surprised that these general properties in stereometry have not been noticed by anybody, as far as I know, but still more that the most important of them, viz., Th. 6 and Th. 11, are so hard to prove; indeed I still cannot prove them in a way that satisfies me.

In the same letter, Euler gives several examples where the two theorems are satisfied.

In his memoir [85], entitled *Demonstratio nonnullarum insignium proprietatum, quibus solida hedris planis inclusa sunt praedita* (Proof of some of the properties of solid bodies enclosed by planes) and written one year after [84], Euler gave proofs of the two results. In the introduction of [85], he declares that his polyhedron formula is part of a more general research he is conducting on polyhedra. In fact, in the letter to Goldbach we mentioned, Euler announces a result on volumes of simplices in terms of their side lengths (a three-dimensional analogue of Heron's formula for the area of triangles), which he proves later in his paper *Demonstratio nonnullarum insignium proprietatum, quibus solida hedris planis inclusa sunt praedita* [85]. Euler writes[73]:

> Although I had uncovered many properties which are common to all bodies enclosed by plane faces and which seemed to be completely analogous to those which are commonly included among the first principles of rectilinear plane figures, still, not without a great deal of surprise did I realize that the most important of those principles were so recondite that all the time and effort spent looking for a proof of them had been fruitless. Nor, when I consulted my friends, who are otherwise extremely versed in these matters and with whom I had shared those properties, were they able to shed any light from which I could derive these missing proofs. After the consideration of many types of solids I came to the point where I understood that the properties which I had perceived in them clearly extended to all solids, even if it was not possible for me to show this in a rigorous proof. Thus, I thought that those properties should be included in that class of truths which we can, at any rate, acknowledge, but which it is not possible to prove.

One advantage of Euler's proof, compared to the one of Descartes, is that it shows in a clear way the combinatorial aspect of the problem, highlighting the notion of edges and faces of the polyhedron.

The proof that Euler gives in [85] is based on an induction on the number of solid angles, reducing them by one at each step. He writes:

> These proofs are in no way inferior to those proofs used in Geometry except that here due to the nature of solids one must use more imagination, in as much as solids are being depicted on a flat surface.

At the same time, Euler was laying down the foundations of combinatorial topology. He writes (Scholion to Proposition 4):

> I admit that I have thus brought to light only the first principles of Solid Geometry, on which this science should be built as it develops further. No doubt it contains many outstanding qualities of solids of which we are so far completely ignorant. [...]

Legendre, in his *Éléments de géométrie* (Note XII) published in 1794 [173], gave a complete proof of Euler's theorem based on geometry. This proof is considered as one of the simplest, and it is repeated in more modern works, e.g. in Hopf [140].

A large number of mathematicians commented on Euler's polyhedron formula, expanding some arguments in Euler's proofs, giving new proofs, and sometimes comparing Euler's work with that of Descartes. To show the diversity of these works, we mention the papers by Andreiev [10], Bertrand [26], Bougaïev [22], Brianchon [27], Catalan [31], Cauchy [32, 33], Feil [113], Gergonne, [130], Grunert, [135], Jonquières [148–152, 154–156], Jordan [157, 158], Lebesgue [168], Lhuillier [177],

---

[73] Translation by C. Frances and D. Richeson.

Poincaré [199, 200], Poinsot [203, 204], Prouhet [208, 209], Steiner [239], Valat [249] and Thiel [244]. We shall quote some of these works below. We also mention that in 1858, the Paris *Académie des Sciences* proposed as a subject for the 1861 *Grand prix*: "To improve, in some important point, the geometric theory of polyherda." Möbius participated and presented a memoir (but did not get the prize).

In 1811, Cauchy brought out a purely combinatorial proof of that theorem. In this proof, one starts by deleting a face of the polyhedron and reduces the problem to another one concerning a planar polygon.[74] In his article *Recherches sur les polyèdres* (Researches on polyhedra) [32], published in 1813, Cauchy writes:

> Euler has determined, in the Petersburg *Mémoires*, year 1758, the relation that exists between the various elements that compose the surface of a polyhedron; and Mr. Legendre, in his *Éléments de Géométrie*, proved in a much simpler manner Euler's theorem, by considerations of spherical polygons. Having been led by some researches to a new proof of that theorem, I reached a theorem which is much more general than the one of Euler, whose statement is the following:
>
> Theorem. If we decompose[75] a polyhedron in as many others as we wish, by taking at will new vertices in the interior, and if we represent by P the number of new polyhedra thus formed, by S the total number of vertices, including those of the initial polyhedron, by F the total number of faces, and by A the total number of edges, then we will have
>
> $$S + F = A + P - 1,$$
>
> that is, the sum of the number of vertices and that of faces will overpass by one the sum of the number of edges that of polyhedra.[76]

Poinsot [203], in 1858, published a proof of Euler's formula using some of Cauchy's arguments. He writes: "This relation, which Euler was the first to prove, does not hold only for convex polyhedra, as one might think, but for polyhedra of any kind." In fact, this statement needs some explanation. We are used today to the fact that Euler's formula is valid for polyhedra which are homeomorphic to a sphere. This notion did not exist at that time, neither the word, nor the idea. One had to

---

[74] A similar proof is given by Hilbert and Cohn-Vossen [138] p. 290.

[75] Cauchy "decomposes" the polyhedron by taking new vertices in the interior of the three-dimensional polyhedron (and not on the boundary surface).

[76] Euler a déterminé, dans les *Mémoires* de Pétersbourg, année 1758, la relation qui existe entre les différents éléments qui composent la surface d'un polyèdre ; et M. Legendre, dans ses *Éléments de Géométrie*, a démontré d'une manière beaucoup plus simple le théorème d'Euler, par la considération des polygones sphériques. Ayant été conduit par quelques recherches à une nouvelle démonstration de ce théorème, je suis parvenu à un théorème plus général que celui d'Euler et dont voici l'énoncé :

Théorème. Si l'on décompose un polyèdre en tant d'autres que l'on voudra, en prenant à volonté dans l'intérieur de nouveaux sommets ; que l'on représente par P le nombre de nouveaux polyèdres ainsi formés, par S le nombre total de sommets, y compris ceux du premier polyèdre, par F le nombre total de faces, et par A le nombre total des arêtes, on aura

$$S + F = A + P - 1,$$

c'est-à-dire que la somme faite du nombre des sommets et de celui des faces surpassera d'une unité la somme faite du nombre des arêtes et de celui des polyèdres.

wait for that to the work of Jordan, who set up the precise hypotheses under which Euler's formula is valid. In his article [155], he writes that Euler's theorem is valid for polyhedra which he calls "simple," or "Eulerian," that is, polyhedra ([155] p. 35) "such that any contour drawn on the surface which does not traverse itself divides this surface into two separate regions; a category that contains as a particular case convex polyhedra."[77] A few pages later (p. 38), Jordan makes the following commentary: "It would have been easy to show that if we can draw on a polyhedron λ different contours which do not intersect each other and which do not divide the surface into separate parts, we would have $S + F = A + 2 - 2\lambda$."[78] In fact, Jordan had extracted the notion we call today "topological surface of finite type," to which the general theory applies, cf. [154] p. 86:

> A surface is said to be of type (m, n) if it is bounded by m closed contours and if furthermore we can draw on it n closed contours that do not intersect themselves nor mutually, without dividing it into two distinct regions.[79]

Then Jordan makes the relation with the polyhedra to which Euler's formula applies: "The polyherda of kind (0, 0) are nothing but those which I called *Eulerian*."[80]

It is interesting to read Lebesgues' comments on some proof of Euler's theorem, because it gives us some hints of how the subject of topology was viewed in those days. Lebesgues' comments are written in 1924 ([168] p. 319):

> I don't agree at all with those who pretend to attribute Euler's theorem to Descartes. Descartes did not state the theorem; he did not see it. Euler perceived it and he fully understood its character. For Euler, the description of the form of a polyhedron must precede the use of the measures of its elements, and this is why he set his theorem as a fundamental theorem. For him, like for us, this is a theorem of enumerative *Analysis situs*; therefore he tried to find it by considerations independent of any metrical theory, that in effect belong to what we call the field of *Analysis situs*. And this is why he left to Legendre the honor of finding a rigorous proof. None of us who had read a little bit of Euler and who were amazed by his prodigious technical masterliness will doubt, even for one second, that if Euler had thought of putting aside his theorem and deducing it from one of its metric corollaries, he would have easily succeeded. (It should be noted that Euler does not at all restrict his researches to convex polyhedra.) It seems to me, on the contrary, that the fact that Descartes passed so closely to the theorem without seeing it, emphasizes Euler's credit. (At least, this is what we believe, because Descartes employed in his notebook some algebraic characters which he used before knowing Viète's characters.) But Leibniz, who found Descartes' notebook enough interesting to copy it, who realized that Descartes' geometry does not apply to questions involving order and position relations, who dreamed of constructing the algebra of these relations and who in advance gave it the name *Analysis situs*, did not notice, in Descartes' notebook Euler's

---

[77] [...] tels que tout contour fermé tracé sur leur surface et ne se traversant pas lui-même divise cette surface en deux régions séparées ; catégorie qui renferme comme cas particulier les polyèdres convexes.

[78] Il serait aisé de démontrer que si l'on peut tracer sur un polyèdre λ contours différents, ne se coupant pas mutuellement et ne divisant pas la surface en parties séparées, on aura $S + F = A + 2 - 2\lambda$.

[79] Une surface sera dite d'espèce (m, n) si elle est limitée par m contours fermés et si l'on peut d'autre part y tracer n contours fermés ne se coupant pas eux-mêmes ni mutuellement, sans la partager en deux régions distinctes.

[80] Les polyèdres de l'espèce (0, 0) ne sont autres que ceux que j'ai appelés *eulériens*.

> theorem which is so fundamental in *Analysis situs*. This theorem really belongs to Euler. As for the proof, one could, may be with a little bit of unfairness, call it the proof of Legendre and Descartes. This proof is metrical, and it is fair to blame it for the fact that it uses notions that are foreign to *Analysis situs*. But one should not exaggerate the value of this grievance.[81]

We now give a quick review of some work of Gauss on topology, another field in which his impact on Riemann was huge.

Gauss was interested in applications of *Geometria situs* (a term he used in his writings), in particular in astronomy, geodesy and electromagnetism. In astronomy, he addressed the question of whether orbits of celestial bodies may be linked (cf. his short treatise entitled *Über die Grenzen der geocentrischen Orter der Planeten*). From his work on geodesy, we mention his letter to Schumacher, 21 Nov. 1825, (from Gauss's *Werke* vol. VIII, p. 400):

> Some time ago I started to take up again a part of my general investigations on curved surfaces, which shall become the foundation of my projected work on higher geodesy. [...] Unfortunately, I find that I will have to go very far afield [...]. One has to follow the tree down to all its root threads, and some of this costs me week-long intense thought. Much of it even belongs to geometria situs, an almost unexploited field.

From Gauss's *Nachlaß*, we know that he worked on a combinatorial theory of knot projections, during the year 1825, and again in 1844. (Gauss's *Werke*, Vol. VIII, pp. 271–286). We already mentioned at the beginning of this section, that we learn from a letter sent by Betti to Tardy that the idea of analyzing a surface by performing successive cuts was given to Riemann by Gauss, in a private conversation. Besides Riemann, Gauss had two students who worked on topology and who were certainly influenced by him: Listing and Möbius.

---

[81] Je ne suis pas du tout d'accord avec ceux qui prétendent attribuer à Descartes le théorème d'Euler. Descartes n'a pas énoncé le théorème ; il ne l'a pas vu. Euler l'a aperçu et en a bien compris le caractère. Pour Euler, la description de la forme d'un polyèdre doit précéder l'utilisation des mesures de ses éléments et c'est pourquoi il a posé son théorème comme théorème fondamental. C'est, pour lui comme pour nous, un théorème d'*Analysis situs* énumérative ; aussi a-t-il cherché à le démontrer par des considérations indépendantes de toute propriété métrique, appartenant bien à ce que nous appelons le domaine de l'*Analysis situs*. Et c'est pourquoi il a laissé à Legendre l'honneur d'en trouver la preuve rigoureuse ; aucun de ceux qui ont quelque peu lu Euler, et qui ont été stupéfaits de sa prodigieuse virtuosité technique, ne doutera un seul instant que si Euler avait pensé à faire passer son théorème au second plan et à le déduire d'un de ses corollaires métriques, il n'y eût facilement réussi. (Il convient d'ajouter qu'Euler ne restreint nullement ses recherches aux polyèdres convexes.) Que Descartes soit passé si près du théorème sans le voir me paraît au contraire souligner le mérite d'Euler. Encore peut-on dire que Descartes était jeune quand il s'occupait de ces questions. (C'est du moins ce que l'on croit, parce que Descartes a employé dans son cahier certains caractères cossiques qu'il utilisait avant de connaître les notations de Viète.) Mais Leibniz qui a trouvé le cahier de Descartes assez intéressant pour le copier, qui a reconnu que la géométrie de Descartes ne s'appliquait pas aux questions où interviennent des relations d'ordre et de position, qui a rêvé de construire l'algèbre de ces relations et l'a nommée à l'avance *Analysis situs*, n'a pas aperçu, dans le cahier de Descartes, le théorème d'Euler si fondamental en *Analysis situs*. Le théorème appartient bien à Euler ; quant à la démonstration, on pourrait, un peu injustement peut-être, la dénommer démonstration de Legendre et Descartes. Cette démonstration est métrique ; il est juste de lui reprocher de faire appel à des notions étrangères à l'*Analysis situs*. Mais il ne faudrait pas s'exagérer la valeur de ce grief.

Riemann introduced the fundamental topological notions for surfaces: connectedness, degree of connectivity, the classification of closed surfaces by their genus. He developed this theory for the purpose of using it in his work on the theory of functions of a complex variable. In his memoir on Abelian functions, he talks about *analysis situs*, referring to Leibniz:

> In the study of functions obtained by the integration of exact differentials, a few theorems of analysis situs are almost essential. Under that name, which was used by Leibniz, although may be in a slightly different sense, it is permitted to designate the theory of continuous magnitudes which studies these magnitudes, not as independent of their position and measurable with respect to each other, but by disregarding all idea of measure and studying them only for what regards their relation of position and inclusion. I intend to treat this subject later, in a way that is completely independent of any measure.

In his habilitation dissertation, Riemann mentions the possibility of working in the new field of topology, talking about the notion of "place." We quote this cryptic passage:

> Measure consists in the superposition of the magnitudes to be compared; it therefore requires a means of using one magnitude as the standard for another. In the absence of this, two magnitudes can only be compared when one is a part of the other; in which case we can only determine the more or less and not the how much. The researches which can in this case be instituted about them form a general division of the science of magnitude in which magnitudes are regarded not as existing independently of position and not as expressible in terms of a unit, but as regions in a manifoldness. Such researches have become a necessity for many parts of mathematics, e.g., for the treatment of many-valued analytical functions; and the want of them is no doubt a chief reason for which the celebrated theorem of Abel and the achievements of Lagrange, Pfaff, Jacobi for the general theory of differential equations, have so long remained unfruitful. Out of this general part of the science of extended magnitude in which nothing is assumed but what is contained in the notion of it, it will suffice for the present purpose to bring into prominence two points; the first of which relates to the construction of the notion of a multiply extended manifoldness, the second relates to the reduction of determinations of place in a given manifoldness to determinations of quantity, and will make clear the true character of an n-fold extent.

He also describes the passage from one dimension to another:

> If in the case of a notion whose specialisations form a continuous manifoldness, one passes from a certain specialisation in a definite way to another, the specialisations passed over form a simply extended manifoldness, whose true character is that in it a continuous progress from a point is possible only on two sides, forward or backwards. If one now supposes that this manifoldness in its turn passes over into another entirely different, and again in a definite way, namely so that each point passes over into a definite point of the other, then all the specialisations so obtained form a doubly extended manifoldness. In a similar manner one obtains a triply extended manifoldness, if one imagines a doubly extended one passing over in a definite way to another entirely different; and it is easy to see how this construction may be continued. If one regards the variable object instead of the determinable notion of it, this construction may be described as a composition of a variability of $n + 1$ dimensions out of a variability of n dimensions and a variability of one dimension.

Riemann's ideas on topology are explained in some sections of Klein's booklet [161]. For instance, Sect. 8 carries the title *Classification of closed surfaces according to the value of the integer p*. Let us comment on a passage from Klein's booklet concerning the classification of surfaces, as an example of his point of view on topology. We know that topology, which was an emerging subject, plays an important role in Riemann surface theory. We already mentioned that Riemann introduced several major notions on surface topology. Klein tried to make a more systematic exposition of these ideas. His book [161] contains a chapter in which the classification of closed surfaces according to genera is presented. On p. 32, he writes:

> That it is impossible to represent surfaces having different p's[82] upon one another, the correspondence being uniform, seems evident. It is not meant, however, that this kind of geometrical certainty needs no further investigation; cf. the explanations of G. Cantor (*Crelle*, t. LXXXIV. pp. 242 *et seq.*). But these investigations are meanwhile excluded from consideration in the text, since the principle there insisted upon is to base all reasonings ultimately on intuitive relations.

Klein then states the converse: between any two surfaces of the same genus it is possible to find a "uniform correspondence." He declares that this statement is more difficult to prove, and he refers to the 1866 article by Jordan [153].[83] This paper is an important milestone in the history of topology, because it contains the first attempt to classify surfaces up to homeomorphism, although there was no precise definition of homeomorphism yet.[84] Jordan's aim, in his paper, is to prove the following theorem, which he states in the introduction:

> In order for two surfaces or pieces of flexible and inextensible surfaces to be be applied onto each other without tear and duplication, the following is necessary and sufficient:
>
> (1) That the number of separated contours that respectively bound these portions of surfaces be the same. (If the surfaces considered are closed, this number is zero.)
> (2) That the maximal number of closed contours which do not self-intersect or intersect each other that we can draw on each of the two surfaces without cutting it into two separate regions be the same on both sides.

Jordan gives the following "definition" of two surfaces being "applicable onto each other." For a modern reader, this definition may seem fuzzy, but one has to remember that this paper was written in the heroic epoch of the foundations of modern topology, that the notion of homeomorphism seems extremely natural for us today, but that it was not so in those times. Jordan writes:

---

[82] We recall that p denotes the genus.

[83] Camille Jordan (1838–1922), who is mostly known for his results on the topology of surfaces and on group theory, also worked on function theory in the sense of Riemann. The title of the second part of his doctoral thesis is: "On periods of inverse functions of integrals of algebraic differentials." The subject was proposed to him by Puiseux, whom we mention in this paper concerning uniformization. Jordan is among the first who tried to study the ideas of Galois, and he is also among the first who introduced group theory in the study of differential equations.

[84] The word "homeomorphism" was introduced by Poincaré in his article [200] but with a meaning that is different from the one it has today. There is a definition of homeomorphism in the 1909 article by Hadamard [136], as being a one-to-one continuous map. This is not correct, unless Hadamard meant, by "one-to-one continuous", "one-to-one bi-continuous." We refer the reader to the paper [183] on the rise and the development of the notion of homeomorphism. This paper contains several quotes, some of which are very intriguing.

> We shall rely on the following principle, which we can consider as evident, and take it if necessary as a definition: *Two surfaces* S, S' *are applicable onto each other if we can decompose them into infinitely small elements such that to any contiguous elements of* S *correspond contiguous elements of* S'.

Besides Klein's booklet, several books and treatises explaining Riemann's ideas appeared in the decades that followed Riemann's work. We mention as examples Neumann's *Vorlesungen über Riemann's Theorie der Abel'schen Integrale* (Lectures on Riemann's theory of Abelian integrals) [186], Picard's *Traité d'Analyse* [197], Appell and Goursat's *Théorie des fonctions algébriques et de leurs intégrales* (Theory of Algebraic functions and their integrals) [16], and there are others. The last two treatises, together with several other French books on the theory of functions of a complex variable, are reviewed in Chap. 8 of the present volume [192].

Among the other important topological notions that were introduced before Riemann and that were used by him, we must mention the notion of *homotopy of paths* and its use in complex analysis (in particular, in the theory of line integrals), especially by Cauchy and Puiseux. This is discussed in detail in Chap. 7 of the present volume [191]. Cauchy published his first work on the subject in 1825 [36]. This is also a topic on which Gauss was a forerunner, but he did not publish anything about it. This is attested in his letter to Bessel, December 18, 1811, published in Volume VIII of his *Collected works* (pp. 90–92), a letter in which Gauss makes the important remark that if one defines integrals along paths in the complex plane, then the value obtained may depend on the path.

Regarding the history of Riemann's ideas on topology, we could have also commented on his predecessors regarding the notion of the discreteness and continuity of space, but this would have taken us too far. We make a few remarks on this matter in Chap. 6 of the present volume [190] .

We end this section by quoting Alexander Grothendieck, from his *Récoltes et semailles* (Harvesting and Sowing),[85] commenting on Riemann's reflections on this theme ([133] Chap. 2 Sect. 2.20):

> It must be already fifteen or twenty years ago since, skimming the modest volume that constitutes Riemann's complete works, I was struck by a remark which he made "incidentally." He observes there that it might be that the ultimate structure of space is "discrete," and that the "continuous" representations which we make of it may be an oversimplification (which may turn out to be excessive on the long run...) of a more complex reality; that for human thought, "the continuous" was easier to grasp than "the discontinuous," and that it serves us, subsequently, as an "approximation" for apprehending the discontinuous. This is an amazingly penetrating remark expressed by a mathematician, at a time where the Euclidean model of physical space was not questioned. In a strictly logical sense, it was rather the discontinuous which, traditionally, served as a technical mode of approaching the continuous.
>
> Moreover, the mathematical developments of the last decades showed an even more intimate symbiosis between continuous and discontinuous structures, which was not yet visualized

---

[85] The complete title is: *Récoltes et semailles : Réflexions et témoignage sur un passé de mathématicien* (Harvesting and Sowing: Reflections and testimony on the past of a mathematician). This is a long manuscript by Grothendieck in which he meditates on his past as a mathematician and where he presents without any compliance his vision of the mathematical milieu in which he evolved, especially the decline in morals, for what concerns intellectual honesty.

> in the first half of this century. The fact remains that finding a model which is "satisfactory" (or, if need be, a collection of such models, linked in the most possible satisfying way...), whether the latter is "continuous," "discrete," or of a "mixed" nature—such a task will surely involve a great conceptual imagination, and a consummate intuition, in order to apprehend and disclose mathematical structures of a new type. This kind of imagination and "intuition" seems to me a rare object, not only among physicists (where Einstein and Schrödinger seem to be among the rare exceptions), but even among mathematicians (and I am talking in full knowledge of the facts).
>
> To summarize, I foresee that the long-awaited renewal (if ever it comes...) will rather come from someone who has the soul of a mathematician, who is well informed about the great problems of physics, rather than from a physicist. But above all, we need a man having the "philosophical openness" required to grasp the crux of the problem. The latter is not at all of a technical nature, but it is a fundamental problem of "natural philosophy."[86]

9 Differential Geometry

In this section, we shall review some milestones in the history of differential geometry, concerning especially the study of geodesics and of curvature, from its beginning until the work of Riemann.

Differential geometry starts with the study of differentiable curves. The notion of curvature of planar curves already appears in works of Newton and of Johann I and

---

[86] Il doit y avoir déjà quinze ou vingt ans, en feuilletant le modeste volume constituant l'œuvre complète de Riemann, j'avais été frappé par une remarque de lui "en passant." Il y fait observer qu'il se pourrait bien que la structure ultime de l'espace soit "discrète", et que les représentations "continues" que nous en faisons constituent peut-être une simplification (excessive, peut-être, à la longue...) d'une réalité plus complexe; que pour l'esprit humain, "le continu" était plus aisé à saisir que "le discontinu", et qu'il nous sert, par suite, comme une "approximation" pour appréhender le discontinu. C'est là une remarque d'une pénétration surprenante dans la bouche d'un mathématicien, à un moment où le modèle euclidien de l'espace physique n'avait jamais été mis en cause; au sens strictement logique, c'est plutôt le discontinu qui, traditionnellement, a servi comme mode d'approche technique vers le continu.

Les développements en mathématique des dernières décennies ont d'ailleurs montré une symbiose bien plus intime entre structures continues et discontinues, qu'on ne l'imaginait encore dans la première moitié de ce siècle. Toujours est-il que de trouver un modèle "satisfaisant" (ou, au besoin, un ensemble de tels modèles, se "raccordant" de façon aussi satisfaisante que possible...), que celui-ci soit "continu," "discret" ou de nature "mixte"—un tel travail mettra en jeu sûrement une grande imagination conceptuelle, et un flair consommé pour appréhender et mettre à jour des structures mathématiques de type nouveau. Ce genre d'imagination ou de "flair" me semble chose rare, non seulement parmi les physiciens (où Einstein et Schrödinger semblent avoir été parmi les rares exceptions), mais même parmi les mathématiciens (et là je parle en pleine connaissance de cause).

Pour résumer, je prévois que le renouvellement attendu (s'il doit encore venir …) viendra plutôt d'un mathématicien dans l'âme, bien informé des grands problèmes de la physique, que d'un physicien. Mais surtout, il y faudra un homme ayant "l'ouverture philosophique" pour saisir le nœud du problème. Celui-ci n'est nullement de nature technique, mais bien un problème fondamental de "philosophie de la nature."

Poincaré who is certainly the major founder of the modern field of topology

First letter by Betti, dated October 6, 1863.

Betti then writes:

"What gave Riemann the idea of the cuts was that Gauss defined them to him, talking about other matters, in a private conversation.
In his writings one finds that analysis situs, that is, the consideration of quantities independently from their measure, is "wichtig"..."

Pág. 101 (134) - 3.1 Gauss

Pág. 100 (133) →

This led Riemann to explain the difference between intrinsic and extrinsic properties of a surface.

He explained that for a sphere, which has an intrinsic geometry different from a plane, the Gaussian curvature multiplied by the area of an infinitesimal geodesic triangle is half the excess of the sum of its angles over π.

This allowed him to express the belief that the geometry of an n-dimensional manifold could be understood by understanding its sectional curvatures.

Pág. 142 (174) Theorem 2.2

If restricted to surfaces of Gauss curvature $K \leq 0$, then the surface is minimal if and only if its Gauss map is conformal.

This paper will first look at the *Hypotheses* in detail, and then consider its relation to Gauss's ideas about differential geometry. Then it will turn to the connections to physics and philosophy, and conclude by looking at the other relevant paper Riemann wrote, the *Commentatio* [27] and the the discussions that it provoked.

2 The *Hypotheses*

Riemann's essay [24] was published posthumously in 1867, and is based on the lecture he gave in 1854 as part of the process of obtaining his Habilitation, the necessary and sufficient qualification for obtaining a teaching position at a German university. As such it was given to the Philosophy Faculty at Göttingen, of which Mathematics was a Department, with Gauss as one of the examiners. These circumstances explain the unfortunate absence of formulae that would otherwise have assisted subsequent readers.

Riemann began by remarking that geometry "takes for granted the notion of space" as well as the first principles of constructions in space. The basic concepts have only nominal definitions and the crucial properties are determined from axioms, but this leaves the relationships between the axioms obscure; in fact, said Riemann, it is not even clear a priori if the relationships are possible.

This opening paragraph makes two points. First, that it is not clear what the axioms or postulates of Euclidean geometry are about; second, that it is not even clear that they are consistent.

But Riemann did not take his analysis in the direction of a more refined study of the axioms. It is likely that he saw the work of Legendre, whose name he mentions, as indicative of the poverty of such work, not only because in all the editions of his *Géométrie* [16] Legendre had failed to prove the parallel postulate, but because Riemann thought that the whole axiomatic attempt to give a geometrical account of physical space was misguided. In unpublished notes from the early 1850 s he called such enquiries "extremely unfruitful" (see Scholz ([30] p. 218)), which, as Scholz points out, makes it very unlikely that Riemann had seen any of Lobachevskii's work.

Instead, Riemann began his paper [24] by remarking that the general notion of quantity was multi-dimensional, and "it emerges from this study that a multi-dimensional object is capable of being measured in different ways and that space is only a particular example of a three-dimensional quantity." Moreover, the properties that characterise space among all three-dimensional quantities can only be determined experimentally. From this perspective the axioms of Euclid are only hypotheses, although highly probable outside "the realms of both the immeasurably great and the immeasurably small."

This opening page is one of the first places where a characteristically modern mathematical approach is taken to what many had seen as a straight-forward question. Riemann did not say that Euclidean geometry needs fixing and offer a proposal. He stepped back and asked himself: what are we studying when we study geometry? His answer was quantity, and for him that was a multi-dimensional object—the sort of thing that is described, as we shall see, with coordinates. In Riemann's opinion a geometer, even a practical one, should not concentrate on the passage from space to a mathematical theory of space (still less take one for granted) but first build up a theory of multi-dimensional quantities, and this he turned to do.

He began Part I of the paper by regretting that apart from some ideas of Gauss [14] published in his second memoir on biquadratic residues and some philosophical remarks of Herbart [15] there was little to guide him. He indicated that there are continuous and discrete manifolds depending on how the elements are determined, and here a manifold is a vague term, little more than a collection of elements. Discrete manifolds in this sense are frequently encountered, said Riemann, but continuous ones less so, and he gave examples of the location of material objects and their colours. To make sense of continuous manifolds we rely on measurement, which presupposes a measuring unit that can be freely transported. When this is not available we have only the general concept of a manifold, and this difficulty may be why the work of Lagrange, Pfaff, and Jacobi on many-valued analytic functions has been so unfruitful so far.

Riemann had already rewritten the theory of functions of a complex variable in his doctoral theses [23], published in 1851. It is likely that his ideas about surfaces were what he was alluding to here, although the great work on Abelian functions would not be published until 1857.

How then to determine position in a manifold? Riemann explained that if the manifold has dimension one then position is determined by moving forwards and backwards using some unspecified concept of length. If this one-dimensional manifold is itself then moved forwards and backwards in a different dimension then a two-dimensional manifold is obtained, and so on. The converse also holds: one can break an n-dimensional manifold down into smaller ones along which some function has a constant value, and exceptional cases aside these sets where the function takes a fixed value are $n - 1$-dimensional submanifolds.

In Part II of his paper [24] Riemann explained how to introduce metrical relations in a manifold on the assumption that lines have a length independent of their position and every line can be measured by every other line. Here he was happy to acknowledge the work of Gauss [12] on curved surfaces (which we shall look at below).

Riemann now supposed that the position of a point in perhaps some region of an n-manifold is determined by its n coordinates $(x_1, x_2, \ldots, x_n)$. He restricted his attention to continuous systems in which the coordinates can vary by amounts dx and sought an expression for the line element ds in terms of the $dx_1, dx_2, \ldots, dx_n$. He further assumed that the length of a line element is unaltered if all its points undergo the same infinitesimal displacement. If moreover distance increases as points move away from the origin and the first and second derivatives are finite then the first derivative must vanish and the second cannot be negative, so Riemann took it to be positive. He deduced that the line element ds could be "the square root of an everywhere positive quadratic form in the variables dx", as for example we take to be the case for space when we write

$$ds = \sqrt{\sum (dx)^2}.$$

Riemann noted that there are other possibilities. For example, ds could be the fourth root of a fourth power expression, but he did not see many possibilities for geometry there and he set this aside.

The quadratic form, however, did interest him. It contains $n(n+1)/2$ coefficients, of which n can be altered by a change of variables, so it depends essentially on $n(n-1)/2$ coefficients that are determined by the manifold. The example of $\sqrt{\sum (dx)^2}$ is therefore special, and Riemann proposed to call such manifolds flat.

To proceed further, Riemann considered the infinitesimal triangle with one vertex at the origin, one on a geodesic out of the origin to the point $(x_1, x_2, \ldots, x_n)$, and one on a geodesic out of the origin to the point $(dx_1, dx_2, \ldots, dx_n)$. The quotient of $\sqrt{\sum (dx)^2}$ by the area of this triangle measures the departure of this infinitesimal region from flatness, and divided by $-3/4$ is in fact the Gaussian curvature of the surface. So the curvature of an n-manifold can be understood by knowing $n(n-1)/2$ surface curvatures (the sectional curvatures, as we would say).

This led Riemann to explain the difference between intrinsic and extrinsic properties of a surface. He explained that for a sphere, which has an intrinsic geometry different from a plane, the Gaussian curvature multiplied by the area of an infinitesimal geodesic triangle is half the excess of the sum of its angles over π. This allowed him to express the belief that the geometry of an n-dimensional manifold could be understood by understanding its sectional curvatures.

Flat manifolds, he observed, have every sectional curvature zero. They are therefore a special case of the manifolds of constant curvature (that is, having the same sectional curvatures everywhere) and in these manifolds geometric figures can be freely moved around without stretching. To give examples of such manifolds he wrote down the metric

$$ds = \frac{1}{1 + \frac{\alpha}{4} \sum x^2} \sqrt{\sum (dx)^2},$$

where α is the curvature.

It was evident that the surfaces of constant positive curvature are spheres; the sphere of radius r has curvature r^{-2}. Riemann gave a complicated description of how to fit all the surfaces of constant curvature into one family. On this description, the cylinder is the example of a surface of zero curvature, and surfaces of constant negative curvature are locally like the saddle-shaped part of a torus.

In the third and final part of his paper [24] Riemann discussed how his ideas might apply to space. If all the sectional curvatures are zero, the space is Euclidean. But if we assume only that there is free mobility of bodies then space is described as a three-dimensional manifold of constant curvature, which can be determined from the knowledge of the sum of the angles in any triangle. Or, one could assume that length is independent of position but not direction.

As for empirical confirmation, the topological structures available to describe three-dimensional manifolds form a discrete set, so exact statements can be made about them even if one can never be certain of their truth. As for the metrical relations, however, these are necessarily inexact because every measurement is imprecise. This has implications for the immeasurably large and the immeasurably small.

The immeasurably large divided into spaces that are infinite and spaces that are merely unbounded, as for example a sphere. That said, Riemann regarded questions about the immeasurably large as irrelevant to the elucidation of natural phenomena, if only because existing astronomical measurements show that any non-zero sectional curvature of space can only be detected in regions vastly greater than the range of our telescopes. This seems to belong to a Göttingen tradition going back to Gauss and extending at least as far as Schwarzschild, who reported on the implications of measurements of the parallel of stars for the curvature of space in 1899 (see (Epple [7])).

Not so questions about the immeasurably small. Here "the concept of a rigid body, and the concept of a light ray, cease to be meaningful". But, Riemann concluded his lecture, these questions take us into physics "which the nature of today's occasion does not allow us to explore".

3 Influences

3.1 Gauss

It is possible to read Riemann's paper [24] in various ways. A modern mathematician can supply the missing details, or, at the other extreme, regard it as almost incoherent. It is possible for a mathematician to offer a comparably deep vision of new mathematics today, but it would be couched in a language of possible definitions, possible methods, and likely theorems that, conjecturally, resolve outstanding problems. Riemann's paper is more philosophical–in the good sense of challenging one to be clear about what is involved in an enquiry–and more speculative.

As Riemann made clear, among the few antecedents he could acknowledge were two papers by Gauss [11, 12]. The one on differential geometry is easy to appreciate. In the 1810s and 1820s Gauss had re-defined the subject in two memoirs. In his *Disquisitiones generales circa superficies curvas* of 1828 he introduced the concept of the intrinsic curvature of a surface. Gauss began his exposition by taking his readers through three definitions of a surface: in the first a surface is given by an expression of the form $z = f(x, y)$; in the second by an expression of the form $f(x, y, z) = 0$; and in the third in the parameterised form $(x(u, v), y(u, v), z(u, v))$. For each of these approaches he showed what the implications were calculating the curvatures of the principal curves at each point, which Euler [8] had showed are a good way to understand how curved a surface is at each point.

Gauss then introduced the map later known as the ‘Gauss map’. At each point P of the surface he supposed there was a vector of unit length and normal to the surface, PP', and he considered the unit vector OQ parallel to PP' that has its base point at the centre of a fixed sphere of unit radius. The image of P' on the surface under the Gauss map is the point Q on the unit sphere.

Gauss then proved that the ‘Gauss map’ has a simple effect on areas: it multiplies the infinitesimal area around a point by an amount equal to the product of the principal curvatures. This product he proposed to call the curvature of the surface, and he showed that it depends only on E, F, and G and their derivatives with respect to u and v, but not on $x(u, v)$, $y(u, v)$, and $z(u, v)$. It is therefore intrinsic to the surface—a result that surprised him so much he called it the Theorema egregium or exceptional theorem.

One reason Gauss regarded the third form of presenting a surface as not only the most general but the most important, was because it allows u and v to be used as coordinates, and because it allows for a study of maps between one surface and another. In particular, given two surfaces defined by

$$\mathbf{r} = (x(u, v), y(u, v), z(u, v)) \text{ and } \mathbf{r}' = (x'(u', v'), y'(u', v'), z'(u', v'))$$

and a map between them, one can compare the line elements

$$ds^2 = E(u, v)du^2 + 2F(u, v)dudv + G(u, v)dv^2$$

and

$$ds'^2 = E'(u', v')du'^2 + 2F'(u', v')du'dv' + G'(u', v')dv'^2,$$

where $E(u, v) = \mathbf{r}_u.\mathbf{r}_u, \ldots, G'(u', v') = \mathbf{r}'_{v'}.\mathbf{r}'_{v'}$.

For example, the map is conformal or angle preserving if

$$ds^2 = \Phi(u', v')ds'^2,$$

for some function Φ, so in particular a map between a plane and a surface with $ds^2 = E(u, v)du^2 + 2F(u, v)dudv + G(u, v)dv^2$ is conformal if and only if $E = G$ and $F = 0$. Gauss [12] had made a detailed study of maps in connection with the survey of Hannover and South Denmark on which he worked in the 1820s, and had explicitly remarked that a map between planes is conformal if and only if it is given by a complex analytic function; this was only one of several occasions when he hinted at a theory of such functions that he was never to pull together and publish. It is very likely, however, that Riemann knew some of these ideas, but it is often impossible to say if he learned of them in discussions with Gauss or only by reading Gauss's papers [11, 12] after Gauss died. However, he wrote explicitly in his doctoral paper (1851) that the conformal nature of a complex analytic map was something that he learned from Gauss's paper [12] on conformal maps, and he stressed the importance of this geometrical aspect of the maps.

So Riemann took two ideas from Gauss's work on geometry. The conformal nature of a complex analytic map (away from any branch points) surely suggested to Riemann that there was significant geometrical features of a surface as early as 1851. But the idea of the intrinsic curvature of a surface was one Riemann took far beyond what Gauss had done with it.

Gauss [12] had identified the intrinsic feature of the geometry of a surface in $\mathbb{R}^3$, but he continued to think of surfaces as lying in $\mathbb{R}^3$. The idea that a region—a surface—with two coordinates u and v and a metric

$$ds^2 = E(u, v)du^2 + 2F(u, v)dudv + G(u, v)dv^2$$

is a fit subject for geometry already, whether or not there an embedding of it in space given by functions $x(u, v)$, $y(u, v)$, and $z(u, v)$ is due entirely to Riemann. It is almost certainly what Gauss had in mind when he said to his friend Wilhelm Weber after listening to Riemann's lecture that the profundity of the ideas that Riemann had put forward had greatly astonished him (see (Dedekind [6] 581)).

But, as Riemann's paltry citations indicate, there was very little done to extend Gauss's ideas of the intrinsic geometry of surfaces in the three decades that separate Gauss's memoir [12] from Riemann's lecture. One of the few papers written on the subject was by H.F. Minding [21], who investigated surfaces of constant negative curvature in his (1839). Bonnet, and Liouville in (Monge [22]), brought Gauss's theory to France, but Riemann went only once to Paris, in 1860, and it is not clear what he knew of French work before.

Riemann had also mentioned Gauss's second memoir on biquadratic residues (Gauss [14]). This is the work in which Gauss introduced what are today called the Gaussian integers, and explained at some length what he had been less overt in his *Disquisitiones Arithmeticae*, that the complex numbers can be thought of as points in a plane. Here (see §16) he stressed the highly intuitive character of this representation, and also–which is what Riemann surely picked up on–that this illuminated the true metaphysics of imaginary quantities.[1]

Gauss went on (§20) to stress that one goes beyond the positive numbers only when what is counted has an opposite (a negative) and what is then counted is not a substance (an object thinkable in itself) but a relation between two objects. More generally one creates new objects when one has a relation that admits a concept of opposite. Then (§22) "The mathematician abstracts totally from the nature of the objects and the content of their relations; he is concerned solely with the counting and the comparison of the relations among themselves." Nonetheless, intuitive representations are helpful and once an intuitive meaning for $\sqrt{-1}$ is completely established "one needs nothing further to admit this quantity into the domain of objects of arithmetic."

By 1850 Riemann did not need to be told that complex numbers were admitted into mathematics. Like Gauss, and Cauchy, he knew that the problem was not with complex numbers but with how to define complex functions. But he may well have appreciated the metaphysics, the abstract character of mathematical objects and their relations, and the connection to intuition that, as we shall now see, was also a theme of Herbart's philosophy [15] and Riemann's physics.[2]

---

[1] See also the English translation, Ewald ([9], I, 312–313).

3.2 Herbart

The emphasis Riemann placed on Herbart's ideas came from Riemann's interest in philosophy. Herbart had been a philosopher at Göttingen from 1805 until his death in 1841, and his main book, the *Psychology as science newly founded on experience, metaphysics and mathematics* [15], appealed strongly to Riemann. But Riemann was also critical: he wrote in the philosophical passages in his collected works (1990, 539) that he could agree with almost all of Herbart's earliest research, but could not agree with his later speculations at certain essential points to do with his Naturphilosophie and psychology. He also identified himself as a Herbartian in psychology and epistemology, but not in ontology and synechology (a discipline concerned with space, time, and motion, and in particular with intelligible space, regarded as a mental construct that makes the explanation of matter possible).

In Riemann's view, natural science is the attempt to comprehend nature by precise concepts, and if concepts yield inaccurate predictions then the concepts must be modified. As a result, the more of nature we understand the more it sinks below the surface of phenomena. Riemann approved of Herbart's anti-Kantian epistemology, because Herbart [15] had argued that all our concepts arise by modifying earlier ones, and the most primitive concepts originate from attempts to understand what our senses tell us, which is why we have the possibility of forming concepts adequate for natural science. In particular they need not be a priori, as the Kantian ones are.

Herbart was a powerful source for the idea of varying quantities–ultimately, manifolds–although Herbart remained fixed on the idea that geometry was necessarily three-dimensional. But Riemann aimed at constructing coherent systems of concepts that could then be matched against the coherence of the natural world. He did not agree with Herbart's account of how our ideas of space are generated from experience, and went directly to systems of mathematical concepts. The elucidation of fundamental concepts was characteristic of Riemann's work, and it was an approach he shared with Herbart even when he did not use the same concepts himself.

3.3 Physics: Newton and Euler [8]

In a note Riemann [28] made on his work (*Werke*, 539) he wrote

> My main work consists in a new formulation of the known natural laws – expressing them in terms of other fundamental ideas – so as to make possible the use of experimental data

---

Pag. 101 (134) - 3.1 Gauss

Pag. 100 (133) →

This led Riemann to explain the difference between intrinsic and extrinsic properties of a surface.

He explained that for a sphere which has an intrinsic geometry different from a plane the Gaussian curvature multiplied by the area of an infinitesimal geodesic triangle is half the excess of the sum of its angles over π.

This allowed him to express the belief that the geometry of an n-dimensional manifold could be understood by understanding its sectional curvatures.

Pag. 142 (174) Theorem 2.2

If restricted to surfaces of Gauss curvature $K \leq 0$ then the surface is minimal if and only if its Gauss map is conformal.

Theorem 2.2 *The Gauss map is conformal at* $P \in \Omega$ *either if the surface is umbilical at* P *or if the mean curvature vanishes. If restricted to surfaces of Gauss curvature* $K \leq 0$ *then the surface is minimal if and only if its Gauss map is conformal.*

We recall here that the stereographic projection is conformal.

Furthermore, when X, Y and Z are considered as holomorphic functions in η, Riemann writes down the pull-back metrics of the Euclidean metric on the respective complex plane as

$$dX \otimes dX' = \frac{\partial x}{\partial \eta}\frac{\partial x}{\partial \eta'} d\eta \otimes d\eta',$$

$$dY \otimes dY' = \frac{\partial y}{\partial \eta}\frac{\partial y}{\partial \eta'} d\eta \otimes d\eta',$$

and

$$dZ \otimes dZ' = \frac{\partial z}{\partial \eta}\frac{\partial z}{\partial \eta'} d\eta \otimes d\eta',$$

all of which, induce isothermal coordinates.

In §8 and §9, Riemann-Hattendorff is concerned with explicit parametrizations of the minimal surface, not in terms of η which was the Gauss map post-composed with the stereographic projection, but a new variable u which takes away the gauge freedom SO(3) arising from the position of the pole of the stereographic projection, which corresponds to the choices of oriented hyperplanes in $\mathbb{R}^3$.

Let α be a point in the yz-plane (or equivalently the η-plane) which is the image by the stereographic projection $P_S : S^2 \setminus \{S\} \to yz$-plane of a point $P_S^{-1}(\alpha) \in S^2 \setminus \{S\}$. (Recall $S = (-1, 0, 0)$.) We introduce a change of variables $\eta_\alpha := e^{i\theta}\frac{\eta-\alpha}{1+\alpha'\eta}$ which represents the transformation law which relates the image η of the stereographic projection of $S^2 \setminus \{S\}$ onto the yz-plane to the image η_α of the stereographic projection of $S^2 \setminus P_S^{-1}\{-\alpha\}$ onto the hyperplane Π_α whose unit normal vector is α. Note that the map $\eta \mapsto \eta_\alpha$ is conformal. For $P \in \Omega$, we then define $x_\alpha(P)$ to be the height of a point P over the hyperplane Π_α.

It is shown then that for $\eta_\alpha := e^{i\theta}\frac{\eta-\alpha}{1+\alpha'\eta}$,

$$(d\log\eta_\alpha)^2 \frac{\partial x_\alpha}{\partial \log\eta_\alpha} = (d\log\eta)^2 \frac{\partial x}{\partial \log\eta},$$

resulting in defining a new variable u

$$u = \int \sqrt{i\frac{\partial x}{\partial \log\eta}} d\log\eta, \tag{2.14}$$

which is independent of the gauge α.

This new variable u, a function in η, effectively contains all the information about the minimal surface Ω. It can be used to recover the three coordinate functions x, y and z as follows. By rewriting x as a function of u in Eq. (2.14) we obtain

$$x = -i \int \left(\frac{du}{d\log\eta}\right)^2 d\log\eta + i \int \left(\frac{du'}{d\log\eta'}\right)^2 d\log\eta'.$$

Recall that $\eta = \eta_0$ is the stereographic projection of $S^2 \setminus \{S\}$ from the south pole $S = (-1, 0, 0)$ so that the north pole $(1, 0, 0)$ is sent to $\alpha = (0, 0)$ in the yz-plane, or the η-plane. And x_0 is the height of the point P in Ω measured from the yz-plane. Analogously, by choosing $\alpha = (1, 0) = 1 + 0i$ in yz-plane, x_α represents the height of P measured from the xz-plane. Namely by substituting

$$\eta_\alpha = \frac{\eta - 1}{1 + \eta}$$

we obtain the representation

$$y = -\frac{i}{2} \int \left(\frac{du}{d\log\eta}\right)^2 \left(\eta - \frac{1}{\eta}\right) d\log\eta + \frac{i}{2} \int \left(\frac{du'}{d\log\eta'}\right)^2 \left(\eta' - \frac{1}{\eta'}\right) d\log\eta'.$$

Similarly, for $\alpha = (0, 1) = 0 + 1i$,

$$\eta_\alpha = \frac{\eta - i}{1 - i\eta}$$

we have

$$z = -\frac{1}{2} \int \left(\frac{du}{d\log\eta}\right)^2 \left(\eta + \frac{1}{\eta}\right) d\log\eta - \frac{1}{2} \int \left(\frac{du'}{d\log\eta'}\right)^2 \left(\eta' + \frac{1}{\eta'}\right) d\log\eta'$$

the height of (x, y, z) over the η_α-plane, which is the xy-plane.

In §10, §11 and §12, the three complex-valued functions X, Y and Z are regarded as holomorphic functions of η, and also of u, and they are locally analytically extended near a point, either in the interior, or on the boundary set of the minimal surface. As for the boundary set, it is bounded by Euclidean lines, line segments, or line segments intersecting at a rational angle $q\pi$ with $q \in \mathbb{Q}$.

In particular, Riemann makes an important geometric observation in §10, where a point P in Ω is regarded as the origin of $\mathbb{R}^3$, and the tangent plane $T_P\Omega$ is identified with the yz-plane. Then Ω is locally the graph of a function $x = x(y, z)$ with

$$x(P) = 0, \qquad \frac{\partial x}{\partial y}(P) = \frac{\partial x}{\partial z}(P) = 0$$

and the scalar function x is locally approximated by a harmonic function over the yz-plane,

$$\frac{\partial^2 x}{\partial y^2} + \frac{\partial^2 x}{\partial z^2} = 0.$$

When the second order Taylor expansion terms are nontrivial, the graph at P has nontrivial curvature, and the eigenvalues of the Hessian of $x(y, z)$ are the principal curvatures of the surface at P, of opposite signs and of the same magnitude, namely the mean curvature vanishes. When all the second order Taylor expansion terms vanish, the complex-valued function X has zeros of higher order.

Namely by supplying the harmonic conjugates $\mathfrak{x}, \mathfrak{y}, \mathfrak{z}$ to the real coordinates x, y and z, one can consider the relation among the complex valued functions X, Y and Z in η. As η can be seen as a holomorphic function in the previously introduced complex variable u, X, Y and Z are in turn holomorphic functions in u. In the consecutive sections §10, §11 and §12, functional equations of these variables are written down, at interior points, interior branch points, unramified as well as ramified boundary points, and at a boundary points where two line segments meet at a rational angle.

In §12, also considered is the situation where the minimal surface is simply connected, unbounded in $\mathbb{R}^3$ and bounded by two non-intersecting infinite lines. In commenting the setting, another geometric observation is made. When the minimal surface is bounded by a line ℓ, choose the coordinates in $\mathbb{R}^3$ so that the x-axis coincides with the line ℓ. Then the unit normal $\nu(P)$ to Ω, written as a vector in $\mathbb{R}^3$, has no x component. When the unit sphere is centered at the origin, and the north pole is on the positive x-axis, the image of the Gauss map $\nu : \ell \to S^2$ lies on the equator $\{(0, y, z) \mid y^2 + z^2 = 1\} \subset \mathbb{R}^3$, and consequently the image η of the stereographic projection $P_S : S^2 \setminus \{S\} \to yz$-plane is the equator $\{|\eta| = 1\}$ itself. Hence $\log \eta = \log |\eta| + i \arg \eta$ is purely imaginary along the boundary line of the x-axis. Then we conclude when x is seen as a function in η instead,

$$i \frac{\partial x}{\partial \log \eta}$$

is real along the boundary line. Similarly if we designate another boundary line as the $\hat{x}$-axis of another coordinate system $(\hat{x}, \hat{y}, \hat{z})$, then

$$i \frac{\partial \hat{x}}{\partial \log \eta}$$

is real along that boundary line. Now recall that the quantity

$$u = \int \sqrt{i \frac{\partial x}{\partial \log \eta}} d \log \eta$$

is independent of the coordinate system on $\mathbb{R}^3$, and hence is independent of the procedure of identifying the x-axis with the boundary line. Namely

$$du = \sqrt{i \frac{\partial x}{\partial \log \eta} d \log \eta}$$

is either real or purely imaginary, depending on the sign of the real number $i \frac{\partial x}{\partial \log \eta}$.

We recollect the construction here: when the minimal surface is bounded by a line segment, either bounded or unbounded, the neighborhood of a boundary point is realized by a conformal map from a region in the unit sphere bounded by a great circle. This fact is reflected in the observation that the function $du/d \log \eta$ is either real or purely imaginary.

Up to this point, several choices of complex parameters are presented; η, u, X, Y, Z, each of which can be used to parameterize the minimal surface Ω locally. In §13, the issue of transcribing one by another among those numbers is treated. The method is effectively what is known as the Schwarz-Christoffel mapping, where in Eq. (2.11) an explicit map $u(t)$ from the upper half t-plane $\mathbb{H}$ to the region in the u-plane, or to be exact, the region that is a ramified cover over the u-plane bounded by totally real or totally imaginary lines, is constructed. The coordinate t of the upper half plane corresponds to u by

$$t = \frac{\text{const.}}{u - b} + \text{terms holomophic in } u$$

where b is a value of u corresponding to a boundary point, and where the constant coefficient of the simple pole $u = b$ is determined by the conditions the imaginary part of t is (1) zero along the boundary, and (2) positive in the interior of the surface. By this local information, u is globally defined by the expression of Eq. (2.11) of the original paper:

$$u = \text{ const.} + \text{const.} \int \sqrt{\frac{\Pi(t-a)\Pi(t-a')\Pi(t-b)}{\Pi(t-c)}} \frac{dt}{\Pi(t-e)}$$

is obtained, where $a = \cup a_i$ denotes the set of branch points in the t-plane, $\Pi(t-a)$ denotes the product of $(t - a_i)$ over i, a' the complex conjugates of a, b the branch points on the real axis, c the pre-images of the vertices of the boundary where two line segments meet, and e stands for vertices in the unbounded sectors spanned by a pair of line segments, where each pair is designated with an angle $\alpha\pi$ between the projections of the two lines to the plane perpendicular to both lines, as well as the length of the shortest connecting line segment between the two lines. In the expression in Eq. (2.11), there appear only square roots due to the fact that Riemann considers only simple branch points, unlike the general formula of Schwarz-Christoffel's (cf [1]) where the power of $(t - c)$ could be any number in $[0, 1]$ representing the exterior angle at a vertex of the polygon.

Note that the function u above is defined over the entire t-plane. This is explained in the original article as

> In order to form the expression for $\frac{du}{dt}$ we must observe that dt is always real along the boundary, and du is either real or pure imaginary. Hence $(du/dt)^2$ is real when t is real. This function can be continuously extended over the line of real values of t by the condition that, for conjugate values t and t' of the variable, the function will also have conjugate values. Then $(du/dt)^2$ is determined for the whole t-plane and turns out to be single-valued.

Thus it is justified that du/dt is identified with the integrand of the complex line integral of Eq. (2.11). In this manner, the function u is represented by the complex variable t on the upper half-space, which then is used to reproduce the minimal surface $\Omega = \{(x(t), y(t), z(t))\}$. The by-product of the construction is the extension of the domain of u over the entire complex plane. In modern textbooks, this fact is expressed in the following important statement, often attributed to Schwarz.

Theorem 2.3 (Reflection Principle) *Let* $U(t)$ *be a minimal surface in isothermal parameters defined in a semi-disk* $D_+ = \{|t| < \varepsilon \mid \mathrm{Im}(t) > 0\}$. *Suppose there exists a line* L *in* $\mathbb{R}^3$ *such that* $U(t) \to L$ *when* $\mathrm{Im}(t) \to 0$. *Then* $U(t)$ *can be extended to a generalized minimal surface defined in the full disk* $D = \{|t| < \varepsilon\}$. *Furthermore this extended surface is symmetric in* L.

By utilizing this *universal* variable t, Riemann-Hattendorff (see also the paper [10], in addition to [9]) sets up an ansatz in the following geometric settings for the boundary of the minimal surface Ω:

- two non-intersecting non-parallel infinite lines, which would produce a part of the helicoid bounded by a pair of ruling lines;
- two lines which intersect at a point and a line on the plane whose normal vector is perpendicular to the first two lines;
- four intersecting line segments obtained by removing two edges that do not touch each other from the one skeleton of an arbitrary tetrahedron. This includes the so-called Schwarz surface under the additional symmetry;
- three infinite lines mutually skewed and nonintersecting, closely investigated in the recent work of B. Daniel [3];
- two circles on a pair of parallel planes, which would produce the celebrated "Riemann example" which is a minimal surface bounded by two parallel infinite lines, and foliated by circles. The example is explained in detail by Meeks-Pérez [6];
- two convex polygons on a pair of parallel planes, with and without symmetries, which include the so-called Schwarz P-surface and Schwarz H-surface.

A copy of the surface bounded by two circles on a pair of parallel planes can be extended across the boundary lines via the reflection, which would result in a complete periodic surface of genus zero. This example has recently received renewed attention in minimal surface theory ([6]), as the following classification [7] was demonstrated:

Theorem 2.4 *The plane, the helicoid, the catenoid and the Riemann minimal examples are the only properly embedded minimal surfaces in* $\mathbb{R}^3$ *with the topology of a planar domain.*

The Schwarz-Christoffel mapping is closely related to the theory of elliptic functions and hypergeometric functions, and those examples Riemann calculated fully make use of these theories. In this article, we will not go into the discussion of the papers [9, 10]. Interested readers are directed to Nitsche's book [11] on the subject, which records all the post-Riemannian development of the subject.

3 Representation Formulas by Riemann and Weierstrass-Enneper

In Osserman's book [12], a *generalized* minimal surface is defined as follows

Definition 3.1 A generalized minimal surface Ω in $\mathbb{R}^n$ is a non-constant map $x(p) : M \to \mathbb{R}^n$, where M is a 2-manifold with a conformal structure defined by an atlas, such that each coordinate function $x_k(p)$ is harmonic on M and furthermore

$$\sum_{k=1}^{n} \phi_k^2(\zeta) = 0 \tag{3.1}$$

where $\zeta = \xi_1 + i\xi_2$ is a complex-valued local coordinae of M, and the embedding $x(p)$ is given by

$$\phi_k(\zeta) = \frac{\partial x_k(\zeta)}{\partial \xi_1} - i\frac{\partial x_k}{\partial \xi_2}.$$

In this article, we are only interested in the case $n = 3$.

As the map $x(p)$ is non-constant, at least one of the functions x_k $(k = 1, 2, 3)$ is non-constant, which then implies that the corresponding holomorphic function $\phi_k(\zeta)$ can have at most isolated zeros. Thus the singular points of the map x satisfying

$$\sum_{k=1}^{n} |\phi_k(\zeta)|^2 = 0 \tag{3.2}$$

can exists at most at isolated points on M.

Now the following procedure to specify generalized minimal surfaces is called the Weierstrass-Enneper representation, first devised by A. Enneper (1864) and Weierstrass (1866). First we specify the triplets of holomorphic data:

Lemma 3.2 (cf. [12]) *Let D be a domain in the complex ζ plane, $\eta(\zeta)$ an arbitrary meromorphic function in D and $f(\zeta)$ an analytic function in D having the property that at each point where $\eta(\zeta)$ has a pole of order m, $f(\zeta)$ has a zero of order at least $2m$. Then the functions*

$$\phi_1 = f\eta, \quad \phi_2 = \frac{1}{2}f(1-\eta^2), \quad \phi_3 = \frac{i}{2}f(1+\eta^2) \tag{3.3}$$

Pag. 344 (371) — In his famous extraordinary theorem (theorema egregium as he called it), Gauss proved that the curvature of a surface which he defined as well, was intrinsic to the surface (surface).

Pag. 543 (563) →

The sectional curvature $K(P)$ agrees with the Gauss curvature at p of the surface ruled by geodesic starting at p with tangent vector $X \in P$.

— Eighteen Essays in Non-Euclidean

* &

Planes of reference give rise to these formations, which define the disciplinary nature of mathematics and science, and essentially shape mathematical and scientific thinking and practice—essentially, but, I would argue, not completely or even most centrally, at least in creative mathematics and science. One might say that creative or, to adopt Thomas Kuhn's language, revolutionary, thought in philosophy and mathematics or science alike is defined by planes of immanence and creation of concepts in Deleuze and Guattari's sense, which always carry individual signatures underneath them [8, p. 50]. Just as there are Plato's ideas, Descartes's cogito, and Leibniz's monads, there are Gauss's curvature, Riemann's manifolds, Dedekind's ideals, and Grothendieck's topoi in mathematics, or Einstein's spaces curved by gravity in general relativity and Heisenberg's matrix variables or Dirac's spinors in quantum physics. This is true even though the functioning of mathematical and scientific concepts does require planes of reference, functions (or other formal mathematical entities), propositions, and so forth.

The difference between philosophy and mathematics or science may instead be, to stay with Kuhn's idiom, in the nature of *normal*, rather than *revolutionary*, practice in each domain. In philosophy, the normal practice consists primarily in understanding, interpreting, and commenting on concepts, while in mathematics and science, the normal practice consists primarily in creating, by means of planes of references, frames of reference, functions and other mathematical or scientific formations, propositions, and so forth. It is true that for Deleuze and Guattari creative, revolutionary philosophical practice is the only true philosophy. However, leaving aside an arguably too restrictive character of this view of philosophy, this is not in conflict with the view of creative mathematics or science advocated here.

Deleuze and Guattari do allow that creative mathematical and scientific thought, such as that of Riemann (one of their primary examples), could have philosophical or artistic, compositional, aspects. But they appear to associate these aspects with *philosophical* or, in Deleuze's language, *inexact* (but philosophically rigorous) thought within mathematical or scientific thought. This philosophical thought is either operative alongside mathematical and scientific thought or enters by way of interference (in the positive sense of interfering wave fronts rather than in the more negative sense of inhibition) between mathematics and philosophy [8, pp. 217–218]. Both types of association are pertinent and important, certainly in Riemann's case. My argument is different, however. I argue that creative *technical*, *exact* mathematical and scientific thought is defined by planes of immanence and multi-component mathematical or scientific concepts, the architecture of which is analogous to that of philosophical concepts in Deleuze and Guattari's sense. That is, even apart from their philosophical strata, *mathematical* and *scientific* planes of immanence and the nature of mathematical or scientific concepts are *analogous* to philosophical thought. It is not only a matter of mathematical and scientific thought becoming philosophical at certain junctures, but a matter of the mathematical and philosophical thought creating parallel homomorphic (partially corresponding to each other), although not isomorphic (fully corresponding to each other), architectures of mathematical and philosophical concepts. They are not isomorphic because of technical, exact, aspects of mathematical and scientific concepts, demanded by the disciplinary nature of mathematics and science, aspects, generally, not found in philosophical concepts.

To bring this point home, I need to say more about Deleuze and Guattari's conceptions of planes of immanence and reference. The plane of immanence, as the plane of the movement of thought, is not "a concept that is or can be thought," but is "the image of thought, the image that thought gives itself of what it means to think" [8, p. 37]. As they say: "Concepts are like multiple waves, rising and falling, but the plane of immanence is the single wave that roles them up and unrolls them" [8, p. 36]. The present argument aims to extend, rather than to juxtapose, the plane of immanence (and the relationship between it and concepts) to mathematical and scientific thought, and to join this plane with the plane of reference. For Deleuze and Guattari, mathematics or science "relinquishes the infinite, infinite speed [of thought], in order to a gain *a reference able to actualize the virtual* [of chaos]. [It] gives reference to the virtual, a reference that actualizes the virtual through functions [or other mathematical objects]" [8, p. 118; translation modified]. Thought's enactment of this process constitutes a plane of reference. Planes of reference do play a major, indeed irreducible, role in mathematical and scientific thinking, especially in the disciplinary functioning of mathematics and science. This, however, is not inconsistent with the view that planes of immanence and the creation of concepts are found in mathematics and science. Mathematical and scientific thought combines both planes (sometimes, as does philosophy, also adding planes of composition) and creates its concepts from this fusion. The processes of thought defined the plane of immanence and specifically the creation of concepts (in Deleuze and Guattari's sense) are equally found in mathematics and science, and, again, define creative thinking there most essentially, analogously to the way it happens in philosophy. Such mathematical planes of immanence and the concepts they give rise to may coexist and interact with philosophical planes of immanence and concepts, but they are not reducible to philosophical planes and concepts. This is because of the equally irreducible interaction between these mathematical planes and concepts with technical, exact aspects of mathematical and scientific thinking.

Thus, in his rethinking of spatiality and geometry, Riemann, not only laid out a philosophical plane of immanence that gives rise to philosophical concepts and architectures, as Deleuze and Guattari rightly argue [7, pp. 483–486] but also introduced *a new mathematical plane of immanence*, which gives rise to multicomponent mathematical concepts, alongside *a mathematical plane of reference*. Riemann's thought shaped the plane of immanence of modern mathematical thought arguably more than that of any other mathematician (although Newton, Gauss, and Galois before Riemann, and Poincaré and Hilbert after him offer some competition). This plane extends well beyond geometry. Riemann made major transformative contributions, especially of a conceptual nature, to many areas of modern mathematics: geometry, topology, analysis, algebra, and number theory–not the least by bringing these fields to bear on each other, and his contributions to physics or philosophy were part of this interactive thinking and practice.

The interactive heterogeneity of Riemann's practice is a crucial aspect of Riemann's mathematics, and it extends beyond mathematics and shapes its mathematical operation from this exterior. Thus, the plane of immanence of Riemann's thought also has a more strictly philosophical dimension and thus creates more strictly philosophical concepts, emphasized by Deleuze and Guattari, rather than only mathematical concepts analogous to philosophical concepts by virtue of their multi-component architecture, stressed here. Riemann's philosophical thought was uncommonly and even nearly uniquely significant for his mathematical or physical thought, although one could think of a few competing cases, such as Weyl, who might have been inspired by Riemann in this respect as well, as he was by many other aspects of Riemann's thought. So were the physical dimensions of Riemann's thought, and this, too, is shared by Weyl, or, earlier Gauss, although this is more common. This role of physics in their work is also essentially connected to the role of philosophy there, which is, again, uncommon, if one speaks of such essential connections, making one's philosophical thinking a constitutive part of one's mathematical thinking, rather than of general philosophical reflections concerning mathematics and science, on the part of mathematicians and scientists.[8] The creation of new mathematics in Riemann was enabled by all three dimensions—mathematical, physical, and philosophical—of Riemann's thought and concepts. Riemann lays out a new plane of immanence of mathematical thought by changing both how to think about geometry or space and how to pursue thinking differently mathematically, via bringing together different mathematical fields and combining them with physical and philosophical concepts. A similar claim could also be made about his thinking concerning physics.

Riemann's Habilitation lecture is a magnificent unfolding of this plane (a geometrical metaphor of "plane" is fitting here). It is a major contribution not only to mathematics but also to physics and philosophy, especially to the philosophy of mathematics and physics, but far from exclusively so, as, for example, Deleuze and Guattari's use of Riemann's concepts shows. It is difficult to overestimate the significance and impact of Riemann's thinking concerning spatiality and geometry in mathematics and physics, in shaping the planes of immanence of thought of both. In mathematics the list of even major areas of impact is nearly inexhaustible, and I shall only mention a few of, arguably, the most important ones. First of all, Riemann's rethinking of geometry in terms of manifoldness crucially expanded the idea of the multiplicity of spaces and geometries themselves. Riemann's view of geometry as, in Deleuze and Guattari's language, topology and typology of manifolds led from the late-nineteenth century on to the extraordinary (a still ongoing) progress of geometry, beginning with the work of Sophus Lie and Felix Klein, and a bit later Élie Cartan [7, p. 483]. This work also connected differential geometry of manifolds and the theory of groups, specifically Lie groups. These connections eventually proved to have a major significance for quantum theory, especially in the theory of elementary particles, which are classified by using Lie groups as symmetry groups, although in connection with the infinite-dimensional spaces. The concept of manifold was also crucial for the development of topology. Initially, it was Riemann's earlier work on Riemann surfaces that had a greater impact. Eventually, topology came to be defined by understanding, which, as I shall explain, follows Riemann, of topological spaces as composed of local neighborhoods of points and (open) subspaces of a given space. It is true that Riemann did not have a concept of topological space. My main concern, however, is the development, transformation of Riemann's concepts (such as manifold) leading to new concepts, such as topological space, which makes Riemann's concepts alive, makes them "live on" in new concepts.

---

[8] Poincaré's extensive (much more extensive than Riemann's) philosophical works (e.g. [28, 29]), while influenced, as were his mathematical works in geometry, by Riemann's Habilitation lecture, may be seen along these lines. I realize that this claim may be challenged, and make it with caution. I would, nevertheless, argue that Riemann's philosophical thinking plays a greater constitutive role in his mathematical thinking than Poincaré's philosophical thinking in his mathematical thinking. The situation is of course different when it comes to physics, which is a major part of Riemann's and Poincaré's mathematical thinking alike, and both made major contributions to physics.

3 Mathematics: Space, Geometry, and the Concept of Manifold

The significance of Riemann's lecture for mathematics, physics, and philosophy, and its impact in all three fields were immense. This impact was delayed until its publication, in 1868, two years after Riemann's death, and fourteen years after it was presented in 1854, although some of Riemann's key ideas contained there and in Riemann's related works became known and had their impact earlier. One can only surmise (a tantalizing surmise!) the consequences for the history of mathematics and physics if the lecture was published more immediately. Riemann opens as follows:

> As is well known, geometry presupposes the concept of space, as well as assuming the basic principles for construction in space. It gives only nominal definitions of these things, while their essential specification appears in the form of axioms. The relationship between these presuppositions is left in the dark; we do not see whether, or to what extent, any connection between them is necessary, or a priori whether any connection between them is even possible.
>
> From Euclid to Lagrange this darkness has been dispelled neither by the mathematicians nor the philosophers who have concerned themselves with it. The reason [ground] [*Grund*] for this is undoubtedly because the general concept of multiply extended magnitudes [*Grösse*], which includes spatial magnitudes, remains completely unexplored. I have therefore first set myself the task of constructing the concept of a multiply extended magnitude from general notions of magnitude. It will be shown that a multiply extended magnitude is susceptible of various metric relations, so that space constitutes only a special case of a triply extended magnitude. From this, however, it is a necessary consequence that the theorems of geometry cannot be deduced from general notions of magnitude, but that those properties that distinguish space from other conceivable triply extended magnitudes can only be deduced from experience. Thus arises the problem of seeking out the simplest data from which the metric relations of space can be determined, a problem that by its very nature is not completely determined, for there may be several systems of simple data that suffice to determine the metric relations of space; for the present purposes, the most important system is that laid down as a foundation of geometry by Euclid. These data are—like all data—not logically necessary, but only of empirical certainty, they are hypotheses [*Hypothesen*]; one can therefore investigate their likelihood, which is certainly very great within the bounds of observation, and afterwards decide on the legitimacy of extending them beyond the bounds of observation, both in the direction of the immeasurably large [*Unmessbargrosse*] and in the direction of the immeasurably small [*Unmessbarkleinen*]. [31, p. 23; translation modified]

> From Euclid to Lagrange this darkness has been dispelled neither by the mathematicians nor the philosophers who have concerned themselves with it. The reason [ground] [*Grund*] for this is undoubtedly because the general concept of multiply extended magnitudes [*Grösse*], which includes spatial magnitudes, remains completely unexplored. I have therefore first set myself the task of constructing the concept of a multiply extended magnitude from general notions of magnitude. It will be shown that a multiply extended magnitude is susceptible of various metric relations, so that space constitutes only a special case of a triply extended magnitude. From this, however, it is a necessary consequence that the theorems of geometry cannot be deduced from general notions of magnitude, but that those properties that distinguish space from other conceivable triply extended magnitudes can only be deduced from experience. Thus arises the problem of seeking out the simplest data from which the metric relations of space can be determined, a problem that by its very nature is not completely determined, for there may be several systems of simple data that suffice to determine the metric relations of space; for the present purposes, the most important system is that laid down as a foundation of geometry by Euclid. These data are—like all data—not logically necessary, but only of empirical certainty, they are hypotheses [*Hypothesen*]; one can therefore investigate their likelihood, which is certainly very great within the bounds of observation, and afterwards decide on the legitimacy of extending them beyond the bounds of observation, both in the direction of the immeasurably large [*Unmessbargrosse*] and in the direction of the immeasurably small [*Unmessbarkleinen*]. [31, p. 23; translation modified]

These introductory reflections are already profound and far-reaching, and Riemann develops the ideas suggested here quite a bit further in the lecture. First of all, Riemann does not appear to be interested in the axiomatic approach to geometry and is even suspicious of axioms of geometry. In contrast to most previous works on non-Euclidean geometry, the parallel postulate is not the starting point of his investigation. The reason is clearly that the concepts of space and of measuring distances in space are not adequately defined. This is what leaves "the relationships between [axioms] in the dark. We do not see whether, or to what extent, any connection between them is necessary, or a priori whether any connection between them is even possible." This questioning of the axioms of geometry was unusual at Riemann's time, and it was much deeper than customary doubts concerning the parallel postulate. The axiomatic approach to non-Euclidean geometry is, thus, abandoned and even implicitly questioned by Riemann, even though it was this approach that led to the discovery of non-Euclidean geometry by Lobachevsky and Bolyai. This may have been one of the reasons why only Gauss, rather than either Lobachevsky (highly regarded by Gauss) or Bolyai, was expressly invoked in the lecture.[9] It is true that Gauss was ultimately unable to establish a possible existence (in the sense of logical consistency) of non-Euclidean geometry, because, unlike Lobachevsky and Bolyai, he did not do this for the three-dimensional case. In spirit, however, Gauss's work on the geometry of two-dimensional surfaces and his concept of curvature as intrinsic to a given surface was much closer to Riemann. For Riemann, Gauss was pursuing a trajectory of thought better suited for the foundations of geometry and more fruitful for its conceptual development. In his famous extraordinary theorem (*theorema egrerium*, as he called it), Gauss proved that the curvature of a surface, which he defined as well, was intrinsic to the surface. More precisely, the theorem states that the Gaussian curvature of a surface does not change if one only bends the surface but does not stretch it. This means that curvature can be fully determined by measuring angles and distances on the surface itself, without considering the way it is embedded in the ambient (three-dimensional) Euclidean space or, in Riemann's terms, manifold, which makes the Gaussian curvature an intrinsic invariant of a given surface.

One nearly has here a two-dimensional conceptual architecture that suggests and even approaches that of Riemann, although major additional thinking is necessary to give this architecture the type of generality Riemann is able to do. Gauss's theorem suggests that one could see the surface as an independent curved manifold and then to generalize this concept to higher dimensions via "the concept of a multiply extended magnitude," mentioned in this passage and the concept of manifold, which is what Riemann did. These concepts also helped him to generalize to higher dimensions Gauss's concept of curvature. To do so required yet another new concept, another great invention of Riemann, the tensor of curvature, and a new form of differential calculus, tensor calculus on manifolds, a generalization of differential calculus. This calculus was fully developed later on, and it played a major role in Einstein's general relativity. The independence of the curvature or of geometry of a given manifold of any dimension from its embedding also allows one to determine, at least in principle, intrinsically whether this space is flat or curved, which is crucial for determining the nature of the physical space we inhabit. For example, as indicated earlier, space is curved in the immediate vicinity of the solar system, because of the gravity of the Sun, planets, and other material entities in the solar system (or locally around other stars), but appears to be on the overage flat on the scale of the observable Universe.[10] In any event, by virtue of inventing his concepts and by using them, Riemann provided a general rigorous grounding to all geometry, Euclidean or non-Euclidean, rather than merely establishing, as Lobachevsky and Bolyai did, the logical possibility of the non-Euclidean geometry of (constant) negative curvature in three dimensions. The absence of a concept, such as that of manifold, leaves us in "the dark," because "we do not see whether, or to what extent, any connection between [axioms] is necessary, or a priori whether any connection between them is even possible."

---

[9] There were other, more extrinsic, reasons, beginning with the fact that Gauss was Riemann's mentor and the chair of his Habilitation committee. Indeed, Gauss selected this topic among three proposed by Riemann (following the rules). The philosopher R. H. Lotze, a fervent opponent of non-Euclidean geometry, was a member of the philosophy faculty, to which Riemann's Habilitation was presented. Later on, Lotze criticized Riemann's approach anyway, as part of his general critique of non-Euclidean geometry (see [16, pp. 222–226] and [33, pp. 97–112]).

Riemann's thinking is conceptual-problematic rather than axiomatic-theorematic: he grounds mathematics, as well as physics, in hypotheses and concepts, concepts-problems, such as the concept of manifold and its subconcepts (distance, curvature, tensor, and so forth). The problem of space and geometry is now posed in terms of finding concepts that are necessary to define space and to give it geometry. A general concept of manifold was assumed to be applicable to any possible space, while specific manifolds, flat or curved, define different spaces or subspaces. In this respect, as foundational thinking, that of Riemann is different from that conforming to Hilbert's concept of "foundations" [*Grundlagen*] in the sense of axiomatic foundations, an idea that Hilbert also tried to apply to physics. One of the problems of his famous 1900 list (Problem 6) was in fact that of the development of (mathematized) axiomatic foundations, system(s) of axioms, for physics, on the model of his own *Foundations of Geometry* [13].[11] That such a system is possible is inevitably a hypothesis. It became clear subsequently that the existence of such a system is a hypothesis even in mathematics, and in view of Gödel's incompleteness theorems in 1931, ultimately a wrong hypothesis, insofar as such a system cannot be proven to be free of contradiction, once it is large enough to include arithmetic, as geometry is.

---

[10] As I qualified earlier, at least this is a workable and widely accepted view, widely but not universally. It has never been established definitively or, in any event, agreed upon whether such a determination is ever rigorously possible, as opposed to having a practically effective and possibly, within its proper limits, the best available theory or, as Poincaré would have it, "convention," without making a real claim concerning "the reality underlying space" [31, p. 33]. Einstein had his doubts too, although he was ultimately inclined to accept the possibility of such a determination, at least in principle, as, it appears, was Riemann, but not Poincaré, with whose position Einstein, nevertheless, had to contend and which he tried to accommodate within his own (e.g. [11, pp. 324–328]).

[11] For the development of Hilbert's ideas, as reflected in different editions of the *Grundlagen*, see [4]. In the first version of the book, Hilbert was closer to Riemann, and he later returned to a more Riemannian view of geometry in the wake of general relativity to which he made important contributions.

While Hilbert's foundational thinking aimed to bring physics closer to mathematics, even to make it mathematics, by giving physics an axiomatic form, that of Riemann brings mathematics closer to physics by grounding it in hypotheses and concepts, rather than in axioms.[12]

Riemann's approach and his concepts arise from the plane of immanence, at once, mathematical, physical, and philosophical, a plane defined by thinking in terms of multi-component concepts, such as that of multiply extended magnitude and manifoldness, rather than in terms of axioms and propositions, an approach that has defined most thinking concerning geometry before and even after Riemann. Riemann's thought is defined by a plane of immanence by virtue of giving rise to multicomponent concepts, rather than only creating frames of reference, functions, or propositions, from a plane of reference, although this is necessary as well. In Riemann, both planes are joined, as they must be in the creation of mathematical or scientific concepts. Thus, functions define both local neighborhoods (as infinitesimally Euclidean) and how local spaces are connected or pass into each other, and metrical relations and curvature, although curvature is ultimately defined by tensors, which are more complex entities.

The parallel postulate is, again, never mentioned in the lecture, although Euclidean geometry is invoked there as the geometry of "flat space," merely a particular and very special case of geometry, where metrical relations take an especially simple form, defined by the Pythagorean theorem. In Gray's words, "[In Riemann] geometry no longer starts with Euclidean geometry" [11, p. 52]. It is the metrical relation characterizing a given space that defines a possible geometry. In other words, the character of this relation is a hypothesis on which a geometry could be based, a hypothesis to be tested physically in order to establish whether such a space corresponds to the actual physical space. Non-Euclidean geometry (Riemann, again, does not use the term) is introduced as such a possible case of geometry, that of a curved, rather than flat, space of either negative or positive curvature, defined by Riemann by the corresponding type of quadratic form determining the metric. Riemann, thus, not only introduces a more general concept of geometry, but also gives a more rigorous conceptual grounding to non-Euclidean geometry of either negative or positive curvature. While the non-Euclidean geometry of negative curvature (hyperbolic geometry) was discovered before Riemann, Riemann's lecture introduced the three-dimensional non-Euclidean geometry of positive curvature (elliptical geometry), keeping in mind that space for Riemann meant the three-dimensional physical space. (The two-dimensional spherical geometry was considered well before Riemann.) Although eclipsed by Riemann's overall achievement in the lecture, this was a major mathematical discovery with important cosmological implications, for example, in its anticipation of the idea, later considered by Einstein, that the universe may be unbounded and yet finite.[13]

---

[12] One might challenge this argument on historical grounds because it would have been difficult, if not impossible, to present a concept such as that of manifold in axiomatic form at the time of Riemann's lecture. That may be true. My point, however, is that Riemann's alternative, conceptual-problematic rather than axiomatic-theorematic, thinking, could still be contrasted to that of Hilbert and lead to a different type of mathematical thinking. It is difficult to say how Riemann would have approached the foundations of geometry if he had means of axiomatizing his concepts. On the other hand, it is possible to argue, as I do here, *on historical grounds*, that Riemann, unlike his predecessors, Lobachevsky and Bolyai, was not pursuing an axiomatic approach to geometry.

Riemann defines the concept of space, again, understood as physical space (as against, the concept of manifold, which is mathematical), as a three-dimensional instance of the concept of continuous manifoldness, in accordance with the hypotheses that he assumed as likely given the experimental data then available. (There is still no definitive data to refute this view, unless perhaps in the very small, say, at the Planck scale.) While a manifold, as defined by Riemann, may be either discrete or continuous, the concept of continuous manifoldness has a richer and more complex architecture, and most of Riemann's lecture is devoted to it. Technically, continuous manifolds considered by Riemann were differentiable manifolds, which means that one can define differential calculus on them. Indeed, they are metrical manifolds, now called Riemannian, which allow for the concept of distance between any two points and thus for geometry.[14] I shall, however, speak of continuous manifolds, following Riemann and his juxtaposition between continuous and discrete manifoldness. In modern use, the term manifold more customarily refers to continuous (but not necessarily differentiable) manifolds, although one also refers to discrete manifolds, which have topological dimension zero, as zero-manifolds. As defined by Riemann, discrete and continuous manifolds do not appear to have that much in common, and in effect form two different concepts.[15]

Riemann's concept of continuous manifoldness was a new concept of geometrical multiplicity. It is a multiplicity of local subspaces, most specifically those, "neighborhoods," associated with each point, out of which a given space is composed. A continuous (differentiable) manifold is understood by Riemann on the model of two-dimensional surfaces, which, as explained earlier, were defined by Gauss in terms of their intrinsic geometry. Riemann defines first the concept of "n-dimensional magnitude," which allows one to determine a position in a manifold by n numerical determinations, in the same way a position is determined by coordinates in the Euclidean space of n dimensions. Riemann is rigorous to extend (scale down) the concept of manifold to one-dimensional manifolds, curves, which, however, also helps him to built up the concept n-dimensional manifold by analogy. He starts with the concept of "a simply extended [one-dimensional] manifold, whose essential characteristic is that from any point in it a continuous movement is possible in only two directions, forwards and backwards." Then, he defines a two-dimensional or "a doubly-extended manifold" by saying that "if one now imagines that this [one-dimensional manifold] passes to another, completely different one, and once again in a well-determined way, that is, so that every point passes to a well-determined point of the other, then the instances for, similarly, a double extended manifold" [31, p. 25]. In other words, one continuously "fills" a surface with curves. Then, one similarly defines a triply extended manifold by imagining a similar continuous passing of a doubly extended manifold to another, thus continuously filling a three-dimensional object with two dimensional-ones, and so forth. "This construction," Riemann says, "can be characterized as a synthesis of a variability of $n + 1$ dimensions from a variability of n dimensions and a variability of one dimension" [31, p. 25]. This construction may have been one of the reasons for his use of the term: a manifold is literally a continuous fold(er) of manifolds of lower dimensions. Conversely, one can unfold a variability of n dimensions, which allows one to determine a position in a manifold by n numerical determinations, generalizing the way a position is determined by coordinates in the Euclidean space of n dimensions.

---

[13] It would be similar to the three-dimensional sphere. As I explained, the currently dominant view or hypothesis (which appears to be confirmed by cosmological measurements) is that the universe is on average flat and is expanding.

[14] As most of his contemporaries, Riemann did not distinguish continuous and differentiable manifolds. It became eventually clear, however, that not all continuous (also called topological) manifolds are differentiable. There are topological manifolds with no differentiable structure, and some with multiple non-diffeomorphic differentiable structures. Thus, there is a continuum of non-diffeomorphic differentiable structures of $\mathbf{R}^4$.

[15] These two concepts could, especially in modern understanding, be subsumed under the same concept. This is because all zero-dimensional manifolds, which are discrete manifolds in Riemann's terms, are continuous (topological) manifolds. In fact they are also differentiable manifolds, because transition functions for them are constant functions, which are continuous and even differentiable. In modern terminology, the distinction between continuous and discrete manifolds in Riemann's lecture would be interpreted as that of zero-dimensional manifolds and positive dimensional manifolds. I am grateful to Ken'ichi Ohshika for helping to clarify this point. It is not inconceivable that Riemann's thought along similar lines, which would explain his choice of the term manifold for both discrete and continuous manifolds, although the term had a more general use at the time. (Georg Cantor, possibly influenced by Riemann's lecture, initially referred to sets as *Mannigfaltigkeiten* but eventually switched to *Mengen*.) It is, however, difficult to be certain on the basis of his lecture or his other writings. I would argue that the difference between these two types of manifolds is still crucial, both in general and for Riemann, especially for his analysis of physical space and geometry. Riemann stressed the significance of the relationships between continuity and discontinuity for mathematics, physics, and philosophy (e.g. [32, pp. 515–524]; [9, pp. 77–80]).

The most defining feature of the concept of manifold (under the assumption than one can measure the length of line-segments, straight or curved) is that it is conceived as infinitesimally Euclidean. This makes a continuous manifold into a conglomerate of local, continuously connected, small open neighborhoods around each point. The concept of neighborhood, again, assumed to be infinitesimally flat and Euclidean, is a component-concept of the concept of manifoldness. This concept of manifold as composed out of local neighborhoods is extendable to a still more general concept of topological space, in which case local neighborhood need no longer be Euclidean and can be defined with a great degree of generality. It is true that Riemann did not have a concept of topological space, in contrast to his concept of a Riemann surface, which had a more direct and immediate impact on the development of topology as an independent mathematical discipline. I would argue, however, that the conceptual architecture defining topological spaces is a generalization of that of Riemann's conceptual architecture of manifoldness as a "space" composed of neighborhoods, or generalizing it even further to other "spaces," a conception that, as will be seen presently, extends to Grothendieck's topos theory.[16] Admittedly, this architecture is presented here in the spirit of modern axiomatic thinking rather than in the spirit of Riemann's conceptual-problematic thinking, but it does, I think, inherit Riemann's conceptual architecture defining his concept of manifold. The theory of Riemann surfaces, too, came to be recast in terms of manifolds. Weyl, who, as his title *The Concept of a Riemann Surface* stated, considered a Riemann surface to be a concept, was the first to expressly define Riemann surfaces as manifolds [20, 35]. Riemann, however, undoubtedly realized that they were manifolds, and they were part of the genealogy of the concept of manifold.

In the case of Riemannian manifolds, while each neighborhood is infinitesimally flat, Euclidean, the manifold as a whole is, in general, not, except in the special case of flat, Euclidean manifolds. A manifold may be negatively or positively curved, and, which is another major innovation of Riemann, this curvature can also be variable. Riemann defined the metric form as a quadratic differential form, by the only formula in his lecture (discounting the coordinate expression for the line element), and assumed that the transition from one local coordinate system to another was differentiable. Thus, he, again, de facto, considered differentiable manifolds with positive definite metrics, Riemannian manifolds. In modern terms, such a manifold is defined by using a differentiable section of positive-definite quadratic forms on the tangent-bundle. While, however, modern technical language can bring out deeper mathematical aspects of Riemann's concepts, it can also displace how Riemann thought, mathematically, physically, and, especially, philosophically, a displacement sometimes found in twentieth-century English translations of Riemann's works, including his Habilitation lecture. One is, accordingly, always in complex negotiations between Riemann's and contemporary technical language, even though and because Riemann is so often ahead of his time, so much our contemporary.

Another important and equally future-oriented conceptual aspect of Riemann's approach is that it allows one to define a geometrical or, more generally, topological space (in modern terminology) not as a multiple, say, a set of points, but as a space that could be covered by maps (Euclidean in the case of manifolds) and in its relation to other spaces. As just explained, in part following Riemann's way of thinking, topology describes a given space not only in terms of its points, continuously connected to each other, but also and most essentially in terms of its open neighborhoods around each point. These neighborhoods are subspaces of this space, the idea that, again, underlies Riemann's concept of manifold, in this case, however, giving each neighborhood a Euclidean geometry. The approach, again, enabled Riemann to define manifolds of any dimension, even infinite-dimensional ones, in terms of its inner properties rather than in relation to the ambient Euclidean space, where a manifold could be placed, against the flat Euclidean background. It is true that, if one appeals, as is usual even in considering Riemann, to open sets, this concept of space retains the concept of set (of points) as a primitive concept.[17] Riemann's way of thinking concerning manifolds, however, also suggests a possibility of thinking of and even defining a space in terms of its relations to other spaces, which allows one to use this structure as more primordial by replacing covering a space by *open sets (of points)* with covering it by *open spaces*. A topological space, defined above in set-theoretical terms, becomes a collection of open spaces as sub-spaces with certain (algebraic) rules for the relationships between them.

---

[16] It is also worth recalling in this connection that Grothendieck's initial primary areas of mathematical research concerned topological vector spaces, which suggests yet another genealogical line in the history of the (broadly) Riemannian problematics in question here.

This way of defining space by its relation to other spaces (as opposed to their constitution as sets of points) leads all the way to Grothendieck's topos theory, inspired by Riemann's ideas of manifolds and of the so-called covering spaces, originating in Riemann's theory of Riemann surfaces. Although it extends far beyond the question of spatiality, including mathematical logic, topos theory is arguably the farthest and most abstract extension of the concept of spatiality available, if one can rigorously speak of spatiality in this case, given an essentially algebraic nature of the concept. It does, however, give important new dimensions to our understanding of spatiality, when we deal in mathematics and elsewhere with objects or concepts that are considered in spatial terms.

It would not be possible here to present topos theory in its proper abstractness and rigor, sometimes prohibitive even for those not trained in the field of algebraic geometry or mathematical logic, where the concept is used as well (e.g. [18]). The essential philosophical ideas involved may, however, be sketched, as an example of both a rich mathematical concept in its own terms and of Riemann's influence on modern mathematics.[18] First, very informally, consider the following way of endowing a space with a structure, generalizing the definition of topological space. One begins with an arbitrarily chosen space, X, potentially any given space, which may initially be left unspecified in terms of its properties and structure. What would be specified are the relationship between spaces applicable to X, such as mapping or covering one or a portion of one, by another. One calls this structure the arrow structure $Y \rightarrow X$ (X is the space under consideration), where the arrow designates the relationship(s) in question. One can also generalize the notion of neighborhood or of an open subspace of (the topology of) a topological space in this way, by defining it as a relation between a given point and space (a generalized neighborhood or open subspace) associated with it. This procedure enables one to specify a given space not in terms of its intrinsic structure (e.g., a set of points with relations among them) but sociological[ly], throughout its relationships with other spaces of the same category, say, that of Riemannian spaces as manifolds [17], p. 7]. Some among such spaces may play a special role in defining the initial space, *X*, and algebraic structures (such as homotopy and cohomology, as Riemann realized in the case of covering spaces over Riemann surfaces. Indeed, the concept of covering space was one of the main inspirations for Grothendieck's concept of topos. The so-called *étale* topos (of a scheme), one of the main motivations for the concept of topos, is directly linked to the concept of covering space, as the term *étale* suggests.

---

[17] Thus, Ferreirós's discussion of Riemann in [11, pp. 39–80] appears to me to displace Riemann's thinking into the axiomatic and set-theoretical register, dominant in the wake of Cantor, a displacement arguably due to Ferreirós's insufficient attention to the nature of Riemann's mathematical concepts, to Riemann's concept of mathematical concept. In fairness, Ferreirós does relate Riemanns view of axioms to his concept of "hypothesis" and distinguishes it from the understanding of axioms developed in the twentieth-century philosophy of mathematics and mathematical logic. It does not appear to me, however, that Riemann thinks either in terms of axioms or, especially, in terms of sets (of points), as Ferreirós contends, although it could be and subsequently has been translated into these terms (e.g. [22]). See also Note 12 above.

[18] It would be instructive on both counts, to consider, as part of this genealogy, Dedekind's and Noether's work in algebra, reflecting the impact of Riemann's work on modern algebra, and even apart from his work on the distribution of primes and his famous hypothesis concerning the ζ-function. See [19] on Noether's work in this connection.

To make this scheme more rigorous and to explain (albeit still quite informally) the concept of topos, I need to explain in my own words category theory. It was introduced in as part of the cohomology theory in algebraic topology in 1940 and later extensively used by Grothendieck in his approach to algebraic geometry, leading to the concept of topos. Category theory considers multiplicities (which need not be sets) of mathematical objects conforming to a given concept, such as the category of Riemannian manifolds, and the arrows or morphisms, the mappings between these objects that preserve this structure. Studying morphisms allows one to learn about the individual objects involved, often to learn more than we would by considering them only or primarily individually. In a certain sense, by appealing to the conceptual determination of each manifold, Riemann already thinks categorically. Thus, one does not have to, and Riemann does not, start with a Euclidean space, whether seen in terms of sets of points or otherwise. Instead the latter is just one specifiable object of a large categorical multiplicity, here that of the category of Riemannian manifolds, an object marked by a particularly simple way we can measure the distance between any two points. Categories themselves may be viewed as such objects, and in this case one speaks of "functors" rather than "morphisms." Topology relates topological or geometrical objects, such as manifolds, to algebraic ones, especially, as in the case of homotopy and cohomology theories, groups, a concept, it is true, not used by Riemann, as against Poincaré, who made it central to his geometrical and topological thinking, which established his uniquely significant role in the rise of algebraic topology. Thus, in contrast to geometry (which relates its spaces to algebraic aspects of measurement), topology, almost by its nature, deals with functors between categories of topological objects, such as manifolds, and categories of algebraic objects, such as groups.

Now, a topos in Grothendieck's sense is a category of spaces and arrows over a given space, used especially for the purpose of allowing one to define richer algebraic structures associated with this space, as explained above. There are certain additional conditions such categories must satisfy, but this is not essential at the moment. To give a simple example, for any topological space *S*, the category of sheaves on *S* is a topos. The concept of topos is, however, very general, and extends far beyond spatial or space-like mathematical objects (thus, the category of finite sets is a topos); indeed it replaces the latter with a more algebraic structure of categorical and topos-theoretical relationships between objects. On the other hand, it derives from the properties of and (arrow-like) categorical relationships between properly topological objects, such as Riemann surfaces or manifolds. The conditions, mentioned above, that categories that form topoi must satisfy have to do with these connections. The concept of topos is especially suited to deal in the way we do with standard manifolds with objects, such as certain (discrete) algebraic varieties, which are solutions of polynomial equations and are space-like, that cannot be meaningfully defined otherwise sufficiently analogously to continuous spaces, specifically in order to define nontrivial cohomology or homotopy groups for them. This had been an outstanding problem of algebraic geometry, arising from the so-called Weil conjectures for algebraic varieties over finite fields, which was solved with the help of topos theory, specifically the concept of *étale* topos, mentioned above (e.g. [1]). What both types of objects now share are analogously defined topoi associated with them and, as a result, analogously defined algebraic structures associated with them, equally enabling the necessary functoriality in both cases.

Topos theory allows for such esoteric constructions as non-trivial or non-punctual single-point "spaces" or, conversely, spaces (topoi) without points (first constructed by Pierre Deligne), sometimes slyly referred to by mathematicians as "pointless topology." Philosophically, this notion is far from pointless, especially if considered within the overall topos-theoretical framework. In particular, it amplifies a Riemannian idea that "space," especially is defined by its relation to other spaces, as a more primary object than a "point" or, again, a "set of points." Space becomes a Leibnizean, "monadological" concept, insofar as points in such a space (when it has points) may themselves be seen as a kind of monads, thus also giving a non-trivial structure to single-point spaces. These monads are certain elemental but structured entities, spaces, rather than structure-less entities (classical points), or at least as entities defined by (spatial) structures associated to and defining them [3]. Naturally, my appeal to monads here is qualified and metaphorical. Leibniz's monads are elemental souls, the atoms of soul-ness, as it were. But one might say that the space thus associated to a given point is the soul of this point, which defines its nature or structure, not unlike an infinite-dimensional Hilbert space associated with an elementary particle, such as an electron, in quantum mechanics and enabling us to predict its behavior. In other words, not all points are alike insofar as the mathematical (and possibly philosophical) nature of a given point may depend on the nature or structure of the space or topos to which it belongs or with which it is associated in the way just described. This approach also gives a much richer architecture to spaces with multiple points, such as Riemann's manifold (in which this architecture is inherent), and one might see (with caution) such spaces as analogous to Leibniz's universe composed by monads. It also allows for different (mathematical) universes associated with a given space, possibly a single-point one, in which case a monad and a universe would coincide. Grothendieck's topoi are such possible universes, possible worlds, or even com-possible worlds in Leibniz's sense, without assuming, like Leibniz (in dealing with the physical world), the existence of only one of them, the best possible one.

The outcome of Riemann's investigation into the foundations of geometry was, thus, a new mathematics of great generality, power, and potential, which involved not only new geometry, but also new topology and analysis (the tensor calculus on manifolds). Although it was Riemann's theory of continuous or, again, differentiable manifolds that had the greatest impact, the concept of discrete manifolds was important for Riemann's argument, and it is important for the modern understanding of both spatiality and geometry in mathematics, physics, and philosophy. While a discrete manifold has topological dimension zero, it may still be seen as multiply extended, if defined as forming a very fine lattice with very small intervals between points, which can be "filled," as it were, to form a continuous space of the corresponding topological dimensions. It is also possible to introduce metrical relations for discrete manifolds. This concept is important in the context of the relationships between physical, dynamical forces in nature and the nature of space or, to return to Riemann's terms, the physical "reality underlying space," although Riemann is cryptic on such metrical relations. Crucially, however, he does allow for the possibility that the physical "reality underlying space" might be "a discrete manifold" [31, p. 33]. This possibility has been entertained even before Riemann and has been even more often considered since, especially more recently. Also, mathematically, finite geometries were beginning to be developed, usually in more axiomatic ways, around Riemann's time as well, later on also under the impact of his geometrical thinking.[19] As indicated earlier, Riemann saw the relationships between continuity and discontinuity as foundationally central to mathematics, physics, and philosophy (e.g., [32, pp. 515–524]; [10, pp. 77–80]), a view confirmed by the subsequent developments in the foundations of mathematics, from Dedekind and Cantor on, and quantum physics. The latter uses continuous (technically, differential) mathematics to predict, in probabilistic terms, irreducibly discrete phenomena, that is, phenomena that are not, and that possibly cannot be, assumed to be connected to each other by a continuous physical process [27, pp. 232].

4 Physics: "The Reality Underlying Space"

As noted from the outset, Riemann's contribution to physics in his lecture was as important as his contribution to mathematics there. Riemann's terms space and geometry refer to the three-dimensional space and its geometry, in accordance with the use of these terms at the time, although this was soon to change. We now speak not only of manifolds of any dimensions, as Riemann does, but also of their geometry and refer to them as "spaces," or of discrete spaces and geometries, without necessarily assuming any connections between these objects and physical (or phenomenal) spatiality. While Riemann allows that "the reality underlying space" may prove to be discrete at a very small scale, this is not the same as extending, as was done subsequently, the terms "space" and "geometry" to finite entities defined by certain geometrical-like properties. On the other hand, closer to Riemann's view of what "the reality underlying space" could in principle be, some physical theories, dealing with such connections, suggest that the ultimate reality underlying space might be discrete or, as in superstring and brane theories, that physical space has a dimension

---

[19] For the discussion of some of these developments, see the chapter by V. Pambuccian, H. Struve, and R. Struve [21] and other chapters in the part of this volume that addresses later developments of Riemann's work.

$$\mathrm{Curv}^g(X,Y)Z = \left(\nabla_X\nabla_Y - \nabla_Y\nabla_X - \nabla_{[X,Y]}\right)Z, \qquad X,Y,Z \in \mathfrak{X}(\mathcal{M})$$

where ∇ is the metric-compatible, torsion-free connection associated to g

$$\mathrm{Riem}^g(W,Z,X,Y) = \langle W, \mathrm{Curv}^g(X,Y)Z\rangle, \qquad W,X,Y,Z \in \mathfrak{X}(\mathcal{M})$$

where $\langle\,,\,\rangle$ denotes scalar product with g. In terms of this tensor Riemann's characterization of flat space is

Theorem 2.1 (Local characterization of flat space, Riemann [47]) *A Riemannian manifold $(\mathcal{M},g)$ is locally isometric to the flat space with the same dimension and signature if and only if $Riem^g = 0$.*

Being intended to all faculty members, Riemann's lecture contains hardly any formula (see Chap. 4 in Spivak's comprehensive treatise [73] for a detailed exposition of Riemann's lecture) so no detailed proof of this claim is given there. Not even an explicit form of the Riemann tensor in a general coordinate system appears there. Following Spivak [73], such an explicit expression, and a proof of the fact that its non-vanishing is an obstruction for a metric being locally flat, appeared first in an unpublished paper, known as the *Commentatio*, submitted in 1861 to the Paris Academy and which appeared in the second edition of the collected works of Riemann [62]. However, as emphasized in [26] (see also [34]), this unpublished paper was primarily concerned with a problem of heat conduction proposed by the Academy in 1858, so its primary concern was not in Geometry, and it is debatable whether our modern understanding of the field might be biasing the interpretation of its results (see the interesting discussion on this *Commentatio* in [34] and references therein). In any case, an explicit expression of what we now know as the Riemann tensor appeared for the first time in this unpublished paper by Riemann. The first explicit proof that the vanishing of this tensor is sufficient for a metric being (locally) flat was given by Elwin Bruno Christoffel [17]. The proof of Theorem 2.1 is so central in differential geometry that many different proofs have been given. Spivak's treatise includes seven explicit proofs, which very nicely illustrate how differential geometry has evolved over the years from a discipline where the use of coordinates was central, to a mature theory where geometric objects fully independent of coordinates are the basic entities.

Another fundamental local characterization of Riemannian manifolds involves manifolds of constant sectional curvature. Recall that the sectional curvature of a two-plane $\Pi \subset T_p\mathcal{M},\ p \in (\mathcal{M},g)$ with non-degenerate induced first fundamental form h is defined as

$$K(p;\Pi) = \frac{\mathrm{Riem}^g(X,Y,X,Y)}{h(X,X)h(Y,Y) - h(X,Y)^2}, \qquad \{X,Y\} \text{ any basis of } \Pi.$$

The sectional curvature $K(p;\Pi)$ agrees with the Gauss curvature at p of the surface ruled by geodesics starting at p with tangent vector $X \in \Pi$. A Riemannian manifold has constant curvature k if $K(p;\Pi) = k$ for all $p \in \mathcal{M}$ and all non-degenerate plane $\Pi \in T_p\mathcal{M}$. A well-known lemma by Friedrich Schur [70] asserts that any Riemannian manifold with sectional curvature $K(p, \Pi) = k(p)$ independent of Π is in fact of constant curvature.

For any $k \in \mathbb{R}$, define the manifold $\mathbb{M}_k^{(p,q)}$ as the subset $B(K) \subset \mathbb{R}^{p+q}$

$$B(K) := \{x \in \mathbb{R}^{p+q};\, 1 + \frac{k}{4}(\eta_{ij}^{(p,q)} x^i x^j) > 0\},$$

endowed with the metric g_k given by

$$\begin{aligned} g_k &:= \frac{1}{\left(1 + \frac{k}{4}(\eta_{ij} x^i x^j)\right)^2} \eta_{ij}^{(p,q)} dx^i dx^j, \\ \eta^{(p,q)} &:= \mathrm{diag}(\underbrace{-1, \ldots, -1}_{p}, \underbrace{1, \ldots, 1}_{q}) \end{aligned}$$

(it is easily seen that $B(K)$ is connected for all values of k and all signatures (p, q)). Spaces of constant curvature are all isometric to this space. This is already mentioned without proof in Riemann's inaugural lecture [47] and it was also known to Eugenio Beltrami [4].

Theorem 2.2 *Let* $(\mathcal{M}, g)$ *be a Riemannian manifold of constant sectional curvature* k *and signature* (p, q)*. Then* $(\mathcal{M}, g)$ *is locally isometric to* $\mathbb{M}_k^{(p,q)}$.

Riemannian manifolds of constant curvature are also locally characterized by the condition that the Killing algebra of $(\mathcal{M}, g)$ has maximal dimension. Recall that a Killing vector is a vector field $\xi \in \mathfrak{X}(\mathcal{M})$ satisfying $\mathcal{L}_\xi g = 0$ where $\mathcal{L}$ denotes Lie derivative. The set of Killing vectors $\mathcal{K}$ in a manifold defines a finite-dimensional algebra (with respect to the Lie bracket) called Killing algebra. If the manifold has dimension n, the Killing algebra has dimension $\dim(\mathcal{K}) \leq \frac{n(n+1)}{2}$ and whenever equality is attained, the manifold is called maximally symmetric. A classical result by Luigi Bianchi [6] asserts that maximally symmetric spaces are precisely those of constant sectional curvature.

Theorem 2.3 (Bianchi [6]) *A Riemannian manifold* $(\mathcal{M}, g)$ *is maximally symmetric if and only if it has constant sectional curvature.*

Another important class of Riemannian manifolds singled out by the properties of its isometry group is the class of Riemannian symmetric spaces. These are defined as Riemannian manifolds $(\mathcal{M}, g)$ such that, at any point $p \in \mathcal{M}$ there exists an isometry $\Psi_p : \mathcal{M} \to \mathcal{M}$, $\Psi_p^\star(g) = g$ satisfying $\Psi_p(p) = p$ and $d\Psi_p|_p = -\mathrm{Id}|_p$, i.e. this isometry leaves p invariant and reverses any vector at p. Riemannian symmetric spaces can be locally characterized in terms of the Riemann tensor, as first proved by Élie Cartan.

Theorem 2.4 (Locally symmetric spaces, Cartan [12]) *A Riemannian manifold* $(\mathcal{M}, g)$ *is locally isometric to a Riemannian symmetric space if and only if the curvature tensor satisfies*

$$\nabla Riem^g = 0.$$

The Riemann tensor can be decomposed in its trace and its trace-free parts. The trace part defines the Ricci tensor $\mathrm{Ric}^g(X, Y) = \mathrm{tr}_g \mathrm{Curv}^g(X, \cdot)Y$ from which the scalar curvature is defined as $\mathrm{Scal}^g = \mathrm{tr}_g \mathrm{Ric}^g$. Useful tensors defined in terms of the Ricci tensor are the Schouten tensor Sch^g (in dimension $n > 2$) and the Einstein tensor Ein^g:

$$\mathrm{Sch}^g := \frac{1}{n-2}\left(\mathrm{Ric}^g - \frac{1}{2(n-1)}\mathrm{Scal}^g g\right), \qquad \mathrm{Ein}^g = \mathrm{Ric}^g - \frac{1}{2}\mathrm{Scal}^g.$$

The Weyl tensor is the trace-free part of the Riemann tensor, defined as

$$\mathrm{Weyl}_g = \mathrm{Riem}^g - \mathrm{Sch}^g \odot g$$

where $\odot$ is the Kulkarni-Nomizu product on symmetric tensors

$$\begin{aligned}(A \odot B)(X_1, X_2, X_3, X_4) =& A(X_1, X_3)B(X_2, X_4) - A(X_1, X_4)B(X_2, X_3)\\ &+ A(X_2, X_4)B(X_1, X_3) - A(X_2, X_3)B(X_1.X_4).\end{aligned}$$

Hermann Weyl introduced [79] the tensor named after him in an attempt to find a theory of gravitation invariant under scale (conformally invariant). The Weyl tensor has the fundamental property that $\mathrm{Weyl}_{\Omega^2 g} = \mathrm{Weyl}_g$ where $\Omega \in C^\infty(\mathcal{M}, \mathbb{R}^+)$. Thus, it vanishes automatically in any locally conformally flat space. Schouten [66] proved that the vanishing of this tensor is also sufficient in dimension $n \geq 4$ (in dimension $n = 2$ the Weyl tensor is not defined and in $n = 3$ it vanishes identically). As is well-known, in dimension $n = 2$ any space is locally conformally flat. In dimension three, the necessary and sufficient condition for local conformal flatness was obtained by Émile Cotton [16] in terms of the vanishing of the so-called Cotton tensor, which in dimension $n > 2$ is defined as

$$\mathrm{Cott}(X, Y, Z) = (n-2)\left((\nabla_Z \mathrm{Sch})(X, Y) - (\nabla_Y \mathrm{Sch})(X, Z)\right),$$

where $X, Y, Z \in \mathfrak{X}(\mathcal{M})$. This tensor is conformally invariant in any space with vanishing Weyl tensor (hence always in dimension three). Summarizing the discussion above, we have

Theorem 2.5 (Locally conformally flat spaces, Cotton, Weyl and Schouten) *A Riemannian manifold $(\mathcal{M}^n, g)$ $n \geq 3$ of signature (p, q) is locally isometric to a conformally flat space $(\mathbb{R}^n, \Omega^2\eta^{(p,q)})$, $\Omega \in C^\infty(\mathbb{R}^n, \mathbb{R}^+)$ if and only if*

(i) If $n = 3$, the Cotton tensor vanishes.
(ii) If $n \geq 4$, the Weyl tensor vanishes.

1 Introduction

We consider the geometrical problem of constructing a triangle using a straightedge and compass so that its three vertices lie on a given circle and its three sides when produced pass through three given points. Pappus of Alexandria formulated and solved this problem in the special case where the three given points are aligned. This is Proposition 117 of Book VII of the *Collection* [1]. Lagrange provided an algebraic solution, proving that the vertices of the triangle are constructible points. He communicated his solution to Jean de Castillon, who reproduced it in the first section of his paper "Sur une nouvelle propriété des sections coniques" (On a new property on conic sections) [2]. In the rest of his this paper, Castillon proceeded to show that the vertices of the triangle remain constructible when the circle is replaced by an ellipse or a hyperbola. Later, the solution due to Lagrange was published in his *Oeuvres complètes* under the title "Solution algébrique d'un problème de géométrie" (Algebraic solution of a geometry problem) [3]. Euler gave another solution and commented on the case where the given circle and the three given points are on a sphere [4]. Interestingly, this article is followed by one due to Nicolas Fuss, a young collaborator of Euler, who similar to Pappus, studies the special case where the three given points lie on a line [5]. Eugène-Charles Catalan also studied this problem in his book *Théorèmes et problèmes de géométrie élémentaire* (Theorems and problems of elementary geometry) [6] where he says that such a problem is known as the "Castillon problem" (see the footnote at p. 222 of [6]).

In this chapter, we first recall the algebraic solution due to Lagrange. The idea behind such a solution is to prove that the vertices of the triangle are constructible. More precisely, it is to prove that the coordinates of the vertices are roots of some quadratic polynomials with constructible coefficients. Let us recall the notion of constructibility that is relevant here. Let $\mathcal{S}$ be a given set of points in the Euclidean plane with cardinality at least 2.[1] We say that a circle is *constructible from* $\mathcal{S}$ if its center is an element of $\mathcal{S}$ and its radius is the distance between two elements of $\mathcal{S}$. We say that a line is constructible from $\mathcal{S}$ if it passes through two elements of $\mathcal{S}$. We say that a point in the Euclidean plane is *constructible in one step* from $\mathcal{S}$ if it is an intersection point of two constructible lines, one constructible line and a constructible circle, or two constructible circles. We then say that a point P of the Euclidean plane is *constructible* from $\mathcal{S}$ if there exists a finite sequence of points $P_1, P_2, \ldots, P_n = P$ such that P_1 is constructible in one step from $\mathcal{S}$ and for any i $(2 \leq i \leq n)$, the point P_i is constructible in one step from $\mathcal{S} \cup \{P_1, \ldots, P_{i-1}\}$. In particular, let us denote two points from $\mathcal{S}$ by O and I and set the distance from O to I as 1. We can now introduce the Cartesian coordinate system in the Euclidean plane where the coordinates of O and I are $(0, 0)$ and $(1, 0)$ respectively. We say that a number x is *constructible from* $\mathcal{S}$ if it is a coordinate of a constructible point from $\mathcal{S}$. It is elementary to prove that the set of constructible numbers from $\mathcal{S}$ forms a field such that the square root of any non-negative constructible number from $\mathcal{S}$ is still a constructible number from $\mathcal{S}$. In particular, a root of a quadratic polynomial with constructible (from $\mathcal{S}$) coefficients is constructible.

In the next section, we recall Lagrange's solution. We then study the problem where the given circle and the three given points are on a sphere and give a solution in the lineage of Lagrange.

2 Lagrange's solution

The problem is to construct a triangle MNP inscribed in a given circle $\mathcal{C}$ of radius r so that the three edges of the triangle NM, MP, and PN when produced pass through three given points A, B, and C respectively (see Figure 1). This construction should not require more than the given objects and a straightedge and a compass. To be more precise, the set we are dealing with consists of six points, the two points O and I defined above, the point of coordinates $(r, 0)$, and the three points A, B, and C. Let us just add that the center of the given circle can be taken as the origin O.

---

[1] We are using a modern way to formulate constructibility. Needless to say, Lagrange did not use this language of set theory or of fields.

We notice that the vertices M, N, and P are constructible if the angles $x = \widehat{AOM}$, $y = \widehat{AON}$ and $z = \widehat{AOP}$ are constructible, where an angle is said to be constructible if its sine (or equivalently cosine) is constructible. We set the lengths of segments

$$OA = a, \quad OB = b, \quad OC = c.$$

We denote the angles $\widehat{AOB}$ and $\widehat{AOC}$ by m and n. Here, 1, a, b, c, $\cos(m)$, $\cos(n)$, and r are constructible. In the triangle AON, we have

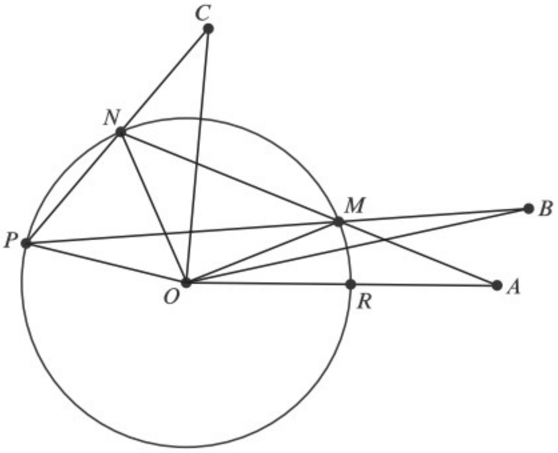

Figure 1. An inscribed triangle MNP such that NM, MP, and PN when produced pass through A, B, and C respectively

$$\widehat{ONA} = \frac{1}{2}(\pi - \widehat{NOM}) = \frac{\pi}{2} - \frac{y-x}{2}$$

and

$$\widehat{OAN} = \pi - \widehat{AON} - \widehat{ONA} = \frac{\pi}{2} - \frac{y+x}{2}.$$

Using the sine law in the triangle AON, we have

$$\frac{OA}{ON} = \frac{\sin(\widehat{ONA})}{\sin(\widehat{OAN})} \implies \frac{a}{r} = \frac{\cos\left(\frac{y-x}{2}\right)}{\cos\left(\frac{y+x}{2}\right)}.$$

This reduces to

$$\begin{aligned}
&a\Big(\cos\left(\frac{y}{2}\right)\cos\left(\frac{x}{2}\right)-\sin\left(\frac{y}{2}\right)\sin\left(\frac{x}{2}\right)\Big)\\
&\qquad=r\Big(\cos\left(\frac{y}{2}\right)\cos\left(\frac{x}{2}\right)+\sin\left(\frac{y}{2}\right)\sin\left(\frac{x}{2}\right)\Big)\\
&\implies (a-r)\cos\left(\frac{y}{2}\right)\cos\left(\frac{x}{2}\right)=(a+r)\sin\left(\frac{y}{2}\right)\sin\left(\frac{x}{2}\right)\\
&\implies \tan\left(\frac{x}{2}\right)\tan\left(\frac{y}{2}\right)=\frac{a-r}{a+r}.
\end{aligned}\tag{1}$$

In the triangle BOP, we find

$$\widehat{OPB}=\frac{\pi}{2}-\frac{z-x}{2}\quad\text{and}\quad\widehat{OBP}=\frac{\pi}{2}+m-\frac{z+x}{2}.$$

Using the sine law in the triangle BOP, we have

$$\frac{BO}{PO}=\frac{\sin(\widehat{OPB})}{\sin(\widehat{OBP})}\implies\frac{b}{r}=\frac{\cos\left(\frac{(z-m)-(x-m)}{2}\right)}{\cos\left(\frac{(z-m)+(x-m)}{2}\right)}$$

which reduces to

$$\tan\frac{x-m}{2}\tan\frac{z-m}{2}=\frac{b-r}{b+r}.\tag{2}$$

Similarly, in the triangle COP, we have

$$\widehat{OPC}=\frac{\pi}{2}-\frac{z-y}{2}\quad\text{and}\quad\widehat{OCP}=\frac{\pi}{2}+n-\frac{z+y}{2}.$$

This leads to

$$\tan\left(\frac{y-n}{2}\right)\tan\left(\frac{z-n}{2}\right)=\frac{c-r}{c+r}.\tag{3}$$

The goal is now to determine the unknowns x, y, and z from equations (1)–(3). For simplicity, let us set

$$\tan\left(\frac{x}{2}\right)=s,\quad\tan\left(\frac{y}{2}\right)=t,\quad\tan\left(\frac{z}{2}\right)=u,\quad\tan\left(\frac{m}{2}\right)=p,\quad\tan\left(\frac{n}{2}\right)=q,$$

$$\frac{a-r}{a+r}=\alpha,\quad\frac{b-r}{b+r}=\beta,\quad\frac{c-r}{c+r}=\gamma.$$

Here, α, β, γ, p, and q are constructible since a, b, c, m, n, and r are constructible. Equations (1)–(3) now become

$$s\times t=\alpha,\quad\frac{s-p}{1+ps}\times\frac{u-p}{1+pu}=\beta,\quad\frac{t-q}{1+qt}\times\frac{u-q}{1+qu}=\gamma.$$

The first and the second give

$$t = \frac{\alpha}{s} \quad \text{and} \quad u = \frac{\beta(1+ps) + p(s-p)}{(s-p) - \beta p(1+ps)}. \tag{4}$$

Substituting the first and the second in the third gives

$$\frac{\alpha - qs}{\alpha q + s} \times \frac{p(-p+q) + \beta(1+pq) + (p - q + \beta p(1+pq))s}{-(1+\beta)p + \beta q - p^2 q + (1 - \beta p^2 + (1+\beta)pq)s} = \gamma. \tag{5}$$

For conciseness, we set

$$F = p(-p+q) + \beta(1+pq) \quad \text{and} \quad G = p - q + \beta p(1+pq).$$

We also set

$$H = -(1+\beta)p + \beta q - p^2 q \quad \text{and} \quad K = 1 - \beta p^2 + (1+\beta)pq.$$

Therefore, F, G, H, and K are constructible since β, p, and q are constructible. Equation (5) now becomes

$$\frac{\alpha - qs}{\alpha q + s} \times \frac{F + Gs}{H + Ks} = \gamma$$

which implies

$$(\gamma K - Gq) \times s^2 + (\gamma H - \alpha G + \alpha q(\gamma K - F)) \times s + \alpha(\gamma H q - F) = 0. \tag{6}$$

The coefficients of this quadratic equation in s are constructible, hence s is also constructible. This implies that the right-hand sides of the two equations in (4) are constructible and thus implying that t and u are constructible. Thus

$$\cos(x) = \frac{1 - s^2}{1 + s^2}, \quad \cos(y) = \frac{1 - t^2}{1 + t^2}, \quad \cos(z) = \frac{1 - u^2}{1 + u^2}$$

are constructible. For the existence of the vertices M, N, and P, the angles $\frac{x}{2}$, $\frac{y}{2}$, and $\frac{z}{2}$ and hence the tangents s, t, and u should be real. When s is real, (4) implies $t, u \in \mathbb{R}$. Hence we have proved that when equation (6) admits real roots, a triangle exists and is constructible so that its vertices lie on a given circle and its three edges when produced pass through three given points. When equation (6) does not admit real roots, such a triangle does not exist.

Remark 2.1. We now give an example where such a triangle does not exist. Let the three given points and the centre of the given circle be collinear such that $m = n = 0$. This implies

$$p = \tan\left(\frac{m}{2}\right) = 0 \quad \text{and} \quad q = \tan\left(\frac{n}{2}\right) = 0.$$

Substituting these values, we find $F = \beta$, $G = 0$, $H = 0$, and $K = 1$. Thus, equation (6) becomes

$$\gamma \times s^2 - \alpha\beta = 0$$

with discriminant

$$4\alpha\beta\gamma = 4 \times \frac{a-r}{a+r} \times \frac{b-r}{b+r} \times \frac{c-r}{c+r}.$$

This is negative when only one of the three points is in the interior of the circle or when all three are in the interior. Thus, by continuity, there exist approximately collinear points ($m \approx n \approx 0$, $m, n \neq 0$) with either only one of the points in the interior or all three in the interior such that the discriminant is negative. In all these cases, the triangle to be inscribed does not exist.

3 Constructibility on the sphere

We define here a notion of constructibility on the sphere. This requires the use of an auxiliary Euclidean plane. Let us assume that the sphere is of radius 1. We report on the auxiliary plane two points at distance 1. Let us denote these two points by O and I. Now, let $\mathcal{S}_+$ be a set of points on the sphere. On the plane, we draw circles centered at O of radius the chord distance between two points of the given set. We set $\mathcal{S}_0$ as the set which consists of the two points O, I and the intersection points of those circles with the half-line starting at O and passing through I. We say that a circle is *constructible* from $\mathcal{S}_+$ if its pole is a point of $\mathcal{S}_+$ and the chord distance to the pole is a constructible number from $\mathcal{S}_0$. Like for the case of constructibility in the plane, we say that a point on the sphere is *constructible in one step* from $\mathcal{S}_+$ if it is an intersection point of two constructible circles. Thus, a point P on the sphere is called constructible if there exists a finite sequence of points $P_1, P_2, \ldots, P_n = P$ such that P_1 is constructible in one step from $\mathcal{S}_+$ and for $2 \leq i \leq n$, P_i is constructible in one step from $\mathcal{S}_+ \cup \{P_1, \ldots, P_{i-1}\}$.

Following our definition of constructibility on the sphere, we state some consequences which shall be useful in Section 4.

Lemma 3.1. *A great circle on the sphere is constructible if one of its poles is constructible.*

Proof. Let C be the centre of the sphere and P the constructible pole (see Figure 2). Let Q be an arbitrary point on the great circle with pole P. This implies $PC = QC = 1$ and $\widehat{PCQ} = \frac{\pi}{2}$ so that $PQ = \sqrt{2}$. Thus the chord distance of a point on the great circle from its pole is constructible on the plane implying that the great circle is constructible □

Lemma 3.2. *A geodesic through two given points on the sphere is constructible.*

Proof. Let P and Q be the two given points (see Figure 3). We construct the two great circles whose poles are P and Q respectively. Let a point of intersection be called C'. We have the chord lengths $PC' = QC' = \sqrt{2}$. Thus the great circle whose pole is C' passes through P and Q. Since C' is constructible, geodesic through P and Q is constructible. □

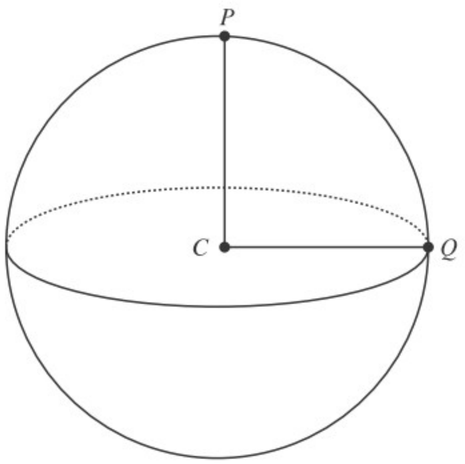

Figure 2

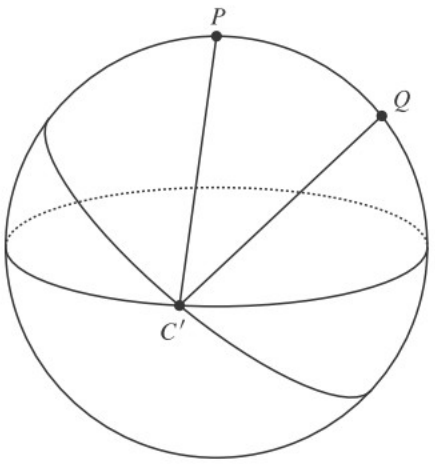

Figure 3

Lemma 3.3. *The sine of the angular separation between two constructible points on the sphere is constructible in the Euclidean plane.*

Proof. Let D and E be two given points on the sphere (see Figure 4). Construct the geodesic DE and extend it. Using a compass, find the point F on the extended geodesic so that $\mathrm{crd}(DE) = \mathrm{crd}(EF)$ where crd denotes the chord length. We have $\mathrm{crd}(DF) = 2\sin(DE)$. Since the chord distance on the sphere is constructible on the plane, $\sin(DE)$ is constructible in the Euclidean plane. ☐

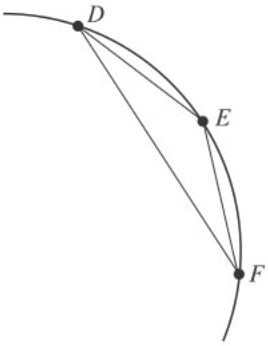

Figure 4. Determination of the sine of the angular separation between two constructible points

Lemma 3.4. *Suppose an angle θ is constructible in the Euclidean plane. Let D and E be two points on the sphere. Then, it is possible to construct a great circle arc DG such that $\widehat{EDG} = \theta$.*

Proof. Construct the great circle $\mathcal{C}_D$ with pole D. Extend the geodesic DE in the direction of E and denote the first point of intersection with this great circle by F (see Figure 5). Since θ is constructible in the Euclidean plane, $2\sin\left(\frac{\theta}{2}\right)$ is also constructible. Construct the circle $\mathcal{C}_F$ with pole F and chord distance to the pole set at $2\sin\left(\frac{\theta}{2}\right)$. Let G be a point of intersection of $\mathcal{C}_D$ and $\mathcal{C}_F$ so that $\mathrm{crd}(FG) = 2\sin\left(\frac{\theta}{2}\right)$. Thus the great circle arc FG subtends an angle θ at the centre of the sphere. Therefore, it also subtends the same angle θ at D since D is the pole of the great circle arc FG. Hence, joining DG, we have $\widehat{FDG} = \theta$. ☐

Lemma 3.5. *Suppose DE and DG are two great circle arcs on the sphere. The angle $\widehat{EDG}$ is constructible in the Euclidean plane*

Proof. The proof is very similar to that of Lemma 3.4. ☐

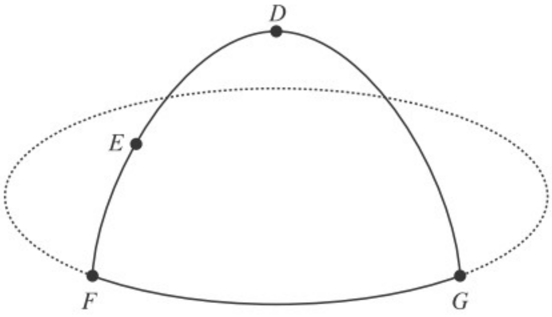

Figure 5. Given DE, constructing DG such that the angle at D is a given angle

4 Extension of the problem to spherical geometry

We now consider the extension of this construction problem to spherical geometry. Here, the problem remains to construct a triangle MNP using a straightedge and a compass whose vertices lie on a given circle $\mathcal{C}$ and whose edges when produced pass through three given points A, B, and C. However, the given circle and the three given points now lie on a sphere instead of the Euclidean plane (see Figure 6).

Let O be a pole of the circle $\mathcal{C}$. We set, as before, $OM = ON = OP = r$, $OA = a$, $OB = b$, $OC = c$, $\widehat{AOB} = m$, and $\widehat{AOC} = n$. We denote the unknown angles $\widehat{AOM}$, $\widehat{AON}$ and $\widehat{AOP}$ by x, y, and z respectively.

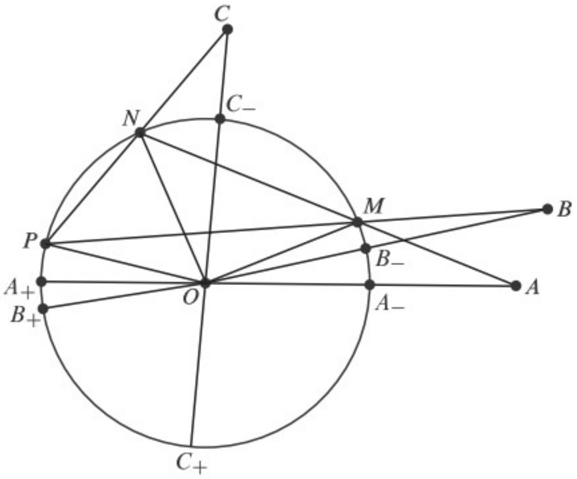

Figure 6. The circle $\mathcal{C}$ is on the surface of a sphere

By Lemma 4.2 (to be given below), the geodesic AMN intersecting the circle $\mathcal{C}$ at M and N gives the relation

$$\tan\left(\frac{x}{2}\right)\tan\left(\frac{y}{2}\right) = \frac{\sin(a-r)}{\sin(a+r)} = \alpha_+.$$

This is reminiscent of equation (1). Similarly, the geodesics BMP and CNP give identities reminiscent of equations (2) and (3):

$$\tan\left(\frac{x-m}{2}\right)\tan\left(\frac{z-m}{2}\right) = \frac{\sin(b-r)}{\sin(b+r)} = \beta_+$$

and

$$\tan\left(\frac{y-n}{2}\right)\tan\left(\frac{z-n}{2}\right) = \frac{\sin(c-r)}{\sin(c+r)} = \gamma_+.$$

As before, we set

$$\tan\left(\frac{x}{2}\right) = s, \quad \tan\left(\frac{y}{2}\right) = t, \quad \tan\left(\frac{z}{2}\right) = u, \quad \tan\left(\frac{m}{2}\right) = p, \quad \tan\left(\frac{n}{2}\right) = q.$$

Since the angles m and n are constructible on the sphere, by Lemma 3.5, they are constructible on the plane. Hence, $p = \tan\left(\frac{m}{2}\right)$ and $q = \tan\left(\frac{n}{2}\right)$ are also constructible on the plane. We also set F, G, H, and K:

$$\begin{aligned} F &= p(-p+q) + \beta_+(1+pq), \\ G &= p - q + \beta_+ p(1+pq), \\ H &= -(1+\beta_+)p + \beta_+ q - p^2 q, \\ K &= 1 - \beta_+ p^2 + (1+\beta_+)pq. \end{aligned}$$

With this notation, we obtain the equations

$$t = \frac{\alpha_+}{s}, \quad u = \frac{\beta_+(1+ps) + p(s-p)}{(s-p) - \beta_+ p(1+ps)}, \quad \frac{\alpha_+ - qs}{\alpha_+ q + s} \times \frac{F+Gs}{H+Ks} = \gamma_+. \tag{7}$$

It is clear that s, t, and u are constructible in the Euclidean plane if α_+, β_+, and γ_+ are constructible on the plane. Extending the great circle arcs OA, OB, and OC, and denoting the point of intersections with the circle by $A_\pm$, $B_\pm$, and $C_\pm$ as shown in Figure 6, we find $AA_\pm = a \pm r$, $BB_\pm = b \pm r$, and $CC_\pm = c \pm r$ that are constructible on the sphere. Hence, by Lemma 3.3, $\sin(a \pm r)$, $\sin(b \pm r)$, and $\sin(c \pm r)$ are constructible on the plane that implies α_+, β_+, and γ_+ and hence s, t, and u are constructible in the Euclidean plane. As shown before in the planar case, when $s \in \mathbb{R}$, the angles x, y, and z are real and are constructible in the Euclidean plane. By Lemma 3.4, we can construct geodesics OM, ON, and OP so that they make angles x, y, and z with OA so that the vertices M, N, and P are constructible. When $s \notin \mathbb{R}$, the required triangle does not exist. We have thus generalized the algebraic solution due to Lagrange to the spherical setting.

Remark 4.1. We give an example where the triangle to be inscribed does not exist. Consider the limiting case where the three given points A, B, and C approach O that is the pole of the given circle. In this limit, OA, OB, and OC vanish so that α_+, β_+, and γ_+ approach -1. Similarly, when A, B, and C approach the antipodal point of O, α_+, β_+, and γ_+ approach -1. In both limits,

$$-F \approx K \approx 1 + p^2 \quad \text{and} \quad G \approx H \approx -q(1 + p^2).$$

The quadratic equation in s (third equation of (7)) now becomes

$$\left(\frac{1 + qs}{q - s}\right)^2 \approx -1$$

that has no real roots. Thus, there exist A, B, and C near O (or near the antipodal point of O) so that the inscribed triangle does not exist.

It remains to prove the following lemma.

Lemma 4.2. *Let $\mathcal{C}$ be a small circle on a sphere with pole O. Let A be a point on the sphere. Let a geodesic through A intersect $\mathcal{C}$ at points M and N. Then, we have*

$$\tan\left(\frac{1}{2}\widehat{AOM}\right)\tan\left(\frac{1}{2}\widehat{AON}\right) = \frac{\sin(OA - OM)}{\sin(OA + OM)}.$$

Proof. For conciseness, let us set $OM = r$, $OA = a$, $\widehat{AOM} = x$, and $\widehat{AON} = y$ (see Figure 7). By Lemma 2.3 in [7], in the triangle AOM, we have

$$\tan(\widehat{OAM}) = \frac{2\sin(OM)}{\tan\left(\frac{1}{2}\widehat{AOM}\right)\sin(OA + OM) + \cot\left(\frac{1}{2}\widehat{AOM}\right)\sin(OA - OM)},$$

while in the triangle AON, we have

$$\tan(\widehat{OAN}) = \frac{2\sin(ON)}{\tan\left(\frac{1}{2}\widehat{AON}\right)\sin(OA + ON) + \cot\left(\frac{1}{2}\widehat{AON}\right)\sin(OA - ON)}.$$

Since $\widehat{OAN} = \widehat{OAM}$ and $OM = ON$, this implies

$$\begin{aligned}\sin(a + r)\tan\left(\frac{x}{2}\right) + \sin(a - r)\cot\left(\frac{x}{2}\right)\\ = \sin(a + r)\tan\left(\frac{y}{2}\right) + \sin(a - r)\cot\left(\frac{y}{2}\right).\end{aligned}$$

Solving for $\tan\left(\frac{x}{2}\right)$ in terms of $\tan\left(\frac{y}{2}\right)$ in this quadratic equation, we find

$$\tan\left(\frac{x}{2}\right) = \tan\left(\frac{y}{2}\right) \quad \text{or} \quad \tan\left(\frac{x}{2}\right)\tan\left(\frac{y}{2}\right) = \frac{\sin(a-r)}{\sin(a+r)}.$$

When $\tan\left(\frac{x}{2}\right) = \tan\left(\frac{y}{2}\right)$, x and y differ by an integer multiple of 2π implying that M and N coincide. Here, AM is tangent to the circle, hence $\widehat{AMO} = \frac{\pi}{2}$. Thus, we have $\cos(x) = \cot(a)\tan(r)$. This implies

$$\tan\left(\frac{x}{2}\right)\tan\left(\frac{y}{2}\right) = \tan^2\left(\frac{x}{2}\right) = \frac{1-\cos x}{1+\cos x} = \frac{\sin(a-r)}{\sin(a+r)}. \qquad \square$$

1 Introduction

The Gauss–Bonnet theorem is one of the most beautiful equations in mathematics. It says that for an orientable closed surface S in Euclidean space $\mathbb{R}^3$, the “total curvature” is equal to 2π the Euler characteristic of S. That is,

$$\iint\limits_S K\, d\sigma = 2\pi\chi(S).$$

The left-hand side is the integral of K over the whole surface S with respect to the area form $d\sigma$; here K is the Gaussian curvature at each point on the surface. The Gaussian curvature is a geometric quantity which changes as you bend, stretch or scale S in $\mathbb{R}^3$. On the other hand, the Euler characteristic $\chi(S)$ is a topological invariant, a quantity that remains constant no matter how you deform the surface. What makes the Gauss–Bonnet formula remarkable is that it elegantly connects these two very different worlds of geometry and topology.

The above *global Gauss–Bonnet theorem* follows directly from the *local Gauss–Bonnet theorem*; we state a simplified version of it below:

Theorem 1.1 (Gauss). *Let S be a surface in $\mathbb{R}^3$ and let $T = \Delta(A, B, C)$ be a geodesic triangle in S, that is, T is a simply connected subset of S which is bounded by three geodesic segments connecting three points A, B, C. Then*

$$\iint_T K\, d\sigma = (\angle A + \angle B + \angle C) - \pi.$$

Here $\angle A, \angle B, \angle C$ are the interior angles of the triangle. Thus, the right-hand side is the angle excess of T. Indeed, since T is not a planar triangle, we should expect its interior to have non-zero total curvature. In that case the theorem proves that the sum of its angles is not π, and how different it is from π depends on curvature and area of T. Important examples are when K is constant, in which case the angle excess of a triangle T is a constant multiple of its area.

Our goal is to give the reader an informal understanding of the concepts related to the above formula without developing the machinery for a rigorous proof which can be found in many textbooks. The references [1] and [4] are good sources for a complete treatment of the subject. In Section 2, we define geodesic curvature of curves on surfaces and demonstrate its relation with angles on a piecewise geodesic curve. In Section 3, we informally explain the Gaussian curvature and provide a heuristic proof of Gauss–Bonnet formulas.

It is enlightening to know the history of how these ideas developed. Given a surface S smoothly embedded in $\mathbb{R}^3$, at each point $p \in S$ there is a tangent plane T_pS containing all tangent vectors, and there is a unit normal vector $\vec{N}_p$ perpendicular to the surface. Since S is orientable there is a coherent and continuous way to choose $\vec{N}_p$ at every point p. Pick a unit tangent vector $\vec{v} \in T_pS$. There is a unique plane $P_{\vec{v}}$ containing both $\vec{N}_p$ and $\vec{v}$, and this plane intersects S along a curve γ containing p. Locally around p we can parametrize this curve $\gamma\colon [-\epsilon, \epsilon] \to S$ such that $\gamma(0) = p$, $\gamma'(0) = \vec{v}$, and such that it is unit speed. Of course the first derivative $\gamma'(t)$ gives us tangent vectors. We can differentiate again to get the second derivative $\gamma''(t)$ of acceleration vectors. Then let us define $\kappa(\vec{v})$ to be the dot product $\vec{N}_p.\gamma''(0)$. This quantity $\kappa(\vec{v})$ will be called the curvature in the $\vec{v}$ direction at p. Since the curve γ is on the plane $P_{\vec{v}}$, it is easy to see that $\kappa(\vec{v}) = \pm\|\gamma''(0)\|$ and the sign depends on whether $\gamma''(0)$ and $\vec{N}_p$ point to the same or opposite direction. The following theorem is proven by Euler [2]; it precedes Gauss' work on surfaces.

Theorem 1.2 (Euler). *Given the above notations, if $\kappa(\vec{v})$ are not all the same as $\vec{v}$ varies in the tangent plane, then there is a unit tangent vector $\vec{v}_1$ such that $k_1 = \kappa(\vec{v}_1)$ is the minimum, and a unit tangent $\vec{v}_2$ such that $k_2 = \kappa(\vec{v}_2)$ is the maximum. Moreover, $\vec{v}_1$ and $\vec{v}_2$ are perpendicular.*

Here k_1, k_2 are called the principal curvatures of S at p, and $\vec{v}_1, \vec{v}_2$ are the corresponding principal directions.

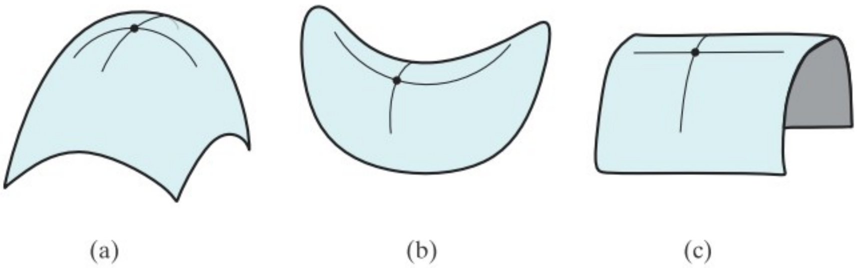
Gauss defined surface curvature as follows [3]. Let $\mathbb{S}^2$ be the unit 2-sphere in $\mathbb{R}^3$. For a smooth surface $S \subset \mathbb{R}^3$, let $\mathcal{G}: S \to \mathbb{S}^2$ be the map taking a point $p \in S$ to its unit normal vector $\vec{N}_p$. This is called the Gauss map. We have the differential map $d\mathcal{G}_p: T_pS \to T_{\mathcal{G}(p)}\mathbb{S}^2$ where T_pS is the tangent plane to S at p and $T_{\mathcal{G}(p)}\mathbb{S}^2$ is the tangent plane to the unit sphere at $\mathcal{G}(p)$.

Definition 1.3. Let $\vec{v}_1, \vec{v}_2$ be tangent vectors at p. The *Gaussian curvature* at p is defined to be

$$K = \frac{\text{Area of the parallelogram spanned by } \mathcal{G}(\vec{v}_1), \mathcal{G}(\vec{v}_2)}{\text{Area of the parallelogram spanned by } \vec{v}_1, \vec{v}_2}.$$

Of course this is an informal version of a more rigorous definition. We can think of K as the scaling factor of the Gauss map on infinitesimal area near p.

It is then showed that the curvature K at p equals the product of the principal curvatures, that is, $K = k_1k_2$. This result gives us a geometric understanding of curvature of surfaces. At a point on S, K is positive if its principal curvatures are of the same sign, which is when the principal tangent curves bend in the same direction at p; K is negative when the principal tangent curves bend in opposite directions; and K is zero when one of the principal tangent curves is flat at p. Figure 1 demonstrates the local picture around points of positive, negative, and zero curvatures.



(a) (b) (c)

Figure 1

When a surface is smoothly embedded in $\mathbb{R}^3$, it inherits an infinitesimal metric which is given in coordinates by the 1st fundamental form. This metric, later known as the Riemannian metric—a notion of distance on the surface—exists without the need of embedding the surface into 3-space. Gauss formulated a more sophisticated description of K in terms of the 1st and 2nd fundamental forms, which in turn can be computed purely using the 1st fundamental form. This result is called Gauss' *Theorema egregium* [3], translated by "remarkable theorem." Indeed the theorem shows that the curvature K depends only on the Riemannian metric of the surface, hence it is an *intrinsic* property of the surface and it can be computed purely by measurements of distances and angles on the surface. This result and the works of Bernhard Riemann that follows mark the beginning of Differential Geometry, a very important and beautiful area of mathematics.

Assuming the *Theorema Egregium*, in Section 3, we will use an informal intrinsic definition of the Gaussian curvature to prove the local Gauss–Bonnet theorem.

2 Geodesic curvature and geodesics

We will now define the notion of geodesics which will be important to understand curves on surfaces. Let S be a smooth surface in 3-space. Consider a smooth curve $\gamma\colon [a,b] \to S$ of unit speed, that is, $\|\gamma'(t)\| = 1$. At the point $\gamma(t)$, the curve's tangent vector is given by $\gamma'(t)$ and its acceleration vector is $\gamma''(t)$. Since the curve is unit speed, the acceleration vector is perpendicular to the tangent vector. (One can see this by moving the base point of vector $\gamma'(t)$ to 0, so that $\gamma'(t)$ becomes a path on the unit sphere, which makes the vector $\gamma''(t)$ tangent to this path at the point $\gamma'(t)$, hence $\gamma'(t) \perp \gamma''(t)$.) Now let $(\gamma'(t))^{\perp}$ be the plane of all vectors perpendicular to $\gamma'(t)$.

We have a natural orthonormal basis for $(\gamma'(t))^{\perp}$ given by $\{\vec{N}_{\gamma(t)}, \vec{N}_{\gamma(t)} \times \gamma'(t)\}$. Recall that $\vec{N}_{\gamma(t)}$ is the unit normal vector to the surface and $\vec{N}_{\gamma(t)} \times \gamma'(t)$ is the cross product which is perpendicular to both $\vec{N}_{\gamma(t)}$ and $\gamma'(t)$. Since $\gamma''(t) \in (\gamma'(t))^{\perp} = \operatorname{span}\{\vec{N}_{\gamma(t)}, \vec{N}_{\gamma(t)} \times \gamma'(t)\}$, we have a unique decomposition

$$\gamma''(t) = k_n(t)\vec{N}_{\gamma(t)} + k_g(t)(\vec{N}_{\gamma(t)} \times \gamma'(t))$$

for $k_n(t), k_g(t) \in \mathbb{R}$.

Definition 2.1. We define the *geodesic curvature* of the curve γ at point $p = \gamma(t)$ to be $k_g(t)$.

Definition 2.2. A geodesic on S is a unit speed curve whose geodesic curvature is 0 everywhere along the curve.

The geodesic curvature is a real valued quantity measuring how much the curve is veering left or right at a given point, left and right is distinguished by the sign of $k_g(t)$. The curve is geodesic when informally speaking it is always going straight, and more precisely, it is geodesic when the acceleration vector $\gamma''(t)$ is either 0 or perpendicular to the surface.

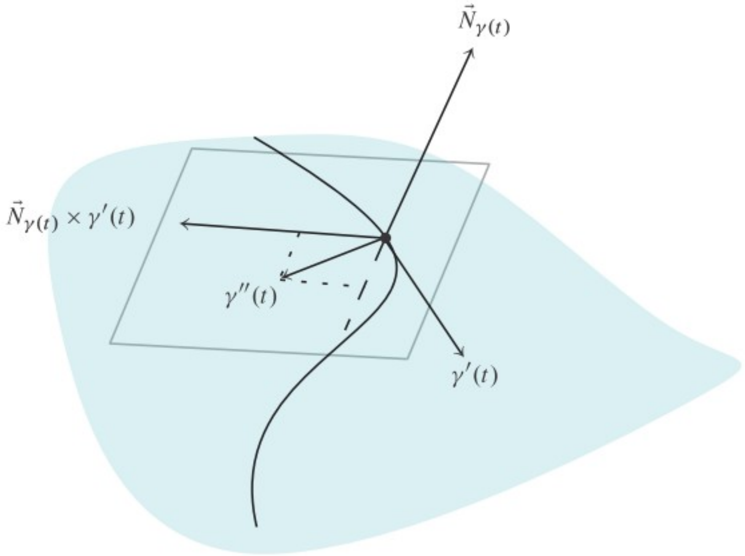


Figure 2

Using this definition one can easily see that geodesics on a plane are straight lines, and circles on a plane has constant geodesic curvature inversely proportional to the circle's radius. Indeed, suppose γ is a unit speed parametrized planar circle of radius r, so $\gamma\colon [0, 2\pi r] \to \mathbb{R}^2$ given by $\gamma(t) = \big(r\cos\big(\frac{t}{r}\big), r\sin\big(\frac{t}{r}\big)\big)$. We can check that

$$\gamma'(t) = \Big(-\sin\Big(\frac{t}{r}\Big), \cos\Big(\frac{t}{r}\Big)\Big) \quad \text{and} \quad \gamma''(t) = \frac{1}{r}\Big(-\cos\Big(\frac{t}{r}\Big), -\sin\Big(\frac{t}{r}\Big)\Big).$$

We can choose $\vec{N}_{\gamma(t)}$ so that $\vec{N}_{\gamma(t)} \times \gamma'(t) = \big(-\cos\big(\frac{t}{r}\big), -\sin\big(\frac{t}{r}\big)\big)$ thus the geodesic curvature is $k_g(t) = \frac{1}{r}$.

Note that for the case of planar circles, the acceleration vector $\gamma''(t)$ always points towards the center of the circle. Using this fact one can see that great circles on a sphere, i.e. circles which are intersection of the sphere with a plane through the center, are geodesics of the sphere.

We defined the geodesic curvature making full use of the ambient space $\mathbb{R}^3$. However, it can be defined intrinsically in a way that depends on the introduction of the unique *Levi-Civita connection* determined by the Riemannian metric. We will not develop this general machinery here.

For the remaining part of this section we will explore how geodesic curvature is related to angles. Given a smooth unit speed arc $\gamma\colon [a,b] \to S$, we can integrate the geodesic curvature with respect to arc-length:

$$\int_{\gamma} k_g \, ds = \int_{a}^{b} k_g(t) dt.$$

Think of this quantity as the *total geodesic curvature* of the arc γ. Now suppose that our surface is the $\mathbb{R}^2$ plane, we will compute the total geodesic curvature of γ as the change in direction of the tangent vector $\gamma'(t)$ as t goes from a to b. Since γ is of unit speed, we can think of $\gamma'(t)$ as a parametrized path on the unit circle $\mathbb{S}^1$. For simplicity let us suppose that $k_g(t) \geq 0$ on the whole curve γ. (For curves with k_g changing sign, we can always decompose into a concatenation of sub-arcs so that on each arc k_g is either non-positive or non-negative.) Then we have

$$\int_{a}^{b} k_g(t) dt = \int_{a}^{b} \|\gamma''(t)\| dt.$$

The right-hand side is exactly the definition of arclength for the path $\gamma'(t)$ which starts at $\gamma'(a)$ and ends at $\gamma'(b)$. Since the arc $\gamma'(t)$ is on the unit circle, its length is $\Theta + k2\pi$ where Θ is the angle between the $\gamma'(a)$ and $\gamma'(b)$ as vectors based at 0, and $k \in \mathbb{Z}$ records how many times the path $\gamma'(t)$ winds around the unit circle.

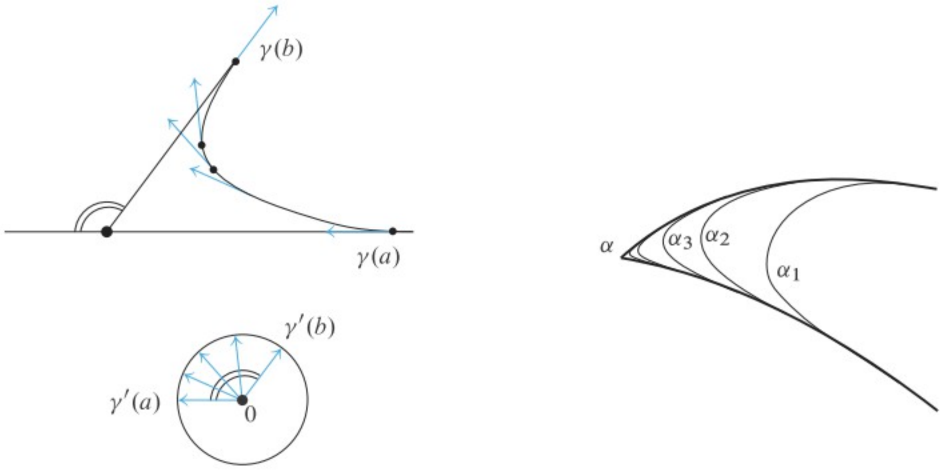
Remark 2.3. The total geodesic curvature of a planar curve γ is equal to the total amount of turning (measured by angle) of the tangent vector $\gamma'(t)$.

We also have the following claim which will be justified below.

Remark 2.4. We can think of an angle as infinitely concentrated geodesic curvature.

Consider two infinite unit speed geodesic rays $a_1, a_2\colon [0,\infty) \to S$ starting at the same point $p_0 = a_1(0) = a_2(0)$. Let $\Theta \in [0,\pi]$ be the angle between $-a_1'(0)$ and $a_2'(0)$. We let $\alpha\colon \mathbb{R} \to S$ be the piecewise geodesic curve so that $\alpha(s) = a_2(s)$ for $s \in [0,\infty)$, and $\alpha(s) = a_1(-s)$ for $s \in (-\infty, 0]$. So Θ is the *exterior angle* at the vertex $p_0 = \alpha(0)$.

One can construct a sequence of smooth curves $\alpha_1, \alpha_2, \ldots$ approximating α by smoothing out the angle as follows. Let $U_1 \supset U_2 \supset \cdots$ be a sequence of open discs all centered at p_0 such that the radius of U_i approaches 0 as $i \to \infty$. We let $\bar{U}_i = S \backslash U_i$ be their complements. We can construct smooth unit speed curves α_i so



(a) (b)

Figure 3. (a) Illustration for Remark 2.3; (b) illustration for Remark 2.4

that up to a reparametrization it agrees with α in $\bar{U}_i$. In other words, α_i agrees with α everywhere except in a small disc U_i around the vertex p_0. Integrating the geodesic curvature of these approximating curves we have

$$\int\limits_{\alpha_i} k_g\, ds = \int\limits_{\alpha_i \cap U_i} k_g\, ds + \int\limits_{\alpha_i \cap \bar{U}_i} k_g\, ds = \int\limits_{\alpha_i \cap U_i} k_g\, ds$$

since $\alpha_i \cap \bar{U}_i$ is where α_i agrees with α which have 0 geodesic curvature. Now since the U_i's are getting smaller, the geometry on U_i gets closer to planar geometry where Remark 2.3 applies. Along $\alpha_i \cap U_i$, the total turning angle for the tangent vectors $\alpha_i'(t)$ approaches Θ, so $\int_{\alpha_i \cap U_i} k_g\, ds \to \Theta$, and therefore

$$\int\limits_{\alpha} k_g\, ds = \lim_{i \to \infty} \int\limits_{\alpha_i} k_g\, ds = \Theta.$$

It makes sense for α, a curve which is geodesic except at one point, to still have a total geodesic curvature measure-concentrated at p_0. Indeed there are points on $\alpha_i \cap U_i$ where the geodesic curvature approaches infinity as i increases.

The full statement of the local Gauss–Bonnet theorem is as follows.

Theorem 2.5 (Gauss). *Let S be a surface in $\mathbb{R}^3$ and let D be an open simply connected region on S whose boundary ∂D is smooth except at n vertices where the exterior angles at these vertices are $\theta_1, \ldots, \theta_n$.*

$$\iint\limits_D K\, d\sigma = 2\pi - \left(\sum_{i=1}^{n} \theta_i + \int\limits_{\partial D} k_g\, ds \right)$$

where $\int_{\partial D} k_g\, ds$ is computed as a sum of integrals over the smooth segments of ∂D.

If $n = 0$, that is, if ∂D is smooth with no vertices, then the equation reduces to $\iint_D K\, d\sigma = 2\pi - \int_{\partial D} k_g\, ds$. This simplified case can be proven by working in an orthogonal uv-coordinate patch and writing both K and k_g in terms of the first fundamental form quantities E, G and partial derivatives. The formula follows after applying the Gauss–Green theorem. This is the rigorous approach as seen in [1].

Now suppose that ∂D has $n \geq 1$ vertices. We can approximate D by a sequence of open domains D_i with smooth boundary ∂D_i agreeing with ∂D on almost all the smooth parts and replacing the angles with short arcs of large geodesic curvature, just like our discussion following Remark 2.4. So as ∂D_i approach ∂D we have the *total measure* of geodesic curvature:

$$\lim_{D_i \to D} \int\limits_{\partial D_i} k_g\, ds = \sum_{i=1}^{n} \theta_i + \int\limits_{\partial D} k_g\, ds.$$

Moreover,

$$\lim_{D_i \to D} \iint\limits_{D_i} K\, d\sigma = \iint\limits_D K\, d\sigma.$$

Thus theorem 2.5 follows from the case where ∂D is smooth.

3 The Gauss–Bonnet theorem

One thing we did not explain was how in a coordinate patch, the Gaussian curvature can be expressed as the exterior derivative of geodesic curvature—an essential step to prove the Gauss–Bonnet theorem. To explain this we will define the curvature in a different way, hoping to informally justify the Gauss–Bonnet theorem with a different perspective.

Suppose P is a geodesic polygon on S with k vertices. We only consider the case when P bounds a simply connected interior. Let $\phi_1, \dots, \phi_k$ be the interior angles of P. We can consider following quantity representing the *angle excess of* P:

$$\delta(P) := \sum_{i=1}^{k} \phi_i - (k-2)\pi = 2\pi - \sum_{i=1}^{k} (\pi - \phi_i).$$

Note that $(k-2)\pi$ is the sum of interior angles of a Euclidean k-gon, and 2π is the sum of exterior angles. If we "add" a triangle T next to P (see Figure 4), we obtain a new geodesic polygon Q of $k+1$ vertices. Let $\alpha_1, \alpha_2, \alpha_3$ be the interior angles of T and $\beta_1, \dots, \beta_{k+1}$ be the interior angles of Q.

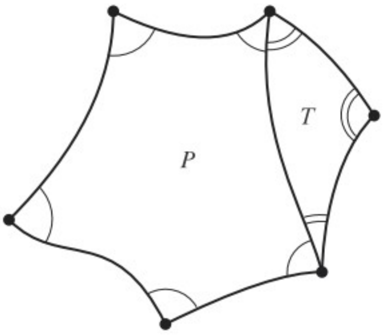


Figure 4

Remark 3.1. Angle excess is *additive*, that is, the angle excess of the new polygon Q is the sum of angle excesses of P and T:

$$\delta(Q) = \sum_{i=1}^{k+1} \beta_i - (k-1)\pi = \sum_{i=1}^{k} \phi_i - (k-2)\pi + \sum_{i=1}^{3} \alpha_i - \pi = \delta(P) + \delta(T).$$

Let p be a point on the smooth surface $S \subset \mathbb{R}^3$. Let $T = \Delta(A, B, C)$ be a geodesic triangle on S. We now define the curvature at p to be

$$K(p) = \lim_{T \to p} \frac{\delta(T)}{\text{Area}(T)} = \lim_{T \to p} \frac{(\angle A + \angle B + \angle C) - \pi}{\text{Area}(T)}.$$

The limit is taken over smaller and smaller geodesic triangles T containing p in a way such that the vertices A, B, C approach p. We will take for granted that this limit exists not depending on how the vertices approach p, and that it varies continuously as p varies in S. This is an intrinsic definition of the curvature because measurements of angles and area are taken on the surface S without refering to how S is embedded in $\mathbb{R}^3$.

Theorem 3.2 (Gauss). *Let S be a surface in $\mathbb{R}^3$ and let $T = \Delta(A, B, C)$ be a geodesic triangle in S, that is, T is a simply connected subset of S which is bounded by three geodesic segments connecting three points A, B, C. Then*

$$\iint_T K\, d\sigma = (\angle A + \angle B + \angle C) - \pi.$$

Informal proof. Since the closure of T is compact, for any $\epsilon > 0$, we can divide T into n sub-triangles $T_{\epsilon,1}, \dots, T_{\epsilon,n}$ such that each $T_{\epsilon,i}$ is of diameter less than ϵ. Here n depends on ϵ by this relation $n \approx \left(\frac{\text{diameter}(T)}{\epsilon}\right)^2$.

We choose a point $p_{\epsilon,i}$ in each $T_{\epsilon,i}$. Applying Riemann integration using the sub-triangles $T_{\epsilon,i}$ we have the following heuristic argument

$$\begin{aligned}\iint_T K\, d\sigma &= \lim_{\epsilon\to 0} \sum_{i=1}^{n} \big(K(p_{\epsilon,i}) \operatorname{Area}(T_{\epsilon,i})\big)\\ &= \lim_{\epsilon\to 0} \sum_{i=1}^{n} \frac{\delta(T_{\epsilon,i})}{\operatorname{Area}(T_{\epsilon,i})} \operatorname{Area}(T_{\epsilon,i})\\ &= \delta(T) = (\angle A + \angle B + \angle C) - \pi \qquad \text{(by Remark 3.1).}\end{aligned}$$

Therefore we obtain the local Gauss–Bonnet formula. The above argument works not only for triangles but for geodesic polygons in general. □

We have the global Gauss–Bonnet immediately after the following elegant proof.

Theorem 3.3 (Gauss). *Let S be a smooth closed surface then*

$$\iint_S K\, d\sigma = 2\pi\chi(S).$$

where $\chi(S)$ is the Euler characteristic.

Proof. We give S a triangulation by geodesic triangles T_i. Suppose that the number of vertices, edges, and faces are V, E, F respectively. We have $\chi(S) = V - E + F$ by Euler's famous formula. This is a topological invariant of the surface S not depending on the triangulation. Since each triangle has three edges, we have $3F$ equals the total number of edges double counting each edge twice, because each edge belongs to two faces. So $3F = 2E$, which implies $\chi(S) = V - E + F = V - \frac{F}{2}$.

Let $\beta_1^{(i)}, \beta_2^{(i)}, \beta_3^{(i)}$ be the interior angles of triangle T_i. Now applying Theorem 3.2 we have

$$\begin{aligned}\iint_S K\, d\sigma &= \sum_{i=1}^{F} \iint_{T_i} K\, d\sigma = \sum_{i=1}^{F} \delta(T_i)\\ &= \sum_{i=1}^{F} (\beta_1^{(i)} + \beta_2^{(i)} + \beta_3^{(i)} - \pi)\\ &= \sum_{i=1}^{F} (\beta_1^{(i)} + \beta_2^{(i)} + \beta_3^{(i)}) - F\pi\\ &= 2\pi V - F\pi\\ &= 2\pi\chi(S).\end{aligned}$$

□

Theorem 3.2 can be applied similarly to obtain a Gauss–Bonnet formula for surfaces with cone points.

Corollary 3.4. *Let S be a surface with k cone points and cone angles $\theta_1, \dots, \theta_k$, then*

$$\iint_S K\, d\sigma = 2\pi\chi(S) + \sum_{i=1}^{k} (\theta_i - 2\pi).$$

1 Introduction

The problem of cartography, that is, the problem of constructing the mappings from the sphere S^2 (or from a subset of S^2) to the Euclidean plane E^2 which are "best" in some sense is an ancient problem, and several prominent mathematicians have been studying it from antiquity to our days. The word "best" refers to mappings which present the least distortion with respect to distances, angles or areas, or a combination of these.

In the sequel, by a mapping from S^2 to E^2 we mean a map defined either on the whole sphere S^2 or, on a subset of S^2.

In 1777, Euler published three memoirs on cartography:

(i) "De repraesentatione superficiei sphaericae super plano" (On the representation of spherical surfaces on a plane) [2];

(ii) "De proiectione geographica superficiei sphaericae" (On the geographical projections of spherical surfaces) [3];

(iii) "De proiectione geographica Deslisliana in mappa generali imperii russici usitata" (On Delisle's geographic projection used in the general map of the Russian empire) [4].

In the first memoir, he studied the following three kinds of maps:

(1) maps where the images of all meridians are perpendicular to a given horizontal axis and all parallels are parallel to it;

(2) maps which are conformal;

(3) maps which preserve area and such that the images of all meridians intersect the images of the parallels at right angles.

All these maps considered by Euler will be referred to as *geographical projections*.

Two years later, Lagrange published two memoirs on cartography [6, 7] in which he observed that there exist infinitely many, essentially different, angle-preserving (conformal) projections from S^2 to E^2 in the following sense: any two are not equal and they remain so after a composition by a similarity of E^2. Subsequently, Lagrange dealt with the problem of finding the minimal deviation map amongst all these conformal projections. To that end, he defined at each point a *magnification ratio*, which is a deviation factor from conformality at this point.

In the nineteenth century, the French mathematician and cartographer Nicolas-Auguste Tissot made a thorough investigation of geographical projections from S^2 to E^2 and he studied several of their distortion properties. Following his ideas [11], we shall recall the definition of the distortion $D_f(p)$ of f at a point $p \in S_1$, see Definition 2.2 below, where $f : S_1 \to S_2$ is a non-conformal map of class C^1 between two Riemannian surfaces. After the work of Tissot, the term *quasiconformal map* was generated and the problem of existence and uniqueness of the best quasiconformal map between Riemann surfaces was revealed as an important and difficult problem.

For the origin and development of cartography and its relation with quasiconformal maps, we refer the reader to the paper by Papadopoulos [9] which inspired the author to write the present chapter. The paper [10], also by Papadopoulos, contains biographical material on Tissot, and a review of some of his main ideas. We note incidentally that both Grötzsch and Teichmüller, who are usually referred for the early work on quasiconformal maps, refer to Tissot; cf. the history in [9] and [10].

We now explain the results.

The sphere S^2 is parameterized by the map

$$\xi : (t,u) \in [-\pi,\pi] \times \left[-\frac{\pi}{2}, \frac{\pi}{2}\right] \longrightarrow (\cos(t)\cos(u), \sin(t)\cos(u), \sin(u)). \qquad (1)$$

For t fixed, the u-curves $\xi(t,\cdot)$ are the *meridians* of S^2 and are geodesics for the spherical metric. Setting $u = 0$, the curve $\xi(\cdot,0)$ is the *equator* of S^2 while the t-curves $\xi(\cdot, u)$, $u \neq 0$ are circles parallel to the equator and they are called *parallels* of S^2. The parallels are not geodesics. The circle $\xi(0, \cdot)$ will be called *prime meridian.* The pair (t, u) define the geographical coordinates of S^2, namely t is the *latitude* and u is the *longitude* of S^2. Thus, the equator and the prime meridian serve as axes of S^2 with respect to which the geographical coordinates are measured.

In what follows, we always assume that ξ is restricted to the open set $(-\pi, \pi) \times \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$ because on this set ξ is one-to-one. We shall denote by S_0 the subset $\xi\left((-\pi, \pi) \times \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)\right) \subset S^2$. By means of ξ, each point $e \in S_0$ with $e = \xi(t, u)$ will be identified with the pair (t, u) if no confusion is likely.

A differentiable map $f(t, u) = (x(t, u), y(t, u))$ from S_0 to E^2 is called *regular* if $\left(\frac{\partial x}{\partial t}, \frac{\partial y}{\partial t}\right) \neq (0, 0)$ and $\left(\frac{\partial x}{\partial u}, \frac{\partial y}{\partial u}\right) \neq (0, 0)$. We denote by $\mathcal{Q}$ the class of all regular maps of class C^r, $r \geq 2$ from S_0 to E^2 which preserve area and which send all meridians and parallels to perpendicular curves of E^2. In fact, the elements of $\mathcal{Q}$ are all the geographical projections which satisfy the third hypothesis in Euler's work [2] to which we referred to above. It is not hard to see that the elements of $\mathcal{Q}$ cannot be conformal maps.

If $f(t, u) = (x(t, u), y(t, u)) \in \mathcal{Q}$, we set

$$m_f(t, u) = \sqrt{\left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2}. \tag{2}$$

One can observe that $m(t, u)$ is the length in E^2 of the tangent vector to the curve $f(t, \cdot)$. We will be writing $m(t, u)$ if there is no confusion on the map f.

Finally, there is a simple area-preserving geographical projection $f_0 \in \mathcal{Q}$ which was introduced and studied by Lambert in [8, Section 6] (see also [12], pp.76–85). This projection, known as *Lambert's cylindrical equal area projection*, was rediscovered by Euler in [2]. It is defined by the formula

$$f_0(t, u) = (t, \sin(u)).$$

The goal of this note is to prove that the distortion $D_{f_0}(t, u)$ of f_0 has remarkable extremal properties with respect to the distortion of the maps $f \in \mathcal{Q}$, namely, for every t and u fixed the value $D_{f_0}(t, u)$ appears either as a maximum or as a minimum of the values $\{D_f(t, u),\ f \in \mathcal{Q}\}$.

We have the following theorem which permits us to estimate the deviation from conformality of the mappings $f \in \mathcal{Q}$, where the conformality structure on S^2 is induced from the standard Riemannian metric $ds = \sqrt{\cos^2(u)dt^2 + du^2}$ of S^2.

Theorem 1.1. *If $f(t, u) = (x(t, u), y(t, u)) \in \mathcal{Q}$, then for each $(t, u) \in S_0$,*

(i) $D_{f_0}(t, u) \leq D_f(t, u)$ *if* $m_f(t, u) \geq 1$ *or* $m_f(t, u) \leq \cos(u)$;

(ii) $D_{f_0}(t, u) \geq D_f(t, u)$ *if* $\cos(u) \leq m_f(t, u) \leq 1$.

In the last paragraph, following Euler's method, we will find explicit maps $f \in \mathcal{Q}$ and we will show that some of them satisfy the inequality $m_f(t,u) \leq \cos(u)$ for each $(t,u) \in S_0$. Therefore, the distortion of these maps is bounded below by the distortion of f_0 for each $(t,u) \in S_0$.

Remark 1.2. Tissot in [11, Chapitre troisième] studied concrete geographical projections which preserve area and which he referred to as "projections authaliques" (see [11], № 70). He made a thorough analysis of these projections and he calculated their distortion, in the sense of Definition 2.2 below, at certain points of the sphere including the equator and the poles. Using this, Tissot compiled numerical tables containing, among other things, useful information about the distortion of these projections (see the Complement in [11]). However, since all projections considered by Tissot are contained in the set $\mathcal{Q}$, Theorem 1.1 can be used to find estimates of their distortion which become quite accurate near the poles and the equator. For instance, for any map $f \in \mathcal{Q}$, the distortion $D_f(t,u)$ goes to infinity (resp. to 1) as (t,u) approaches the poles (resp. the equator) provided that $D_f(t,u)$ is bounded below (resp. above) by $D_{f_0}(t,u)$.

2 The distortion of area-preserving geographical projections

Let A be a linear isomorphism from E^2 to E^2 which is not conformal and let us denote by $\|\cdot\|$ the Euclidean norm. Let C_r be the circle of radius $r > 0$ centered at the origin O. It is well known that each C_r is sent by A to an ellipse L_r centered at O. Furthermore, there is a unique pair v_1, v_2 of perpendicular unit vectors of E^2 such that Av_1, Av_2 are perpendicular. This result was proven by Tissot in ([11], Chapitre Premier, № 3) by a simple continuity argument. Below, we reprove it in a geometric way.

The following proposition summarizes basic and nice properties of A which are used below.

Proposition 2.1. (1) *All the ellipses L_r are homothetic with homothety center O. If a_r is the great axis of L_r and b_r its small axis, then $a_1/b_1 = a_r/b_r$ for each r.*

The ratio a_1/b_1 is called the ***distortion*** *of A.*

(2) *There is a unique pair v_1, v_2 of perpendicular unit vectors of E^2 such that Av_1, Av_2 are perpendicular. Thus, if $\|v_1\| = \|v_2\|$ and if $\|Av_1\| > \|Av_2\|$ then $a_1/b_1 = \|Av_1\|/\|Av_2\|$.*

(3) *A and A^{-1} have the same distortion.*

Proof. Let a_1, b_1 be the great and small axis of L_1 respectively and let w_1, w_2 be normal vectors in the direction of the great and small axis of L_1 respectively with $\|w_1\| = a_1$, $\|w_2\| = b_1$. Let v_1, v_2 be unit vectors such that $A(v_1) = w_1$ and $A(v_2) = w_2$. Obviously $\|w_1\| < \|A(v)\| < \|w_2\|$ for each unit vector $v \neq v_1, v_2$. From the linearity of A we have also $\|A(\lambda v_1)\| < \|A(\lambda v)\| < \|A(\lambda v_2)\|$ and $\|A(\lambda v_1)\|/\|A(\lambda v_2)\| = \|w_1\|/\|w_2\| = a_1/b_1$. Thus statement (1) follows easily.

In order to show that the vectors v_1 and v_2 are perpendicular, we consider a circle C'_a (resp. C'_b) centered at the origin and tangent to L_1 at the two points where the great axis (resp. small axis) intersects L_1. Obviously C'_b is contained in the interior of L_1 and L_1 is contained in the interior of C'_a. Let K_a (resp. K_b) be the image of C'_a (resp. C'_b) by A^{-1}. Then K_a, K_b are homothetic ellipses centered at the origin which must be tangent to C_1 at the endpoints of the vectors v_1, v_2. This implies immediately that v_1, v_2 are perpendicular and unique and thus statement (2) is proven. Finally statement (3) follows easily from (2). ☐

The above properties of linear isomorphisms of E^2 give rise to the following definition of the distortion of a diffeomorphism of class C^1 between Riemannian surfaces, i.e. surfaces equipped with Riemannian metrics.

Definition 2.2 (distorsion). Let S_1,S_2 be two Riemannian surfaces and let $f:S_1 \to S_2$ be a diffeomorphism of class C^1. At each point $p \in S_1$ the differential df_p between the tangent spaces T_pS_1 of S_1 and the tangent space $T_{f(p)}S^2$ sends the unit circle C of T_pS_1 centered at the origin to an ellipse $L = df_p(C)$. Denoting by a and b the great and the small axis respectively of L, the *distortion* $D_f(p)$ of f at p is the distortion of the linear map df_p and is defined as the ratio a/b.

In Definition 2.2, if df_p preserves the angles then $D_f(p) = 1$ since $a = b$. Thus, if f is conformal then $D_f(p) = 1$ for each $p \in S_1$.

The real function $D_f : S_1 \to \mathbb{R}$ will be referred to as the *distortion function* of f.

As a special case, let $f : \Omega \to f(\Omega)$ be a C^1-diffeomorphism between the plane domains Ω and $f(\Omega)$. Let $z = (t, u) = t + iu$ be a coordinate system on Ω and let $w = f(z) = x + iy$ be a coordinate system on $f(\Omega)$. If we consider on Ω and $f(\Omega)$ the standard Euclidean metric, the distortion of f at $z_0 \in \Omega$ may be defined as previously and will be denoted by $\bar{D}_f(z_0)$, as a reminder of the fact that it is defined with respect to the Euclidean metric.

The following well-known formula can be found in many books (see for example [5], p. 2)

$$\bar{D}_f(z_0) = \frac{|f_z(z_0)| + |f_{\bar{z}}(z_0)|}{|f_z(z_0)| - |f_{\bar{z}}(z_0)|} \geq 1. \tag{3}$$

where $f_z = 1/2(f_t - if_u)$ and $f_{\bar{z}} = 1/2(f_t + if_u)$.

Obviously, if S_1, S_2 are Riemann surfaces and f is a C^1-diffeomorphism between them, the distortion $\bar{D}_f(p)$ can be defined for each $p \in S_1$. This can be done by covering S_1 (resp. S_2) by an atlas of charts which defines the Riemann structure on S_1 (resp. on S_2).

First, we will calculate the distortion function of the map

$$\xi \colon (-\pi, \pi) \times \left(-\frac{\pi}{2}, \frac{\pi}{2}\right) \subset E^2 \longrightarrow S_0,$$

given by formula (1). The differential $d\xi_{(t,u)}$ of the map ξ sends the vectors $v_1 = (1, 0)$ and $v_2 = (0, 1)$ of the tangent space $T_{(t,u)}E^2$ to the vectors

$$r_1 = (-\sin(t)\cos(u), \cos(t)\cos(u), 0),$$

$$r_2 = (-\cos(t)\sin(u), -\sin(t)\sin(u), \cos(u))$$

respectively, of the tangent space $T_{\xi(t,u)}S^2 \subset E^3$. If we denote by $\langle \cdot, \cdot \rangle$ the Euclidean dot product, we have

$$\langle r_1, r_2 \rangle = 0, \quad \|r_1\| = \cos(u), \quad \|r_2\| = 1.$$

This implies that the unit circle C in $T_{(t,u)}E^2$ is sent to an ellipse $L = d\xi_{(t,u)}(C)$ in $T_{\xi(t,u)}S^2$ whose great axis has length 1 and the small one has length $\cos(u)$. Therefore, the distortion $D_\xi(t, u)$ of the map ξ at (t, u) is $1/\cos(u)$. Thus, if we consider the inverse of the map ξ, say $\eta = \xi^{-1} \colon S_0 \to (-\pi, \pi) \times \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$, and if $e = \xi(t, u)$, we have

$$D_\eta(e) = \frac{1}{\cos(u)} \tag{4}$$

since from Proposition 2.1 the distortion of $d\xi_{(t,u)}$ is equal to the distortion of $d\eta_e$, where $e = \xi(t, u)$.

Now let $U = (-\pi, \pi) \times \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$ and $g \colon U \to f(U) \subset E^2$ be C^1-diffeomorphism such that the differential $dg_{(t,u)}$ sends the unit vectors $v_1 = (1, 0)$, $v_2 = (0, 1)$ of $T_{(t,u)}U$ to perpendicular vectors, say w_1, w_2 in $T_{g(t,u)}E^2$. Set $G = g \circ \eta \colon S_0 \to \mathbb{E}^2$.

We have the following lemma.

Lemma 2.3. *Let $e = \xi(t, u) \in S_0$. The distortion $D_G(t, u)$ of G at e is given by the product*

$$D_G(t, u) = \frac{1}{\cos(u)} \bar{D}_g(t, u). \tag{5}$$

Proof. Since $d\eta_e$ sends the vectors r_1, r_2 of T_eS^2 to v_1, $v_2 \in T_{(t,u)}U$ and $dg_{(t,u)}$ sends v_1, v_2 to the perpendicular vectors w_1, w_2 in $T_{g(t,u)}E^2$, the proof follows easily combining relation (4) and statement (2) of Proposition 2.1. □

Lemma 2.4. *Let* $f_0 \colon S_0 \to E^2$ *be the projection* $f_0(t,u) = (t, \sin(u))$. *Then*

$$D_{f_0}(t,u) = \frac{1}{\cos^2(u)}. \tag{6}$$

Proof. The differential $df_{0_{(t,u)}}$ is expressed by the matrix $A = \left(\begin{smallmatrix} 1 & 0 \\ 0 & \cos(u) \end{smallmatrix}\right)$. Since $A(1,0) = (1,0)$ and $A(0,1) = (0, \cos u)$, we have from statement (2) of Proposition 2.1 that $\bar{D}_{f_0}(t,u) = 1/\cos(u)$ and from Lemma 5 that $D_{f_0}(t,u) = 1/\cos^2(u)$. □

3 Proof of the main theorem

Let $f \colon S_0 \to E^2$, $f(t,u) = (x(t,u), y(t,u))$ be a geographical projection belonging to the set $\mathcal{Q}$. We recall that f is a regular, area-preserving map of class C^r, $r \geq 2$, which sends the families of meridians and parallels to families of perpendicular curves in E^2.

We start with the general formulas

$$dx = p\,du + q\,dt, \quad dy = r\,du + s\,dt, \tag{7}$$

where

$$p = \frac{\partial x}{\partial u}, \quad q = \frac{\partial x}{\partial t}, \quad r = \frac{\partial y}{\partial u}, \quad s = \frac{\partial y}{\partial t}.$$

Since the images of meridians and parallels are cut perpendicularly, $pq + rs = 0$ (see [1] or [2]). Therefore, there is a function $n(t,u)$ such that

$$s = -np, \quad q = nr. \tag{8}$$

Since f is regular, $n(t,u) \neq 0$ for each (t,u). Therefore, we may assume that n is positive. In fact, if n is negative we may work similarly.

From (7) and (8) we have

$$dx = p\,du + nr\,dt, \quad dy = r\,du - np\,dt. \tag{9}$$

Following an idea of Euler, we consider the points $e = (t,u)$, $e_1 = (t + dt, u)$, $e_2 = (t, u + du)$ in S_0 and we set

$$E = f(t,u), \quad E_1 = f(t + dt, u), \quad E_2 = f(t, u + du).$$

We have, as in [1],

$$\lim_{du\to 0}\frac{|e_2-e|}{|du|}=1,$$

$$\lim_{dt\to 0}\frac{|e_1-e|}{|dt|}=\cos(u),$$

$$\lim_{du\to 0}\frac{\|E_2-E\|}{|du|}=\sqrt{\left(\frac{\partial x}{\partial u}\right)^2+\left(\frac{\partial y}{\partial u}\right)^2}=\sqrt{p^2+r^2},$$

$$\lim_{dt\to 0}\frac{\|E_1-E\|}{|dt|}=\sqrt{\left(\frac{\partial x}{\partial t}\right)^2+\left(\frac{\partial y}{\partial t}\right)^2}=n\sqrt{p^2+r^2}.$$

Therefore, the projection f is area-preserving if and only if

$$n(p^2+r^2)|du||dt|=\cos(u)|du||dt|$$

or

$$n=\frac{\cos(u)}{p^2+r^2}. \tag{10}$$

From (9) and (10) we have

$$dx=pdu+\frac{r\cos(u)}{p^2+r^2}dt,\quad dy=rdu-\frac{p\cos(u)}{p^2+r^2}dt.$$

To simplify the calculations, we set

$$p=m\cos(\phi)\quad\text{and}\quad r=m\sin(\phi),$$

where

$$m=\sqrt{\left(\frac{\partial x}{\partial u}\right)^2+\left(\frac{\partial y}{\partial u}\right)^2}>0,$$

and we have

$$dx=m\cos(\phi)du+\frac{\cos(u)\sin(\phi)}{m}dt,\quad dy=m\sin(\phi)du-\frac{\cos(u)\cos(\phi)}{m}dt.$$

Setting $m(t,u) = k(t,u)\cos(u)$ we have $k(t,u) > 0$ for each (t,u) and the relations above take the form

$$dx = k\cos(u)\cos(\phi)du + \frac{\sin(\phi)}{k}dt, \quad dy = k\cos(u)\sin(\phi)du - \frac{\cos(\phi)}{k}dt. \tag{11}$$

We may verify immediately that a solution of (11) is obtained by setting $k = 1$, $\phi = \frac{\pi}{2}$. Thus we have

$$x(t,u) = t, \quad y(t,u) = \sin(u)$$

which gives Lambert's equal area projection.

Remark 3.1. Setting $k = a$, $\phi = \varphi_0$, where a, φ_0 are arbitrary constants, the formulas

$$x(t,u) = a\sin(u)\cos(\varphi_0) + \frac{t\sin(\varphi_0)}{a}, \quad y(t,u) = a\sin(u)\sin(\varphi_0) - \frac{t\cos(\varphi_0)}{a}$$

determine a more general solution of (11). This solution differs from the previous one only in that the meridians are no longer normal to the x-axis. Actually, it is not hard to show that if k is constant in the relation (11) then the angle ϕ must be constant.

Now we can prove Theorem 1.1, which is restated below.

Theorem 1.1*. *For each* $f \in \mathcal{Q}$,

(i) *if* $m_f(t,u) \geq 1$ *or* $m_f(t,u) \leq \cos(u)$, *then*

$$D_{f_0}(t,u) = \frac{1}{\cos^2(u)} \leq D_f(t,u);$$

(ii) *if* $\cos(u) \leq m_f(t,u) \leq 1$, *then*

$$D_{f_0}(t,u) = \frac{1}{\cos^2(u)} \geq D_f(t,u).$$

Proof. From (11) we have

$$\frac{\partial x}{\partial(u)} = k\cos(u)\cos(\phi), \quad \frac{\partial x}{\partial t} = \frac{\sin(\phi)}{k},$$

$$\frac{\partial y}{\partial u} = k\cos(u)\sin(\phi), \quad \frac{\partial y}{\partial t} = -\frac{\cos(\phi)}{k}.$$

Therefore, we may compute immediately the Jacobian of f and verify that it sends the tangent vectors $v_1 = (1,0)$ and $v_2 = (0,1)$ of $T_{(t,u)}E^2$ to the perpendicular vectors $w_1 = \big(\sin\big(\frac{\phi}{k}\big), -\cos\big(\frac{\phi}{k}\big)\big)$ and $w_2 = (k\cos(u)(\phi), k\cos(u)\sin(\phi))$ of $T_{f(t,u)}\mathbb{E}^2$. Thus Lemma 2.3 can be applied and we have

$$D_f(t,u) = \frac{1}{\cos(u)}\bar{D}_f(t,u).$$

In order to compute the term $\bar{D}_f(t,u)$, we use formula (3) and the formulas

$$A(t,u) = f_z = \frac{1}{2}(f_t - i f_u) = \frac{1}{2}\Big(\Big(\frac{\partial x}{\partial t} + \frac{\partial y}{\partial u}\Big) + i\Big(\frac{\partial y}{\partial t} - \frac{\partial x}{\partial u}\Big)\Big), \tag{12a}$$

$$B(t,u) = f_{\bar{z}} = \frac{1}{2}(f_t + i f_u) = \frac{1}{2}\Big(\Big(\frac{\partial x}{\partial t} - \frac{\partial y}{\partial u}\Big) + i\Big(\frac{\partial y}{\partial t} + \frac{\partial x}{\partial u}\Big)\Big). \tag{12b}$$

Therefore the equality

$$f_z = \frac{1}{2}\Big(\Big(\frac{\sin(\phi)}{k} + k\cos(u)\sin(\phi)\Big) + i\Big(-\frac{\cos(\phi)}{k} - k\cos(u)\cos(\phi)\Big)\Big)$$

implies

$$\begin{aligned}
|f_z| &= \frac{1}{2}\sqrt{\Big(\frac{\sin(\phi)}{k} + k\cos(u)\sin(\phi)\Big)^2 + \Big(-\frac{\cos(\phi)}{k} - k\cos(u)\cos(\phi)\Big)^2} \\
&= \frac{1}{2}\sqrt{\frac{1}{k^2} + k^2\cos^2(u) + 2\cos(u)} \\
&= \frac{1}{2}\sqrt{\Big(\frac{1}{k} + k\cos(u)\Big)^2} \\
&= \frac{1}{2}\Big|\frac{1}{k} + k\cos(u)\Big|.
\end{aligned}$$

So,

$$|A(t,u)| = \frac{1}{2}\Big|\frac{1}{k(t,u)} + k(t,u)\cos(u)\Big| = \frac{1}{2}\Big(\frac{1}{k(t,u)} + k(t,u)\cos(u)\Big) > 0. \tag{13a}$$

Similarly, we may prove that

$$|B(t,u)| = \frac{1}{2}\Big|\frac{1}{k(t,u)} - k(t,u)\cos(u)\Big|. \tag{13b}$$

We also have

$$1 \le 1/\sqrt{\cos(u)} \le \frac{1}{\cos(u)}.$$

These quantities separate the real line into four intervals. Therefore, we distinguish the following cases, depending on which interval the value $k(t,u)$ is located in.

CASE I: $k(t,u) \geq 1/\sqrt{\cos(u)}$. This is equivalent to

$$m(t,u) = k(t,u)\cos(u) \geq \sqrt{\cos(u)}.$$

Then, $(k(t,u))^2 \geq 1/\cos(u) \implies 1/k(t,u) - k(t,u)\cos(u) \leq 0$ and from (13) we have

$$|B(t,u)| = \frac{1}{2}\Big|\frac{1}{k(t,u)} - k(t,u)\cos(u)\Big| = \frac{1}{2}\Big(-\frac{1}{k(t,u)} + k(t,u)\cos(u)\Big). \quad (14)$$

Therefore, from (13a) and (14), we have

$$\bar{D}_f(t,u) = \frac{|A(t,u)| + |B(t,u)|}{|A(t,u)| - |B(t,u)|} = (k(t,u))^2\cos(u). \quad (15)$$

Now we distinguish the following two subcases.

SUBCASE $\mathrm{I_a}$: $k(t,u) \geq 1/\cos(u)$. We have $m(t,u) = k(t,u)\cos(u) \geq 1$, and thus

$$k(t,u) \geq \frac{1}{\cos(u)} \implies (k(t,u))^2 \geq \frac{1}{\cos^2(u)}.$$

Combining the last relation with (15),

$$\bar{D}_f(t,u) = (k(t,u))^2\cos(u) \geq \frac{1}{\cos(u)} = \bar{D}_{f_0}(t,u)$$

and Lemma 2.3 implies that

$$D_{f_0}(t,u) = \frac{1}{\cos^2(u)} \leq D_f(t,u) = (k(t,u))^2.$$

SUBCASE $\mathrm{I_b}$: $1/\sqrt{\cos(u)} \leq k(t,u) \leq 1/\cos(u)$. We have $\sqrt{\cos(u)} \leq m(t,u) \leq 1$, and therefore the equality

$$\bar{D}_f(t,u) = (k(t,u))^2\cos(u) \leq \bar{D}_{f_0}(t,u) = \frac{1}{\cos(u)}$$

implies

$$D_f(t,u) = (k(t,u))^2 \leq D_{f_0}(t,u) = \frac{1}{\cos^2(u)}.$$

CASE II: $k(t,u) \le 1/\sqrt{\cos(u)}$. This is equivalent to

$$m(t,u) = k(t,u)\cos(u) \le \sqrt{\cos(u)}.$$

First, we remark that

$$k(t,u) \le 1/\sqrt{\cos(u)} \iff 1/k(t,u) - k(t,u)\cos(u) \ge 0$$
$$\implies |B| = \frac{1}{2}\left|\frac{1}{k(t,u)} - k(t,u)\cos(u)\right| = \frac{1}{2}\Big(\frac{1}{k(t,u)} - k(t,u)\cos(u)\Big).$$

Therefore,

$$\bar{D}_f(t,u) = \frac{|A(t,u)| + |B(t,u)|}{|A(t,u)| - |B(t,u)|} = \frac{1}{(k(t,u))^2\cos(u)}. \tag{16}$$

We distinguish the following two subcases.

SUBCASE $\mathrm{II_a}$: $k(t,u) \le 1$. We have $m(t,u) \le \cos(u)$. So, from (16), the equality

$$\bar{D}_{f_0}(t,u) = \frac{1}{\cos(u)} \le \bar{D}_f = \frac{1}{(k(t,u))^2\cos(u)}$$

implies

$$D_{f_0}(t,u) = \frac{1}{\cos^2(u)} \le D_f = \frac{1}{(k(t,u))^2\cos^2 u}.$$

SUBCASE $\mathrm{II_b}$: $1 \le k(t,u) \le 1/\sqrt{\cos(u)}$. We have $m(t,u) \le \sqrt{\cos(u)}$. Thus the equality

$$\bar{D}_f(t,u) = \frac{1}{k^2\cos(u)} \le \bar{D}_{f_0}(t,u) = \frac{1}{\cos(u)}$$

implies

$$D_f(t,u) = \frac{1}{k^2\cos^2(u)} \le D_{f_0}(t,u) = \frac{1}{\cos^2(u)}. \qquad \square$$

Remark 3.2. For a geographical projection $f \in \mathcal{Q}$ we may compute the distortion $\bar{D}_f(t,u)$ at a point $(t,u) \in S_0$ in a more direct way, without using formula (3). Indeed, we have seen that the differential $df_{(t,u)}$ sends the tangent vectors $v_1 = (1,0)$ and $v_2 = (0,1)$ of $T_{(t,u)}E^2$ to the perpendicular vectors $w_1 = (\sin(\phi)/k, -\cos(\phi)/k)$ and $w_2 = (k\cos(u)\cos(\phi), k\cos(u)\sin(\phi))$ of $T_{f(t,u)}E^2$ respectively. On the other hand, we have $\|w_1\| = 1/k$ and $\|w_2\| = k\cos(u)$. Therefore, considering the cases $\mathrm{I_a}$, $\mathrm{I_b}$, $\mathrm{II_a}$, and $\mathrm{II_b}$ above, we may find which of the the values $\|w_1\|$ and $\|w_2\|$ are greater and calculate the term $\bar{D}_f(t,u)$.

Now, we will show that there exist geographical projections f from S_0 to E^2 which satisfy $m_f(t,u) \leq \cos(u)$ for each $(t,u) \in (-\pi,\pi) \times \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$. In fact in [2] (see p. 36ff of the corresponding translation), Euler resolves the system of equations (11) finding particular solutions as follows.

Setting $v = \sin(u)$ in (11), we get

$$dx = k\cos(\phi)dv + \frac{\sin(\phi)}{k}dt, \quad dy = k\sin(\phi)dv - \frac{\cos(\phi)}{k}dt.$$

Assuming that k is a function only of v which is equal to V and the angle ϕ is a function only of t and equal to T,

$$dx = V\cos(T)dv + \frac{\sin(T)}{V}dt, \quad dy = V\sin(T)dv - \frac{\cos(T)}{V}dt. \tag{17}$$

From equations (17) we obtain

$$x = \cos(T)\int Vdv = \frac{1}{V}\int \sin(T)dt \tag{18a}$$

and

$$y = \sin(T)\int Vdv = -\frac{1}{V}\int \cos(T)dt. \tag{18b}$$

Therefore,

$$V\int Vdv = \frac{1}{\cos(T)}\int \sin(T)dt = a$$

and

$$-V\int Vdv = \frac{1}{\sin(T)}\int \cos(T)dt = -a.$$

where a is a constant. Differentiating the relation $\int Vdv = a/V$ with respect to the variable v, we have

$$Vdv = -\frac{adV}{V^2} \implies dv = -\frac{adV}{V^3}$$

and integrating we have

$$v + c = \frac{a}{2V^2} \implies V = \sqrt{\frac{a}{2(v+c)}}, \tag{19}$$

where c is a constant and $a/(v+c) > 0$.

Similarly, for the function T, we have

$$\int \sin(T)dt = a\cos(T) \quad \text{and} \quad \int \cos(T)dt = -a\sin(T).$$

Differentiating one of these relations we have

$$dT = -\frac{dt}{a} \implies T = -\frac{t}{a}.$$

Finally, for (19) by a simple integration, we obtain

$$\int Vdv = \sqrt{2a(v+c)},$$

hence

$$\begin{cases} x = \sqrt{2a(v+c)}\cos\left(\frac{t}{a}\right) = \sqrt{2a(\sin(u)+c)}\cos\left(\frac{t}{a}\right), \\ y = -\sqrt{2a(v+c)}\sin\left(\frac{t}{a}\right) = \sqrt{2a(\sin(u)+c)}\sin\left(\frac{t}{a}\right). \end{cases} \tag{20}$$

From (20), it follows that

$$\begin{cases} \frac{y}{x} = -\tan\left(\frac{t}{a}\right), \\ \sqrt{x^2+y^2} = \sqrt{2a(v+c)}. \end{cases} \tag{21}$$

From the first equation in (21), it is clear that all meridians are represented by straight lines emerging as radii from a single fixed point. The second formula implies that all parallels are portrayed as concentric circles. These projections are referred to as *azimuthal geographical projections*.

Finally from (20), we have

$$m^2(t,u) = \left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2 = \frac{\cos^2(u)}{2a(\sin(u)+c)}$$

and it is not difficult to see that there are constants a and c such that $m(t,u) \leq \cos(u)$ for each $(t,u) \in S_0$.

Acknowledgements. The author would like to thank Vincent Alberge and Athanase Papadopoulos for very helpful suggestions and observations which improved this work in many ways.

1 Geometry of polygons

1.1 Heron's theorem

Heron of Alexandria (c. 60 BC) is credited with the following formula that relates the area S of a triangle to its side lengths a, b, c:

$$S^2 = (s-a)(s-b)(s-c)s, \tag{1}$$

where $s = \frac{1}{2}(a+b+c)$ is the semiperimeter.

In the present section of our work we deal with the hyperbolic plane instead of the Euclidean one. The hyperbolic plane under consideration is equipped with a Riemannian metric of constant curvature $k = -1$. All the necessary definitions from hyperbolic geometry can be found in the book [8].

By definition, a *cyclic polygon* in the hyperbolic plane is a convex polygon inscribed in a curve of constant geodesic curvature (i.e. circle, horocycle or one branch of an equidistant line). Useful information about cyclic polygons can be found in [62] and [63]. In particular, it is shown in [62] that any cyclic polygon in the hyperbolic plane is uniquely determined (up to isometry) by the ordered sequence of its side lengths. In addition, among all hyperbolic polygons with fixed positive side lengths there exist polygons of maximal area. Every such a maximal polygon is cyclic (see [63]).

The following four non-Euclidean versions of Heron's formula in the hyperbolic plane are known since a long time.

Theorem 1.1 (Heron's formula in $\mathbb{H}^2$). *Let T be a hyperbolic triangle with side lengths a, b, c. Then its area $S = S(T)$ is given by each of the following formulas*:

(i) *sine of $\frac{1}{2}$ area formula,*

$$\sin^2\left(\frac{1}{2}S\right) = \frac{\sinh(s-a)\sinh(s-b)\sinh(s-c)\sinh(s)}{4\cosh^2\left(\frac{1}{2}a\right)\cosh^2\left(\frac{1}{2}b\right)\cosh^2\left(\frac{1}{2}c\right)};$$

(ii) *tangent of $\frac{1}{4}$ area formula,*

$$\tan^2\left(\frac{1}{4}S\right) = \tanh\left(\frac{1}{2}(s-a)\right)\tanh\left(\frac{1}{2}(s-b)\right)\tanh\left(\frac{1}{2}(s-c)\right)\tanh\left(\frac{1}{2}s\right);$$

(iii) *sine of $\frac{1}{4}$ area formula,*

$$\sin^2\left(\frac{1}{4}S\right) = \frac{\sinh\left(\frac{1}{2}(s-a)\right)\sinh\left(\frac{1}{2}(s-b)\right)\sinh\left(\frac{1}{2}(s-c)\right)\sinh\left(\frac{1}{2}s\right)}{\cosh\left(\frac{1}{2}a\right)\cosh\left(\frac{1}{2}b\right)\cosh\left(\frac{1}{2}c\right)};$$

(iv) *Bilinski formula,*

$$\cos\left(\frac{1}{2}S\right) = \frac{\cosh(a)+\cosh(b)+\cosh(c)+1}{4\cosh\left(\frac{1}{2}a\right)\cosh\left(\frac{1}{2}b\right)\cosh\left(\frac{1}{2}c\right)}.$$

The first two formulas are contained in the book [8], p. 66. The third formula can be obtained by square root extraction of the product of the first two. The fourth one was derived by Stanko Bilinski in [14] (see also [63]).

It should be noted that the analogous formulas in spherical space were known before the hyperbolic ones. For example, the spherical version of (i) is called Cagnoli's Theorem (see [58], Section 100), (ii) is called Lhuilier's Theorem (see [58], Section 102), formula (iv) is due to Euler (see [25]). The proofs of (iii) and (iv) can be found in [58] (Section 103).

1.2 Ptolemy's theorem and annex

We recall a few well-known facts about cyclic quadrilaterals. A convex Euclidean quadrilateral with interior angles A, B, C, D is cyclic if and only if $A+C = B+D = \pi$. A similar result for a hyperbolic quadrilateral was obtained by V. F. Petrov [46] and L. Wimmer [65]. They proved the following result.

Theorem 1.2 (Petrov, 2009, [46]; Wimmer, 2011, [65]). *A convex hyperbolic quadrilateral with interior angles A, B, C, D is cyclic if and only if $A + C = B + D$.*

Note that the sum of angles of a hyperbolic quadrilateral is less than 2π. Hence, for any cyclic hyperbolic quadrilateral we have $A + C = B + D < \pi$.

It was shown in [62] that a cyclic n-gon is uniquely determined up to isometry by the lengths of its sides. Denote the side and diagonal lengths of a quadrilateral as indicated in Figure 1. Then, in the Euclidean case, a quadrilateral is cyclic if and only if $ef = a\,c + b\,d$. This is Ptolemy's theorem. A spherical version of Ptolemy's theorem was established by Darboux and Frobenius. It can be found in the book [37] (p. 180, Proposition 4). In hyperbolic geometry, Ptolemy's identity was proposed by T. Kubota [34] and J. E. Valentine [60].

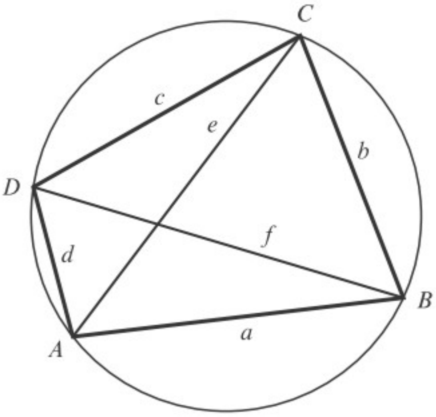

Figure 1. A cyclic quadrilateral Q with angles A, B, C, D

Theorem 1.3 (Ptolemy's identity in $\mathbb{H}^2$). *A convex hyperbolic quadrilateral with side lengths a, b, c, d and diagonal lengths e, f is cyclic if and only if*

$$\sinh\Big(\frac{1}{2}e\Big)\sinh\Big(\frac{1}{2}f\Big) = \sinh\Big(\frac{1}{2}a\Big)\sinh\Big(\frac{1}{2}c\Big) + \sinh\Big(\frac{1}{2}b\Big)\sinh\Big(\frac{1}{2}d\Big).$$

An important supplement to Ptolemy's theorem is the following property of a cyclic quadrilateral in the Euclidean plane. Its side and diagonal lengths are related by the equation

$$\frac{e}{f} = \frac{a\,d + b\,c}{a\,b + c\,d}. \tag{2}$$

Together with Ptolemy's theorem this equation allows one to express the diagonal lengths of a cyclic quadrilateral in terms of its side lengths.

It was noted in [28] that a similar relationship between the sides and diagonals of a cyclic quadrilateral is valid also in hyperbolic geometry. To make the statement true, one can replace the side length a by the quantity $s(a) = \sinh\left(\frac{1}{2}a\right)$. In particular, formula (2) can be rewritten in the following way.

Theorem 1.4. *The side lengths a, b, c, d and diagonal lengths e, f of a cyclic hyperbolic quadrilateral are related by the following equation*

$$\frac{s(e)}{s(f)} = \frac{s(a)s(d) + s(b)s(c)}{s(a)s(b) + s(c)s(d)}.$$

By making use of Theorems 1.3 and 1.4 we derive the following formulas for the diagonal lengths e, f of a cyclic hyperbolic quadrilateral. Then we have

$$s^2(e) = \frac{s(a)s(d) + s(b)s(c)}{s(a)s(b) + s(c)s(d)}(s(a)s(c) + s(b)s(d)), \tag{3}$$

$$s^2(f) = \frac{s(a)s(b) + s(c)s(d)}{s(a)s(d) + s(b)s(c)}(s(a)s(c) + s(b)s(d)). \tag{4}$$

Note that formulas (3) and (4) take place also in Euclidean and spherical geometries. In these cases, instead of the function $s(a)$ one should take the functions $s(a) = a$ and $s(a) = \sin\left(\frac{1}{2}a\right)$ respectively. See [23] and [28] for the arguments in the spherical case.

The above theorems will be used in the next section to obtain a few versions of Brahmagupta's formula for a cyclic hyperbolic quadrilateral.

1.3 Brahmagupta's formula

For polygons with more than three sides, the side lengths do not in general determine the area, but they do if the polygon is convex and cyclic (inscribed in a circle). Brahmagupta, in the seventh century, gave the following formula for a convex cyclic quadrilateral with side lengths a, b, c, d:

$$S^2 = (s-a)(s-b)(s-c)(s-d), \tag{5}$$

where $s = \frac{1}{2}(a+b+c+d)$. See [21], p. 56 for an elementary proof. An interesting consideration of the problem can be found in Möbius's paper [41]. Independently, D. P. Robbins [50] and V. V. Varfolomev [61] found a way to generalize these formulas. The main idea of both papers was to determine the squared area S^2 as a root of an algebraic equation whose coefficients are integer polynomials in the squares of the side lengths. See also [26], [18], and [51] for more detailed considerations.

One can consider Brahmagupta's formula as a generalization of Heron's formula (1).

In this section we consider the four versions of Brahmagupta's formula for a cyclic hyperbolic quadrilateral given by the second named author [38]. They are generalizations of the respective statements (i)–(iv) of Theorem 1.1.

In particular, the first statement (i) has the following analog.

Theorem 1.5 (sine of $\frac{1}{2}$ area formula). *Let Q be a cyclic hyperbolic quadrilateral with side lengths a, b, c, d. Then its area $S = S(Q)$ is given by the formula*

$$\sin^2\Big(\frac{1}{2}S\Big) = \frac{1}{4\mathfrak{N}}\sinh(s-a)\sinh(s-b)\sinh(s-c)\sinh(s-d)(1-\varepsilon),$$

where

$$\mathfrak{N} = \cosh^2\Big(\frac{1}{2}a\Big)\cosh^2\Big(\frac{1}{2}b\Big)\cosh^2\Big(\frac{1}{2}c\Big)\cosh^2\Big(\frac{1}{2}d\Big),$$

$$\varepsilon = \frac{\sinh\big(\frac{1}{2}a\big)\sinh\big(\frac{1}{2}b\big)\sinh\big(\frac{1}{2}c\big)\sinh\big(\frac{1}{2}d\big)}{\cosh\big(\frac{1}{2}(s-a)\big)\cosh\big(\frac{1}{2}(s-b)\big)\cosh\big(\frac{1}{2}(s-c)\big)\cosh\big(\frac{1}{2}(s-d)\big)}$$

and

$$s = \frac{1}{2}(a+b+c+d).$$

Note that the value ε vanishes if $d = 0$. In this case, we get formula (i) again.

Proofs of this theorem and subsequent theorems will be given later, at the end of this section.

The second statement for the case of a hyperbolic quadrilateral has the following form.

Theorem 1.6 (tangent of $\frac{1}{4}$ area formula). *Let Q be a cyclic hyperbolic quadrilateral with side lengths a, b, c, d. Then its area $S = S(Q)$ is given by the formula*

$$\tan^2\Big(\frac{1}{4}S\Big) = \frac{\sinh\big(\frac{1}{4}(-a+b+c+d)\big)\sinh\big(\frac{1}{4}(a-b+c+d)\big)}{\cosh\big(\frac{1}{4}(a+b-c-d)\big)\cosh\big(\frac{1}{4}(a-b+c-d)\big)} \frac{\sinh\big(\frac{1}{4}(a+b-c+d)\big)\sinh\big(\frac{1}{4}(a+b+c-d)\big)}{\cosh\big(\frac{1}{4}(a-b-c+d)\big)\cosh\big(\frac{1}{4}(a+b+c+d)\big)}.$$

It follows from Theorem 1.5 that for any $a, b, c, d \neq 0$ we have $1-\varepsilon > 0$ and $\varepsilon > 0$. Hence, $0 < \varepsilon < 1$. Taking into account these inequalities as an immediate consequence of Theorems 1.5 and 1.6 we obtain the following corollary.

Corollary 1.7. *For any cyclic hyperbolic quadrilateral the following inequalities take place*:

$$\sin^2\left(\frac{1}{2}S\right) < \frac{1}{4\mathfrak{N}}\sinh(s-a)\sinh(s-b)\sinh(s-c)\sinh(s-d)$$

and

$$\tan^2\left(\frac{1}{2}S\right) > \tanh\left(\frac{1}{2}(s-a)\right)\tanh\left(\frac{1}{2}(s-b)\right)\tanh\left(\frac{1}{2}(s-c)\right)\tanh\left(\frac{1}{2}(s-d)\right).$$

By squaring the product of the formulas in Theorems 1.5 and 1.6 we obtain the following result. It can be considered as a direct generalization of statement (iii) in Theorem 1.1.

Theorem 1.8 (sine of $\frac{1}{4}$ area formula). *Let Q be a cyclic hyperbolic quadrilateral with side lengths a, b, c, d. Then its area $S = S(Q)$ is given by the formula*

$$\sin^2\left(\frac{1}{4}S\right) = \frac{1}{\mathfrak{N}'}\sinh\left(\frac{1}{2}(s-a)\right)\sinh\left(\frac{1}{2}(s-b)\right)\sinh\left(\frac{1}{2}(s-c)\right)\sinh\left(\frac{1}{2}(s-d)\right),$$

where

$$\mathfrak{N}' = \cosh\left(\frac{1}{2}a\right)\cosh\left(\frac{1}{2}b\right)\cosh\left(\frac{1}{2}c\right)\cosh\left(\frac{1}{2}d\right)$$

and

$$s = \frac{1}{2}(a+b+c+d).$$

The analogous formula in spherical space can be obtained by replacing sinh and cosh by sin and cos correspondingly (see [37], p. 182, Proposition 5).

Consider a circumscribed quadrilateral Q with side lengths a, b, c, d (Figure 2). In this case we have $a+c = b+d$, hence $s-a = c,\ s-b = d,\ s-c = a,\ s-d = b$. As a result we obtain the following assertion.

Corollary 1.9 (Brahmagupta's formula for bicentric quadrilateral). *Let Q be a bicentric* (*i.e. inscribed and circumscribed*) *hyperbolic quadrilateral with side lengths a, b, c, d. Then its area $S = S(Q)$ is given by the formula*

$$\sin^2\left(\frac{1}{4}S\right) = \tanh\left(\frac{1}{2}a\right)\tanh\left(\frac{1}{2}b\right)\tanh\left(\frac{1}{2}c\right)\tanh\left(\frac{1}{2}d\right).$$

The analogous formula in spherical space can be given by replacing tanh with tan (see [37], p. 46). A Euclidean version of this result is well known (see, e.g., [31]). In that case

$$S^2 = a\,b\,c\,d.$$

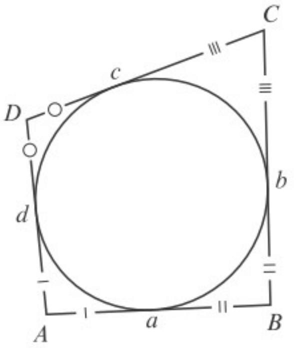

Figure 2. A circumscribed cyclic quadrilateral Q with side lengths a, b, c, d

The next theorem [38] presents a version of the Bilinski formula for a cyclic quadrilateral.

Theorem 1.10 (Bilinski formula). *Let Q be a cyclic hyperbolic quadrilateral with side lengths a, b, c, d. Then its area $S = S(Q)$ is given by the formula*

$$\cos\left(\frac{1}{2}S\right) = \frac{1}{4\mathfrak{N}'}\Big(\cosh a + \cosh b + \cosh c + \cosh d \\ - 4\sinh\left(\frac{1}{2}a\right)\sinh\left(\frac{1}{2}b\right)\sinh\left(\frac{1}{2}c\right)\sinh\left(\frac{1}{2}d\right)\Big).$$

Now we outline the proof of Theorems 1.5, 1.6, 1.8, and 1.10.

Proof. Consider a cyclic hyperbolic quadrilateral Q with side lengths a, b, c, d and interior angles A, B, C, D shown in Figure 1. By the Gauss–Bonnet formula we get the area

$$S = S(Q) = 2\pi - A - B - C - D.$$

To prove Theorem 1.5 let us find the quantities $\sin^2\left(\frac{1}{4}S\right)$ and $\cos^2\left(\frac{1}{4}S\right)$ in terms of a, b, c, d. Since $A + C = B + D$ (see Proposition 1.2) we have

$$2\sin^2\left(\frac{1}{4}S\right) = 1 - \cos\left(\frac{1}{2}S\right) = 1 - \cos(\pi - (A + C)) = 1 + \cos(A + C).$$

Hence,

$$\sin^2\left(\frac{1}{4}S\right) = \frac{1}{2}(1 + \cos(A)\cos(C) - \sin(A)\sin(C)). \tag{6}$$

Now we show that $\cos(A)$, $\cos(C)$, and the product $\sin(A)\sin(C)$ can be expressed in terms of elementary functions in a, b, c, d. To find $\cos(A)$ we use the Cosine rule for the hyperbolic triangle ABD.

$$\cos(A) = \frac{\cosh(a)\cosh(d) - \cosh(f)}{\sinh(a)\sinh(d)}. \tag{7}$$

We note that $\cosh(f) = 2s^2(f) + 1$, $\cosh(a) = 2s^2(a) + 1$, and $\cosh(d) = 2s^2(d) + 1$. Putting these identities into equations (4) and (7) we express $\cos(A)$ in terms of a, b, c, d. After a straightforward calculation we obtain

$$\begin{aligned}\cos(A) = \frac{1}{\widetilde{\mathfrak{N}}}(s^2(a) - s^2(b) - s^2(c) + s^2(d) \\ + 2s(a)s(b)s(c)s(d) + 2s^2(a)s^2(d)),\end{aligned} \tag{8}$$

where

$$\widetilde{\mathfrak{N}} = 2(s(a)s(d) + s(b)s(c))\cosh\left(\frac{1}{2}a\right)\cosh\left(\frac{1}{2}d\right).$$

In a similar way we get the formula

$$\begin{aligned}\cos(C) = \frac{1}{\widetilde{\mathfrak{N}}'}(-s^2(a) + s^2(b) + s^2(c) - s^2(d) \\ + 2s(a)s(b)s(c)s(d) + 2s^2(b)s^2(c)),\end{aligned} \tag{9}$$

where

$$\widetilde{\mathfrak{N}}' = 2(s(a)s(d) + s(b)s(c))\cosh\left(\frac{1}{2}b\right)\cosh\left(\frac{1}{2}c\right)$$

Note that $\sin(A)\sin(C) > 0$ and $\sin^2(A)\sin^2(C) = (1 - \cos^2(A))(1 - \cos^2(C))$. Then we take square roots in the latter equation, where $\cos(A)$ and $\cos(C)$ are given by formulas (8) and (9). Thus we express the product $\sin(A)\sin(C)$ in terms of a, b, c, d. Substituting $\cos(A)$, $\cos(C)$, and $\sin(A) \cdot \sin(C)$ into (6) and simplifying we get

$$\begin{aligned}\sin^2\left(\frac{1}{4}S\right) = \frac{1}{\mathfrak{N}'}\sinh\left(\frac{1}{4}(-a + b + c + d)\right)\sinh\left(\frac{1}{4}(a - b + c + d)\right) \\ \sinh\left(\frac{1}{4}(a + b - c + d)\right)\sinh\left(\frac{1}{4}(a + b + c - d)\right).\end{aligned} \tag{10}$$

This proves Theorem 1.8.

In a similar way, from the identity $\cos^2\left(\frac{1}{4}S\right) = 1 + \cos\left(\frac{1}{2}S\right) = 1 - \cos(A + C)$ we have

$$\begin{aligned}\cos^2\left(\frac{1}{4}S\right) = \frac{1}{\mathfrak{N}'}\cosh\left(\frac{1}{4}(a + b - c - d)\right)\cosh\left(\frac{1}{4}(a - b + c - d)\right) \\ \cosh\left(\frac{1}{4}(a - b - c + d)\right)\cosh\left(\frac{1}{4}(a + b + c + d)\right).\end{aligned} \tag{11}$$

The following lemma can be easily proved by straightforward calculations.

Lemma 1.11. *The expression*

$$H = \frac{\cosh\left(\frac{1}{4}(a+b-c-d)\right)\cosh\left(\frac{1}{4}(a-b+c-d)\right)}{\cosh\left(\frac{1}{4}(-a+b+c+d)\right)\cosh\left(\frac{1}{4}(a-b+c+d)\right)} \frac{\cosh\left(\frac{1}{4}(a-b-c+d)\right)\cosh\left(\frac{1}{4}(a+b+c+d)\right)}{\cosh\left(\frac{1}{4}(a+b-c+d)\right)\cosh\left(\frac{1}{4}(a+b+c-d)\right)}$$

can be rewritten in the form $H = 1 - \varepsilon$, *where*

$$\varepsilon = \frac{\sinh\left(\frac{1}{2}a\right)\sinh\left(\frac{1}{2}b\right)\sinh\left(\frac{1}{2}c\right)\sinh\left(\frac{1}{2}d\right)}{\cosh\left(\frac{1}{2}(s-a)\right)\cosh\left(\frac{1}{2}(s-b)\right)\cosh\left(\frac{1}{2}(s-c)\right)\cosh\left(\frac{1}{2}(s-d)\right)}$$

and

$$s = \frac{1}{2}(a+b+c+d).$$

Taking four times the products of equations (10) and (11) we have

$$\sin^2\left(\frac{1}{2}S\right) = \frac{1}{4\mathfrak{N}}\sinh\left(\frac{1}{2}(-a+b+c+d)\right)\sinh\left(\frac{1}{2}(a-b+c+d)\right) \sinh\left(\frac{1}{2}(a+b-c+d)\right)\sinh\left(\frac{1}{2}(a+b+c-d)\right)H, \tag{12}$$

where H is the same as in Lemma 1.11.

Then the statement of Theorem 1.5 follows from equation (12), Lemma 1.11 and the evident identity $s-a = \frac{1}{2}(-a+b+c+d)$. To prove Theorem 1.6 we divide (10) by (11).

Finally, the Bilinski formula (Theorem 1.10) follows from the identity $\cos\left(\frac{1}{2}S\right) = \cos^2\left(\frac{1}{4}S\right) - \sin^2\left(\frac{1}{4}S\right)$ and the above mentioned equations (10) and (11). □

1.4 Bretschneider's formula

In 1842, Carl Bretschneider [15] related the area of an arbitrary Euclidean quadrilateral to its side lengths and the sum of two opposite angles. The area S of a Euclidean quadrilateral with side lengths a, b, c, d and opposite angles A and C is given by the formula

$$S^2 = (s-a)(s-b)(s-c)(s-d) - a\,b\,c\,d\cos^2\left(\frac{1}{2}(A+C)\right),$$

where $s = \frac{1}{2}(a+b+c+d)$ is the semiperimeter (for a proof see e.g. [47], p. 89).

The statement of the theorem remains valid if one substitutes $A+C$ with the sum of another pair of opposite angles $B+D$. By making use of the identity

$$A+B+C+D=2\pi$$

for any Euclidean quadrilateral we can rewrite the Bretschneider's theorem in the following more symmetric way

$$S^2=(s-a)(s-b)(s-c)(s-d)-a\,b\,c\,d\,\sin^2\Big(\frac{1}{4}(A-B+C-D)\Big).$$

Precisely, this statement allows a generalization for the case of a non-Euclidean quadrilateral. In the particular case of a cyclic quadrilateral (when $A+C=B+D$) we get a Brahmagupta's formula (5). Recall that the sum of angles is not equal to 2π anymore.

The following theorem gives a hyperbolic version of Bretschneider's formula.

Theorem 1.12 (Baigonakova and Mednykh, 2012, [11]). *The area S of a hyperbolic quadrilateral with side lengths a,b,c,d and angles A,B,C,D is given by the formula*

$$\begin{aligned}&\sin^2\Big(\frac{1}{4}S\Big)\\&\quad=\frac{1}{\mathfrak{N}'}\sinh\Big(\frac{1}{2}(s-a)\Big)\sinh\Big(\frac{1}{2}(s-b)\Big)\sinh\Big(\frac{1}{2}(s-c)\Big)\sinh\Big(\frac{1}{2}(s-d)\Big)\\&\qquad-\tanh\Big(\frac{1}{2}a\Big)\tanh\Big(\frac{1}{2}b\Big)\tanh\Big(\frac{1}{2}c\Big)\tanh\Big(\frac{1}{2}d\Big)\sin^2\Big(\frac{1}{4}(A-B+C-D)\Big),\end{aligned}$$

where $s=\frac{1}{2}(a+b+c+d)$ is the semiperimeter.

Proof. Consider the *Poincaré disk model* of the hyperbolic plane. This is the unit disc $U=\{z\in\mathbb{C}\colon |z|<1\}$, provided with the metric $ds=\frac{|dz|}{1-|z|^2}$. The boundary of U consists of the infinitely distant points and called *absolute*. The geodesics in this model are circle arcs and segments orthogonal to the absolute. Let z and w be arbitrary points of the disc U, and 0 be the origin. Then the hyperbolic and Euclidean distances between these points ($\rho(z,w)$ and $|z-w|$ correspondingly) are related by the formula ([13], p. 22–123)

$$|z-w|=\frac{\sinh\big(\frac{1}{2}\rho(z,w)\big)}{\cosh\big(\frac{1}{2}\rho(0,z)\big)\cosh\big(\frac{1}{2}\rho(0,w)\big)}. \tag{13}$$

Consider a hyperbolic quadrilateral $ABCD$ (Figure 3). We suppose that the vertex A coincides with the origin 0. From (13) we find the sides of the Euclidean quadrilateral $ABCD$ with respect to the hyperbolic lengths a, b, c, d, e, f. We have

$$AB = \tanh\left(\frac{1}{2}a\right), \quad BC = \frac{\sinh\left(\frac{1}{2}b\right)}{\cosh\left(\frac{1}{2}a\right)\cosh\left(\frac{1}{2}e\right)}, \tag{14a}$$

$$AD = \tanh\left(\frac{1}{2}d\right), \quad CD = \frac{\sinh\left(\frac{1}{2}c\right)}{\cosh\left(\frac{1}{2}e\right)\cosh\left(\frac{1}{2}d\right)}. \tag{14b}$$

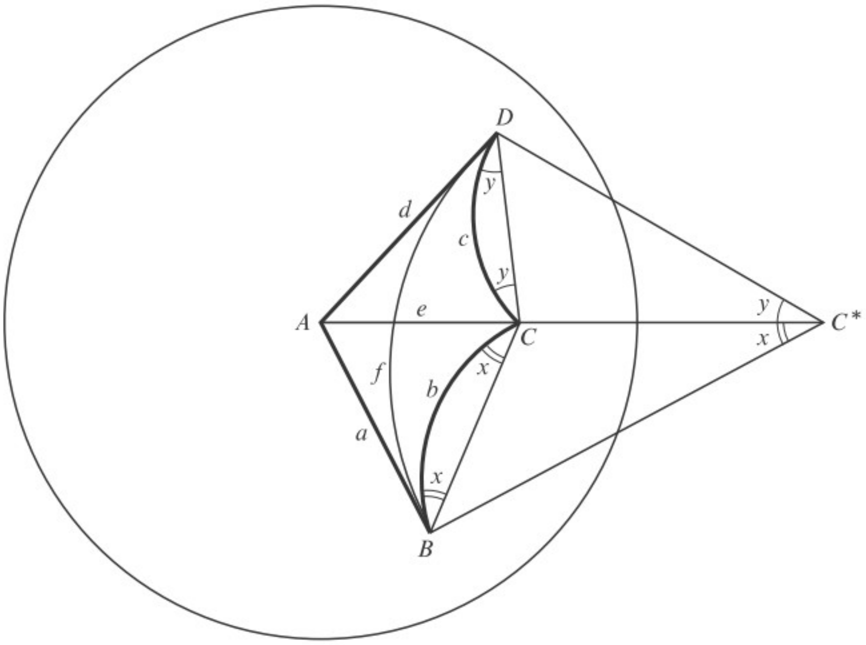

Figure 3. A hyperbolic quadrilateral $ABCD$ in the Poincaré model of $\mathbb{H}^2$

Let C^* be a point symmetric to C with respect to the absolute. To find the Euclidean distances BC^* and DC^* we use the identity $C^* = 1/C$ and the following formula from ([13], p. 123)

$$\tanh\left(\frac{1}{2}\rho(z, w)\right) = \left|\frac{z - w}{1 - z\,\overline{w}}\right|. \tag{15}$$

We get from (13) and (15)

$$BC^* = \frac{\cosh\left(\frac{1}{2}b\right)}{\cosh\left(\frac{1}{2}a\right)\sinh\left(\frac{1}{2}e\right)} \quad \text{and} \quad DC^* = \frac{\cosh\left(\frac{1}{2}c\right)}{\cosh\left(\frac{1}{2}d\right)\sinh\left(\frac{1}{2}e\right)}. \tag{16}$$

Denote the angle between the arc $\widehat{BC}$ and the chord BC by x, and the angle between the arc $\widehat{DC}$ and the chord DC by y. Then the angle measure of $\widehat{BC}$ is $2x$, while the angle measure of $\widehat{CD}$ is $2y$. Recall that the inscribed angle is equal to half of the corresponding cyclic arc. Then we obtain that the angles BC^*C and CC^*D are equal to x and y respectively. Denote by A, B, C, D the interior angles of the hyperbolic quadrilateral $ABCD$, and by $\widehat{A}, \widehat{B}, \widehat{C}, \widehat{D}$ the interior angles of the Eucledean quadrilateral $ABCD$. We have

$$\widehat{A} = A, \quad \widehat{B} = B + x, \quad \widehat{C} = C + x + y, \quad \widehat{D} = D + y.$$

Taking into account that $\widehat{A} + \widehat{B} + \widehat{C} + \widehat{D} = 2\pi$, we have

$$A + B + C + D + 2x + 2y = 2\pi.$$

Hence,

$$x + y = \frac{1}{2}(2\pi - A - B - C - D) = \frac{1}{2}S.$$

From the Euclidean triangle BC^*D we have

$$\sin^2\left(\frac{1}{2}(x + y)\right) = \sin^2\left(\frac{1}{4}S\right) = \frac{BD^2 - (BC^* - DC^*)^2}{4\,BC^* \cdot DC^*}.$$

Now using (14) and (16) we substitute the Euclidean lengths in the latter equation with the hyperbolic ones. Then

$$\begin{aligned}\sin^2\left(\frac{1}{4}S\right) = \frac{1}{4\mathfrak{N}'}\Big(\sinh\left(\frac{1}{2}e\right)\sinh\left(\frac{1}{2}f\right)\Big)^2 \\ - \Big(\cosh\left(\frac{1}{2}a\right)\cosh\left(\frac{1}{2}c\right) - \cosh\left(\frac{1}{2}b\right)\cosh\left(\frac{1}{2}d\right)\Big)^2.\end{aligned} \tag{17}$$

This formula expresses the area of a hyperbolic quadrilateral in terms of its sides and diagonals.

The next step is to find a similar formula for $\sin^2\left(\frac{1}{4}(A - B + C - D)\right)$. First, we need the following Bretschneider relation for the Euclidean quadrilateral $ABCD$ ([47], p. 85)

$$\begin{aligned}(AC \cdot BD)^2 = (AB \cdot CD)^2 + (BC \cdot AD)^2 \\ - 2AB \cdot BC \cdot CD \cdot AD \cos(\widehat{A} + \widehat{C}).\end{aligned}$$

Since

$$\widehat{A} + \widehat{C} = A + C + x + y = \pi + \frac{1}{2}(A - B + C - D),$$

we get

$$\begin{aligned}\cos\Big(\frac{1}{2}(A - B + C - D)\Big) &= -\cos(\widehat{A} + \widehat{C})\\ &= \frac{(AC \cdot BD)^2 - (AB \cdot CD)^2 - (BC \cdot AD)^2}{2\,AB \cdot BC \cdot CD \cdot AD},\end{aligned}$$

or

$$\sin^2\Big(\frac{1}{2}(A - B + C - D)\Big) = \frac{(AB \cdot CD + BC \cdot AD)^2 - (AC \cdot BD)^2}{4\,AB \cdot BC \cdot CD \cdot AD}.$$

As before, by (14) and (16) we obtain

$$\begin{aligned}&\sin^2\Big(\frac{1}{2}(A - B + C - D)\Big)\\ &\quad= \frac{\big(\sinh\big(\frac{1}{2}a\big)\sinh\big(\frac{1}{2}c\big) - \sinh\big(\frac{1}{2}b\big)\sinh\big(\frac{1}{2}d\big)\big)^2 - \big(\sinh\big(\frac{1}{2}e\big)\sinh\big(\frac{1}{2}f\big)\big)^2}{4\sinh\big(\frac{1}{2}a\big)\sinh\big(\frac{1}{2}b\big)\sinh\big(\frac{1}{2}c\big)\sinh\big(\frac{1}{2}d\big)}.\end{aligned} \tag{18}$$

Eliminating the expression $\big(\sinh\big(\frac{1}{2}e\big)\sinh\big(\frac{1}{2}f\big)\big)^2$ from (17) and (18) and making use of standard formulas we finally obtain

$$\begin{aligned}\sin^2\Big(\frac{1}{4}S\Big) = \frac{1}{\mathfrak{N}'}\sinh\Big(\frac{1}{2}(s-a)\Big)\sinh\Big(\frac{1}{2}(s-b)\Big)\sinh\Big(\frac{1}{2}(s-c)\Big)\sinh\Big(\frac{1}{2}(s-d)\Big)\\ - \tanh\Big(\frac{1}{2}a\Big)\tanh\Big(\frac{1}{2}b\Big)\tanh\Big(\frac{1}{2}c\Big)\tanh\Big(\frac{1}{2}d\Big)\\ \sin^2\Big(\frac{1}{4}(A - B + C - D)\Big).\end{aligned}$$

□

The analogous theorem holds in spherical geometry as well (for more details see the recent work [10] or the old papers [12] and [29]).

Theorem 1.13 (Baigonakova and Mednykh, 2012, [11]). *The area S of a spherical quadrilateral with side lengths a, b, c, d and angles A, B, C, D is given by the formula*

$$\begin{aligned}\sin^2\Big(\frac{1}{4}S\Big) &= \frac{\sin\big(\frac{1}{2}(s-a)\big)\sin\big(\frac{1}{2}(s-b)\big)\sin\big(\frac{1}{2}(s-c)\big)\sin\big(\frac{1}{2}(s-d)\big)}{\cos\big(\frac{1}{2}a\big)\cos\big(\frac{1}{2}b\big)\cos\big(\frac{1}{2}c\big)\cos\big(\frac{1}{2}d\big)}\\ &\quad - \tan\Big(\frac{1}{2}a\Big)\tan\Big(\frac{1}{2}b\Big)\tan\Big(\frac{1}{2}c\Big)\tan\Big(\frac{1}{2}d\Big)\sin^2\Big(\frac{1}{4}(A - B + C - D)\Big),\end{aligned}$$

where $s = \frac{1}{2}(a + b + c + d)$ is the semiperimeter.

1.5 Casey's theorem

John Casey generalized Ptolemy's theorem in the following way (see [16], p. 103).

Theorem 1.14 (Casey's theorem). *Let four circles* O_1, O_2, O_3, O_4 *on the Euclidean plane* $\mathbb{E}^2$ *be internally tangent to a circle* O *in the prescribed order. Denote by* t_{ij} *the length of the common external tangent of the circles* O_i, O_j*. Then*

$$t_{12}\, t_{34} + t_{23}\, t_{14} = t_{13}\, t_{24}\,.$$

We say that a common tangent of two circles is *external* if it does not intersect the segment joining the centers of the circles.

The following hyperbolic version of Casey's theorem is given in [7].

Theorem 1.15 (Abrosimov and Mikaiylova, 2015, [7]). *Let four circles* $O_1, O_2,$ O_3, O_4 *on the hyperbolic plane* $\mathbb{H}^2$ *be internally tangent to a circle* O *in the prescribed order. Denote by* t_{ij} *the length of the common external tangent of the circles* O_i, O_j*. Then*

$$\sinh\left(\frac{1}{2}t_{12}\right)\sinh\left(\frac{1}{2}t_{34}\right)+\sinh\left(\frac{1}{2}t_{23}\right)\sinh\left(\frac{1}{2}t_{14}\right)=\sinh\left(\frac{1}{2}t_{13}2\right)\sinh\left(\frac{1}{2}t_{24}\right).$$

Proof. Denote by O_i the centers of the circles respectively (Figure 4). Let R_i be the radii of the circles O_i and K_i the points of tangency with the circle O.

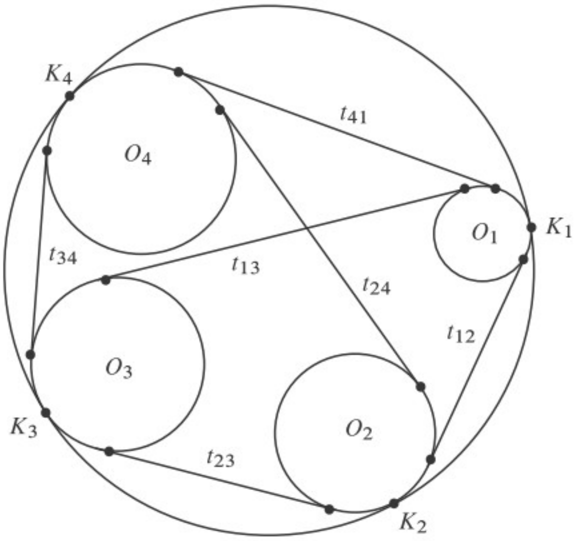

Figure 4

Consider the quadrilateral with sides O_iO_j, R_i, R_j, and t_{ij} (Figure 5). Denote by d the diagonal which divides the quadrilateral into triangles 1 and 2. Since the radii R_i and R_j are orthogonal to the common tangent t_{ij}, we can apply the hyperbolic Pythagorean theorem for triangle 1 (see, e.g., [8])

$$\cosh(d) = \cosh(R_j)\cosh(t_{ij}). \tag{19}$$

Denote the angle between the diagonal d and the tangent t_{ij} by δ. Then by the Sine rule for the hyperbolic triangle 1 we have

$$\sin\delta = \frac{\sinh(R_j)}{\sinh(d)}.$$

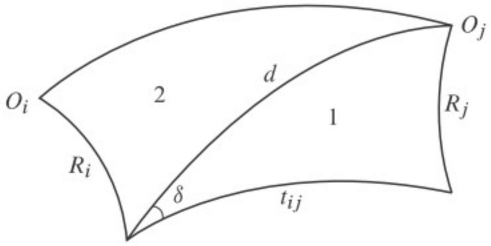

Figure 5

We use the second Cosine rule for the hyperbolic triangle 2 (see, e.g., [8])

$$\cosh(O_iO_j) = \cosh(R_i)\cosh(d) - \sinh(R_i)\sinh(R_j)\cos\left(\frac{\pi}{2} - \delta\right). \tag{20}$$

Substituting $\cosh(d)$ from (20) into (19) we obtain

$$\cosh(O_iO_j) = \cosh(t_{ij})\cosh(R_i)\cosh(R_j) - \sinh(R_i)\sinh(R_j). \tag{21}$$

We apply the first Cosine rule to the triangle OK_iK_j where $OK_i = OK_j = R$ (see Figure 6)

$$\cos(\angle K_iOK_j) = \frac{\cosh^2(R) - \cosh(K_iK_j)}{\sinh^2(R)}. \tag{22}$$

Using the first Cosine rule for the hyperbolic triangle OO_iO_j, where $OO_i = R - R_i$, $OO_j = R - R_j$, we have

$$\begin{aligned}\cosh(O_iO_j) = {} & \cosh(R - R_i)\cosh(R - R_j)\\ & - \sinh(R - R_i)\sinh(R - R_j)\cos(\angle K_iOK_j).\end{aligned}$$

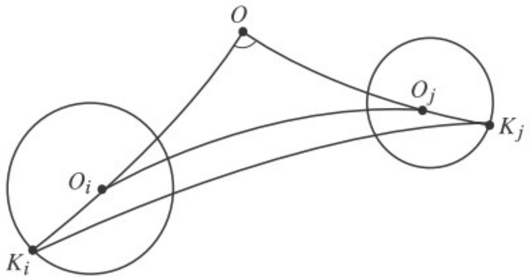

Figure 6

Combining the latter expression with (21) and (22) we obtain

$$\sinh^2\left(\frac{1}{2}K_iK_j\right) = \frac{\sinh^2(R)\cosh(R_i)\cosh(R_j)}{2\sinh(R-R_i)\sinh(R-R_j)}\sinh^2\left(\frac{1}{2}t_{ij}\right). \tag{23}$$

The points of tangency of the circles O_1, O_2, O_3, O_4 with the circle O form a cyclic quadrilateral $K_1K_2K_3K_4$ in $\mathbb{H}^2$. According to the hyperbolic Ptolemy theorem (Theorem 1.3), the segments K_iK_j satisfy the equation

$$\begin{aligned}&\sinh\left(\frac{1}{2}K_1K_3\right)\sinh\left(\frac{1}{2}K_2K_4\right)\\ &\quad= \sinh\left(\frac{1}{2}K_1K_2\right)\sinh\left(\frac{1}{2}K_3K_4\right) + \sinh\left(\frac{1}{2}K_2K_3\right)\sinh\left(\frac{1}{2}K_1K_4\right).\end{aligned} \tag{24}$$

We take the square root of (23) and substitute the expressions for $\sinh\left(\frac{1}{2}K_iK_j\right)$ in (24). Then we divide the resulting equation by

$$\sinh^2 R\sqrt{\frac{\cosh(R_1)\cosh(R_2)\cosh(R_3)\cosh(R_4)}{2\sinh(R-R_1)\sinh(R-R_2)\sinh(R-R_3)\sinh(R-R_4)}}$$

to obtain

$$\sinh\left(\frac{1}{2}t_{13}\right)\sinh\left(\frac{1}{2}t_{24}\right) = \sinh\left(\frac{1}{2}t_{12}\right)\sinh\left(\frac{1}{2}t_{34}\right) + \sinh\left(\frac{1}{2}t_{23}\right)\sinh\left(\frac{1}{2}t_{14}\right).$$

□

The spherical analog of Casey's theorem holds as well [7].

Theorem 1.16 (Abrosimov and Mikaiylova, 2015, [7]). *Let four circles O_1, O_2, O_3, O_4 on the sphere $\mathbb{S}^2$ be internally tangent to a circle O in the prescribed order. Denote by t_{ij} the length of the common external tangent of the circles O_i, O_j. Then*

$$\sin\left(\frac{1}{2}t_{12}\right)\sin\left(\frac{1}{2}t_{34}\right) + \sin\left(\frac{1}{2}t_{23}\right)\sin\left(\frac{1}{2}t_{14}\right) = \sin\left(\frac{1}{2}t_{13}\right)\sin\left(\frac{1}{2}t_{24}\right).$$

One can prove the spherical version of the theorem using the same arguments as in the hyperbolic case. The only difference is to replace hyperbolic trigonometric relations by corresponding spherical ones.

2 Geometry of polyhedra

Calculating volumes of polyhedra is a classical problem, that has been well known since Euclid. It remains relevant nowadays, partly due to the fact that the volume of a fundamental polyhedron is one of the main invariants for a three-dimensional manifold.

2.1 Volume of hyperbolic orthoscheme

Volume formulas for non-Euclidean tetrahedra in some special cases have been known since Lobachevsky, Bolyai and Schläfli. For example, Schläfli [53] found the volume of an orthoscheme in the 3-dimensional sphere $\mathbb{S}^3$. Recall that an *orthoscheme* is an n-dimensional simplex defined by a sequence of edges $(v_0, v_1), (v_1, v_2), \dots, (v_{n-1}, v_n)$ that are mutually orthogonal. In three dimensions, an orthoscheme is also called a *birectangular tetrahedron*. By definition, a 3-dimensional orthoscheme has three dihedral angles $\frac{\pi}{2}$ and three others, which we will refer as *essential* ones (see Figure 7).

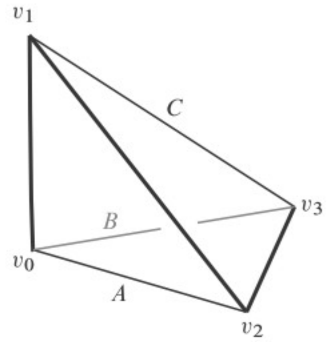

Figure 7. An orthoscheme $T = T(A, B, C)$ with essential dihedral angles A, B, C, all other angles are $\frac{\pi}{2}$

Theorem 2.1 (Schläfli, 1858, [52]). *Let T be a spherical orthoscheme with essential dihedral angles A, B, C. Then its volume $V = V(T)$ is given by the formula*

$$V = \frac{1}{4} S(A, B, C),$$

where

$$\begin{aligned} S\Big(\frac{\pi}{2} - x, y, \frac{\pi}{2} - z\Big) &\\ = \widehat{S}(x, y, z) &\\ = \sum_{m=1}^{\infty} \Big(\frac{D - \sin(x)\sin(z)}{D + \sin(x)\sin(z)}\Big)^m \frac{\cos(2mx) - \cos(2my) + \cos(2mz) - 1}{m^2} &\\ - x^2 + y^2 - z^2, & \end{aligned}$$

and $D \equiv \sqrt{\cos^2(x)\cos^2(z) - \cos^2(y)}$.

The function $S(x, y, z)$ appearing in Theorem 2.1 is called the *Schläfli function*.

The volume of a hyperbolic orthoscheme was obtained independently by Nikolai Lobachevsky [35] and János Bolyai (see [57], [56], or [64]). The following theorem was suggested by G. S. M. Coxeter [20]. It represents a result of Lobachevsky in a very simple form.

Theorem 2.2 (Lobachevsky, 1835, [35]; Coxeter, 1835, [20]). *Let T be a hyperbolic orthoscheme with dihedral angles A, B, C. Then its volume $V = V(T)$ is given by the formula $V = \frac{i}{4} S(A, B, C)$, where $S(A, B, C)$ is the Schläfli function.*

J. Bolyai found the volume of a hyperbolic orthoscheme in terms of planar angles and an edge length. This result was not published during his lifetime. It can be found in the work [57], pp. 111–118 collected on the base of original manuscripts in reliquias by János Bolyai (see also [56] and [64]).

Theorem 2.3 (Bolyai, 1832). *Consider a hyperbolic orthoscheme T with essential dihedral angles along AC, CB, BD, and all other dihedral angles equal to $\frac{\pi}{2}$ (Figure 8). T is given by its planar angles α, β, γ and edge length z. Then its volume $V = V(T)$ can be found by the formula*

$$V = \frac{\tan(\gamma)}{2\tan(\beta)} \int_0^z \frac{u \sinh(u) du}{\Big(\frac{\cosh^2(u)}{\cos^2(\alpha)} - 1\Big)\sqrt{\frac{\cosh^2(u)}{\cos^2(\gamma)} - 1}}.$$

2.2 Volume of ideal tetrahedra and octahedra

An *ideal tetrahedron* is a hyperbolic tetrahedron with all vertices at infinity. Opposite dihedral angles of an ideal tetrahedron are pairwise equal and the sum of dihedral angles at the edges adjacent to one vertex is $A + B + C = \pi$ (see Figure 9).

Figure 9. An ideal tetrahedron $T = T(A, B, C)$ and an ideal octahedron $O = O(A, B, C, D, E, F)$

The volume of an ideal tetrahedron has been known since Lobachevsky [35]. J. Milnor presented it in very elegant form [39].

Theorem 2.4 (Lobachevsky, 1835, [35]; Milnor, 1982, [39]). *Let T be an ideal tetrahedron with dihedral angles A, B and C. Then its volume $V = V(T)$ is given by the formula*

$$V = \Lambda(A) + \Lambda(B) + \Lambda(C),$$

where

$$\Lambda(x) = -\int_0^x \log|2\sin t|dt$$

is the Lobachevsky function.

Corollary 2.5. *The maximal volume of an ideal tetrahedron is attained in the case when the dihedral angles $A = B = C = \frac{1}{3}\pi$. It is equal to*

$$V_{\max} = 3\Lambda\Big(\frac{\pi}{3}\Big) = 1.01494\ldots.$$

A more general case of a tetrahedron with at least one vertex at infinity was investigated by E. B. Vinberg [8].

An *ideal octahedron* is a hyperbolic octahedron with all vertices at infinity. Consider a symmetric ideal octahedron whose opposite dihedral angles are pairwise equal (see Figure 9). By definition, the sum of the dihedral angles at the edges adjacent to any vertex is equal to 2π. We have

$$A + B + C + D = 2\pi, \quad A + C + E + F = 2\pi, \quad B + D + E + F = 2\pi,$$

or

$$C = \pi - A, \quad D = \pi - B, \quad F = \pi - E.$$

Hence, $A, B, C, D, E, F \in (0, \pi)$. The volume formula for such an octahedron is very similar to Milnor's formula for ideal tetrahedra and is given in [9].

Theorem 2.6 (Baigonakova and Mednykh, 2010, [9]). *Let O be a symmetric ideal octahedron with dihedral angles A, B, C, D, E, F. Then its volume $V = V(O)$ is given by the formula*

$$\begin{aligned}\frac{\mathrm{Vol}(O)}{2} &= \Lambda\Big(\frac{1}{2}(\pi + A + B + E)\Big) + \Lambda\Big(\frac{1}{2}(\pi - A - B + E)\Big)\\ &\quad + \Lambda\Big(\frac{1}{2}(\pi + A - B - E)\Big) + \Lambda\Big(\frac{1}{2}(\pi - A + B - E)\Big),\end{aligned}$$

where $\Lambda(x)$ is the Lobachevsky function.

Corollary 2.7. *The maximal volume of an ideal octahedron is attained in the case when $A = B = C = D = E = F = \frac{\pi}{2}$. It is equal to*

$$V_{\max} = 8\Lambda\Big(\frac{\pi}{4}\Big) = 3.66386\ldots.$$

2.3 Seidel's conjecture

In 1986, J. J. Seidel [54] conjectured that the volume of an ideal hyperbolic tetrahedron can be expressed as a function of the determinant and the permanent of its Gram matrix. Recall that the formula expressing the volume of such a tetrahedron in terms of dihedral angles has been known since Lobachevsky and Bolyai (Theorem 2.4). In spite of this, Seidel's problem had not been solved for a long time. Ten years later, a strengthened version of Seidel's conjecture was suggested by Igor Rivin and Feng Luo. They supposed that the volume of a non-Euclidean tetrahedron (hyperbolic or spherical one) depends only on the determinant of its Gram matrix. It was shown in [1] and [2] that the strengthened conjecture is false, while Seidel's conjecture is true within certain conditions.

Consider a non-Euclidean tetrahedron T in the sphere $\mathbb{S}^3$ or in the hyperbolic space $\mathbb{H}^3$. Denote its vertices by numbers $1, 2, 3, 4$. Let A_{ij} denote the dihedral angle at the edge joining vertices i and j. For convenience, we set $A_{ii} = \pi$ for $i = 1, 2, 3, 4$. It is well known [8] that, in the hyperbolic and spherical spaces, the tetrahedron T is uniquely (up to isometry) determined by its Gram matrix $G = \langle -\cos(A_{ij})\rangle_{i,j=1,\ldots,4}$.

Recall that the permanent of a matrix $M = \langle m_{ij}\rangle_{ij=1,2,\ldots,n}$ is defined by

$$\operatorname{per}(M) = \sum_{i=1}^{n} m_{ij}\operatorname{per}(M_{ij}), \quad \operatorname{per}(m_{ij}) = m_{ij},$$

where M_{ij} is the matrix obtained from M by removing the i-th row and j-th column. Conditions for the existence of spherical and hyperbolic tetrahedra in terms of Gram matrices are given in [36] and [59], respectively.

The solution of Seidel's problem, which was posed in [54], is given by the following theorem.

Theorem 2.8 (Abrosimov, 2010, [2]). *In each of the classes of acute or obtuse*[1] *ideal tetrahedra the volume is determined uniquely by the determinant and permanent of the Gram matrix.*

Proof. As is known (see, e.g., [39]), opposite dihedral angles of an ideal tetrahedron are pairwise equal and the sum of the dihedral angles at the edges adjacent to one vertex is $A + B + C = \pi$ (Figure 9).

---

[1] By an *obtuse tetrahedron* we mean a tetrahedron with at least one dihedral angle $> \frac{\pi}{2}$.

Thus, we can take $C = \pi - A - B$. The Gram matrix has the form

$$G = \begin{pmatrix} 1 & -\cos(A) & -\cos(B) & \cos(A+B) \\ -\cos(A) & 1 & \cos(A+B) & -\cos(B) \\ -\cos(B) & \cos(A+B) & 1 & -\cos(A) \\ \cos(A+B) & -\cos(B) & -\cos(A) & 1 \end{pmatrix}.$$

We have

$$\det(G) = -4\sin^2(A)\sin^2(B)\sin^2(A+B),$$
$$\operatorname{per}(G) = 4 + 4\cos^2(A)\cos^2(B)\cos^2(A+B).$$

To prove Theorem 2.8, we show that the dihedral angles of an ideal tetrahedron are uniquely (up to a permutation) determined by $\det G$ and $\operatorname{per} G$ in each of the cases: acute angled tetrahedron and obtuse angled tetrahedron.

Without loss of generality, we can assume that $0 < A \le B \le C = \pi - A - B$. Then the dihedral angles A, B are a priori acute, and the angle C is either acute or obtuse. In the former case, the tetrahedron under consideration is acute-angled, and in the latter case, it is obtuse-angled.

Let us introduce the new variables

$$x = \sin(A)\sin(B), \quad y = \cos(A)\cos(B)$$

and show that, for a fixed left-hand side, the solutions of the system of equations

$$-\frac{1}{4}\det(G) = x^2(1 - (y-x)^2),$$
$$\frac{1}{4}\operatorname{per}(G) = y^2(y-x)^2 + 1$$

correspond to one tetrahedron (up to isometry) in each of the two cases mentioned above.

Suppose that the system has a pair of different solutions (a, b) and (x, y). Then we have

$$a^2(1 - (b-a)^2) = x^2(1 - (y-x)^2),$$
$$b^2(b-a)^2 = y^2(y-x)^2.$$

For the angle C to be acute means that

$$\cos(A)\cos(B) - \sin(A)\sin(B) = -\cos(C) < 0,$$

i.e., both solutions satisfy the inequalities $b(b-a) < 0$ and $x(x-y) < 0$. If the angle C is obtuse, then the reverse inequality holds. This allows us to take a square root in the second equation without loosing solutions:

$$a^2(1-(b-a)^2) = x^2(1-(y-x)^2),$$

$$b\,(b-a) = y\,(y-x).$$

Expressing x from the second equation and substituting the resulting expression into the first one, we obtain a sixth-degree polynomial equation in y. Fortunately, it decomposes into the linear factors and the biquadratic polynomial

$$(b-y)\cdot(b+y)\cdot\big(y^4-(a^2+a^4+2\,ab-2a^3b-b^2+2ab^3-b^4)y^2 \\ +a^4b^2-4a^3b^3+6a^2b^4-4ab^5+b^6\big)=0.$$

Thus, all solutions can be found in radicals. Substituting the expressions for x and y in terms of dihedral angles, we see that different solutions of the system correspond to the same ideal tetrahedron $T(A,B,C)$ up to reordering the dihedral angles. □

Note that, in Theorem 2.8, the assumption that the tetrahedron is either acute-angled or obtuse-angled cannot be dispensed with. This is demonstrated by the following example.

Example 2.9. Consider a pair of ideal tetrahedra, the obtuse-angled tetrahedron $T_1(s,s,\pi-2s)$ and the acute-angled tetrahedron $T_2\big(t,\frac{1}{2}(\pi-t),\frac{1}{2}(\pi-t)\big)$, where

$$s = \arccos\left(\frac{\sqrt{2+\sqrt{4+\sqrt{170\sqrt{17}-698}}}}{2\sqrt{2}}\right),$$

$$t = \arccos\left(\frac{-1+\sqrt{17}+\sqrt{-26+10\sqrt{17}}}{8}\right).$$

The determinants and the permanents of the Gram matrices of these tetrahedra coincide. We have

$$\det(G(T_1)) = \det(G(T_2)) = \frac{107-51\sqrt{17}}{128},$$

$$\operatorname{per}(G(T_1)) = \operatorname{per}(G(T_2)) = \frac{163+85\sqrt{17}}{128}.$$

At the same time, the volumes of the tetrahedra T_1 and T_2 are different and equal to 0.847365 and 1.01483 respectively.

2.4 Volume of a general hyperbolic tetrahedron

Despite the fact that partial results on the volume of non-Euclidean tetrahedra were known, a volume formula for hyperbolic tetrahedra of general type remained unknown until recently. A general algorithm for obtaining such a formula was indicated by W.-Y. Hsiang in [30]. A complete solution was obtained more than ten years later. A general formula was proposed in paper by Y. Cho and H. Kim [17]. However, it was asymmetric with respect to permutation of angles. J. Murakami and Y. Yano [44] proposed a formula expressing the volume by dihedral angles in a symmetric way. A year later, A. Ushijima [59] presented a simple proof of the Murakami–Yano formula. He also investigated the case of a truncated hyperbolic tetrahedron.

It should be noted that in all these studies the volume is expressed as a linear combination of 16 dilogarithms or Lobachevsky functions. The arguments of these functions depend on the dihedral angles of the tetrahedron and some additional parameter, which is the root of some quadratic equation with complex coefficients in a sophisticated form.

The geometric meaning of that formula was explained by P. Doyle and G. Leibon [24] in terms of Regge symmetry. A clear description of these ideas and a complete geometric proof of the formula was given by Y. Mohanty [42]. In particular, she proved the equivalence of Regge symmetry and homogeneity (scissors congruence) in hyperbolic space [43].

In 2005, D. A. Derevnin and A. D. Mednykh [22] proposed the following integral formula for the volume of a hyperbolic tetrahedron.

Theorem 2.10 (Derevnin and Mednykh, 2005, [22]). *Let $T(A,B,C,D,E,F)$ be a compact hyperbolic tetrahedron with dihedral angles A,B,C,D,E,F. Then its volume $V = V(T)$ is given by the formula*

$$V = -\frac{1}{4}\int\limits_{z_1}^{z_2} \log \frac{\cos\left(\frac{1}{2}(A+B+C+z)\right)\cos\left(\frac{1}{2}(A+E+F+z)\right)}{\sin\left(\frac{1}{2}(A+B+D+E+z)\right)\sin\left(\frac{1}{2}(A+C+D+F+z)\right)}$$
$$\frac{\cos\left(\frac{1}{2}(B+D+F+z)\right)\cos\left(\frac{1}{2}(C+D+E+z)\right)}{\sin\left(\frac{1}{2}(B+C+E+F+z)\right)\sin\left(\frac{1}{2}z\right)}\,dz,$$

where z_1 and z_2 are the roots of the integrand satisfied the condition $0 < z_2 - z_1 \leq \pi$.

More precisely,

$$z_1 = \arctan\left(\frac{k_3}{k_4}\right) - \arctan\left(\frac{k_1}{k_2}\right), \quad z_2 = \pi - \arctan\left(\frac{k_3}{k_4}\right) - \arctan\left(\frac{k_1}{k_2}\right),$$

where

$$\begin{aligned} k_1 &= -\cos(S) - \cos(A+D) - \cos(B+E) - \cos(C+F) - \cos(D+E+F) \\ &\quad - \cos(D+B+C) - \cos(A+E+C) - \cos(A+B+F), \\ k_2 &= \sin(S) + \sin(A+D) + \sin(B+E) + \sin(C+F) + \sin(D+E+F) \\ &\quad + \sin(D+B+C) + \sin(A+E+C) + \sin(A+B+F), \\ k_3 &= 2\,(\sin A \sin D + \sin B \sin E + \sin C \sin F), \\ k_4 &= \sqrt{k_1^2 + k_2^2 - k_3^2}, \\ S &= A + B + C + D + E + F. \end{aligned}$$

2.5 Sforza's formula for non-Euclidean tetrahedra

Surprisingly, but more than 100 years ago, in 1907, Giuseppe Sforza found a fairly simple formula for the volume of a non-Euclidean tetrahedron. This fact has became widely known after a discussion between the second named author and J. M. Montesinos at the conference in El Burgo de Osma (Spain), August, 2006. Unfortunately, the outstanding work of Sforza [55] published in Italian has been completely forgotten.

The original arguments by Sforza are based on some identity given by H. W. Richmond [49] besides the Schläfli formula. Then he used the Pascal equation [45] for minors of the Gram matrix and some routine calculations. In this subsection we present another simpler proof of Sforza's formula. The idea of the proof belongs to the authors [6].

Consider a hyperbolic (or a spherical) tetrahedron T with dihedral angles A, B, C, D, E, F. Assume that A, B, C are dihedral angles at the edges adjacent to one vertex and D, E, F are opposite to them correspondingly (see Figure 10). Then the Gram matrix $G(T)$ is defined as follows:

$$G = \begin{pmatrix} 1 & -\cos(A) & -\cos(B) & -\cos(F) \\ -\cos(A) & 1 & -\cos(C) & -\cos(E) \\ -\cos(B) & -\cos(C) & 1 & -\cos(D) \\ -\cos(F) & -\cos(E) & -\cos(D) & 1 \end{pmatrix}.$$

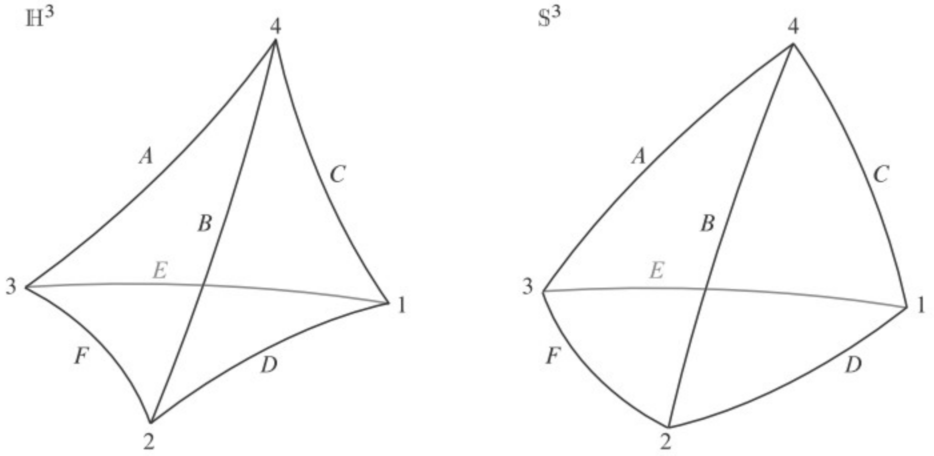

Figure 10. A tetrahedron $T = T(A, B, C, D, E, F)$ in $\mathbb{H}^3$ or $\mathbb{S}^3$

Denote by $\mathcal{C} = \langle c_{ij} \rangle_{i,j=1,2,3,4}$ a matrix of cofactors $c_{ij} = (-1)^{i+j} G_{ij}$, where G_{ij} is (i, j)-th minor of G.

In the following proposition we collect some known results about hyperbolic tetrahedra (see, e.g., [59]).

Proposition 2.11. *Let T be a compact hyperbolic tetrahedron. Then*

(i) $\det(G) < 0$;

(ii) $c_{ii} > 0$, $i \in \{1, 2, 3, 4\}$;

(iii) $c_{ij} > 0$, $i \neq j$; $i, j \in \{1, 2, 3, 4\}$;

(iv) $\cosh(\ell_{ij}) = \frac{c_{ij}}{\sqrt{c_{ii} c_{jj}}}$,

where ℓ_{ij} is the hyperbolic length of the edge joining vertices i and j.

Further, we need the following assertion due to Jacobi ([48], Theorem 2.5.1, p. 12).

Proposition 2.12 (Jacobi theorem). *Let $M = \langle m_{ij} \rangle_{i,j=1,\dots,n}$ be a matrix and $\Delta = \det(M)$ be the determinant of M. Denote by $\mathcal{C} = \langle c_{ij} \rangle_{i,j=1,\dots,n}$ the matrix of cofactors $c_{ij} = (-1)^{i+j} \det M_{ij}$, where M_{ij} is the $(n-1) \times (n-1)$ minor obtained by removing the i-th row and j-th column of the matrix M. Then for any k, $1 \leq k \leq n-1$ we have*

$$\det\langle c_{ij} \rangle_{i,j=1,\dots,k} = \Delta^{k-1} \det\langle m_{ij} \rangle_{i,j=k+1,\dots,n}.$$

One of the main tools for volume calculations in $\mathbb{H}^3$ and $\mathbb{S}^3$ is the classical Schläfli formula.

Proposition 2.13 (Schläfli's formula). *Let X^n be a space of constant curvature K. Consider a family of convex polyhedra P in X^n depending on one or more parameters in a differential manner and keeping the same combinatorial type. Then the differential of the volume $V = V(P)$ satisfies the equation*

$$(n-1)K\,dV = \sum_F V_{n-2}(F)\,d\theta(F),$$

where the sum is taken over all $(n-2)$-facets of P, $V_{n-2}(F)$ is $(n-2)$-dimensional volume of F, and $\theta(F)$ is the interior angle along F.

In the classical paper by Schläfli [52] this formula was proved for the case of a spherical n-simplex. For the hyperbolic case, it was obtained by H. Kneser [33] (for more details, see also [8] and [40]).

Now we are able to prove the following theorem (see also [6]).

Theorem 2.14 (Sforza's formula in $\mathbb{H}^3$). *Let T be a compact hyperbolic tetrahedron with Gram matrix G. Consider $G = G(A)$ as a function of the dihedral angle A. Then the volume $V = V(T)$ is given by the formula*

$$V = \frac{1}{4}\int_{A_0}^{A} \log\Big(\frac{c_{34}(A) - \sqrt{-\det G(A)}\sin(A)}{c_{34}(A) + \sqrt{-\det G(A)}\sin(A)}\Big)\,dA,$$

where A_0 is a suitable root of the equation $\det G(A) = 0$ *and $c_{34} = c_{34}(A)$ is the $(3,4)$-cofactor of the matrix $G(A)$.*

Proof. Let $\Delta = \det(G)$. By the Jacobi theorem (Proposition 2.12) applied to the Gram matrix G for $n = 4$ and $k = 2$ we obtain

$$c_{33}c_{44} - c_{34}^2 = \Delta(1 - \cos^2(A)).$$

By the Cosine rule (Proposition 2.11, (iv)) we get $\cosh(\ell_A) = \frac{c_{34}}{\sqrt{c_{33}c_{44}}}$. Hence,

$$\sinh(\ell_A) = \sqrt{\cosh^2(\ell_A) - 1} = \sqrt{\frac{c_{34}^2 - c_{33}c_{44}}{c_{33}c_{44}}} = \frac{\sqrt{-\Delta}\sin(A)}{\sqrt{c_{33}c_{44}}}.$$

Since $\exp(\pm\ell_A) = \cosh(\ell_A) \pm \sinh(\ell_A)$ we have

$$\exp(\pm\ell_A) = \frac{c_{34} \pm \sqrt{-\Delta}\,\sin(A)}{\sqrt{c_{33}c_{44}}}.$$

Hence,

$$\exp(2\,\ell_A) = \frac{\exp(\ell_A)}{\exp(-\ell_A)} = \frac{c_{34} + \sqrt{-\Delta}\,\sin(A)}{c_{34} - \sqrt{-\Delta}\,\sin(A)}$$

and

$$\ell_A = \frac{1}{2}\,\log\Big(\frac{c_{34} + \sqrt{-\Delta}\,\sin(A)}{c_{34} - \sqrt{-\Delta}\,\sin(A)}\Big).$$

By the Schläfli formula (Proposition 2.13) for $V = V(T)$ we have

$$-dV = \frac{1}{2}\sum_{\alpha} \ell_\alpha\, d\alpha, \quad \alpha \in \{A, B, C, D, E, F\}.$$

By the assumption that the angle A is variable and all the other angles are constant, we get

$$-dV = \frac{1}{2}\,\ell_A\, dA.$$

Note that $\det(G) \to 0$ as $A \to A_0$. Thus, $V \to 0$ as $A \to A_0$. Then integrating both sides of the equation we obtain

$$V = \int\limits_{A_0}^{A} \Big(-\frac{\ell_A}{2}\Big)\,dA = \frac{1}{4}\int\limits_{A_0}^{A} \log\Big(\frac{c_{34} - \sqrt{-\det G}\,\sin(A)}{c_{34} + \sqrt{-\det G}\,\sin(A)}\Big)\,dA,$$

where the lower limit A_0 is a suitable root of the equation $\det G(A) = 0$. □

In the following proposition we collect some known results about spherical tetrahedra (see, e.g., [36]).

Proposition 2.15. *Let T be a spherical tetrahedron. Then*

(i) $\det(G) > 0$;

(ii) $c_{ii} > 0$, $i = 1, \ldots, 4$;

(iii) $\cos(\ell_{ij}) = \frac{c_{ij}}{\sqrt{c_{ii}c_{jj}}}$,

where ℓ_{ij} is the length of the edge joining vertices i and j in $\mathbb{S}^3$.

The next theorem presents a spherical version of Sforza's formula.

Theorem 2.16 (Sforza's formula in $\mathbb{S}^3$). *Let T be a spherical tetrahedron with Gram matrix G. Consider $G = G(A)$ as a function of the dihedral angle A. Then the volume $V = V(T)$ is given by the formula*

$$V = \frac{1}{4i} \int\limits_{A_0}^{A} \log\Big(\frac{c_{34}(A) + i\sqrt{\det\, G(A)}\sin(A)}{c_{34}(A) - i\sqrt{\det\, G(A)}\sin(A)}\Big)\, dA,$$

where A_0 is a suitable root of the equation $\det(G(A)) = 0$ *and $c_{34} = c_{34}(A)$ is the $(3,4)$-cofactor of the matrix $G(A)$.*

The proof is similar to one given in the hyperbolic case.

2.6 Volumes of hyperbolic octahedra with symmetries

In this subsection, we consider octahedra in $\mathbb{H}^3$ and $\mathbb{S}^3$. It is known that a regular ideal octahedron is a fundamental polyhedron for the complement of the Whitehead link embedded into the three-dimensional sphere. Moreover, a hyperbolic manifold of minimum volume (the Matveev–Fomenko–Weeks manifold) and many other manifolds can be obtained by Dehn surgeries on the Whitehead link. Thus, hyperbolic octahedra can serve as fundamental polyhedra for a wide class of manifolds, including ones of small volume. The latter seems to be of particular interest when one deals with hyperbolic manifolds ordered by increasing volume.

The problem of finding a volume formula for an arbitrary non-Euclidean polyhedron is very hard. It was only solved for a general hyperbolic or spherical tetrahedron. Even for an octahedron the problem is still open. But in the case of a polyhedron with nontrivial symmetry, the calculation of the volume is simplified. This fact was first shown by Lobachevsky, who found the volume of an ideal hyperbolic tetrahedron. It follows from the definition of an ideal tetrahedron that its opposite dihedral angles are pairwise equal (i.e. it has a symmetry).

Exact formulas for the volumes of spherical octahedra that have mmm- or $2|m$-symmetry were derived in [3]. The volumes of hyperbolic octahedra with mmm- or $\bar{3}$-symmetry were calculated in [4] and [5] respectively. These studies were initiated by Galiulin, Mikhalev, and Sabitov's paper [27], in which the authors calculated the volumes of Euclidean octahedra with nontrivial symmetry. We show just two from the above mentioned results.

An octahedron is said to *have* $2|m$*-symmetry* if it admits a rotation through an angle of $\frac{2}{3}\pi$ and a mirror symmetry about a plane orthogonal to the axis of rotation (see Figure 11). The $2|m$-symmetry of the octahedron corresponds to the group C_{2h} in the Schoenflies classification, to the group $[2, 2^+]$ in the Coxeter classification, or to the group 2^* in the orbifold classification (see, e.g., [19], [32]). The volume formula for spherical octahedra with $2|m$-symmetry is given in [3].

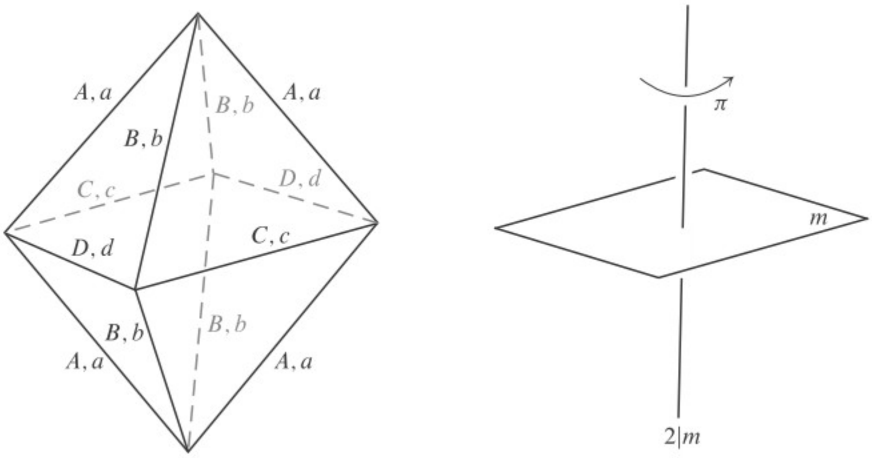

Figure 11. An octahedron $\mathcal{O} = \mathcal{O}(A, B, C, D)$ with $2|m$-symmetry

Theorem 2.17 (Abrosimov, Godoy-Molina, and Mednykh, 2008, [3]). *Let* $\mathcal{O} = \mathcal{O}(A, B, C, D)$ *be a spherical octahedron with dihedral angles* A, B, C, D *that admits a* $2|m$*-symmetry. Then its volume* $V = V(\mathcal{O})$ *is given by the formula*

$$V = 2\int\limits_{\frac{\pi}{2}}^{\theta} \big(\operatorname{arctanh}(X\cos(\tau)) + \operatorname{arctanh}(Y\cos(\tau)) + \operatorname{arctanh}(Z\cos(\tau)) + \operatorname{arctanh}(W\cos(\tau))\big)\frac{d\tau}{\cos(\tau)},$$

where $X = \cos(A)$, $Y = \cos(B)$, $Z = \cos\left(\frac{1}{2}(C + D)\right)$, $W = \cos\left(\frac{1}{2}(C - D)\right)$, *and* θ $\left(0 \le \theta \le \frac{\pi}{2}\right)$ *is a root of the equation*

$$\cos^2(\theta) + \frac{X + Y + Z + W}{XYZ + XYW + XZW + YZW} = 0.$$

Moreover, θ *is determined by the sine–tangent rule*

$$\frac{\sin(A)}{\tan(a)} = \frac{\sin(B)}{\tan(b)} = \frac{\sin\left(\frac{1}{2}(C + D)\right)}{\tan\left(\frac{1}{2}(c + d)\right)} = \frac{\sin\left(\frac{1}{2}(C - D)\right)}{\tan\left(\frac{1}{2}(c - d)\right)} = \tan(\theta).$$

An octahedron is said to *have* $\bar{3}$*-symmetry* if it admits the central symmetry and a rotation through an angle of $\frac{2}{3}\pi$ (see Figure 12). The $\bar{3}$-symmetry of the octahedron corresponds to the group S_6 in the Schoenflies classification, to the group $[2^+, 6^+]$ in the Coxeter classification, or to the group $3\times$ in the orbifold classification (see, e.g., [19] or [32], Chapter 11). The existence criterion and the volume formula for a hyperbolic octahedron with this type of symmetry are given in [5].

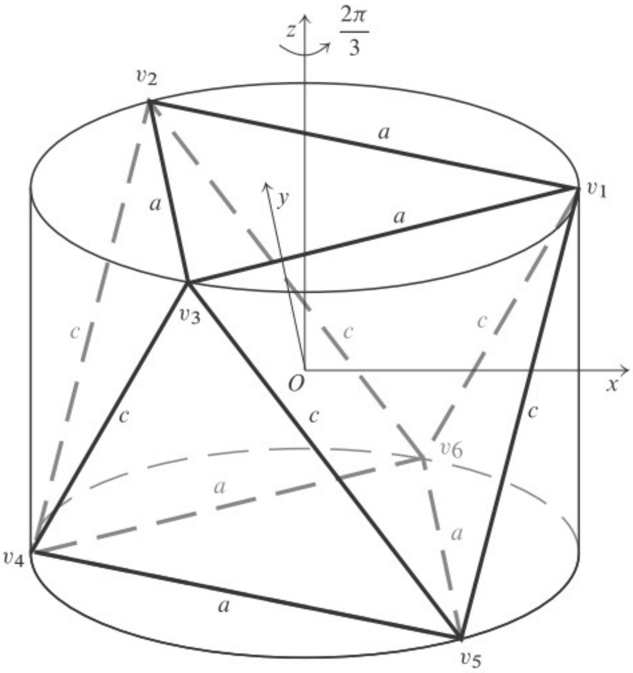

Figure 12. An octahedron $\mathcal{O} = \mathcal{O}(a, c)$ with $\bar{3}$-symmetry

Theorem 2.18 (Abrosimov, Kudina, and Mednykh, 2015, [5]). *Let* $a, c > 0$ *be some numbers. Then the following statements are equivalent:*

(i) *there exists a compact hyperbolic octahedron* $\mathcal{O}(a, c)$ *with edge lengths* a, c *that admits a* $\bar{3}$*-symmetry*;

(ii) *the inequality*

$$\frac{\sinh^2\left(\frac{1}{2}a\right)}{\sinh^2\left(\frac{1}{2}c\right)} < 3$$

holds.

Theorem 2.19 (Abrosimov, Kudina, and Mednykh, 2015, [5]). *Let* $\mathcal{O} = \mathcal{O}(a, c)$ *be a compact hyperbolic octahedron with edge lengths* a, c *that admits a* $\bar{3}$*-symmetry. Then its volume* $V = V(\mathcal{O})$ *is given by the formula*

$$V = 3 \int\limits_{0}^{a} \frac{t\,F + (1 + 2\cosh(t))c\,G}{(1 + 2\cosh(t))\Delta}\, dt,$$

where

$$\begin{aligned} F &= 1 + 2\cosh(t) + 2\cosh^2(t) + \cosh^3(t) \\ &\quad - 2\cosh(c) - 2\cosh(t)\cosh(c) - \cosh^2(c) \\ &\quad - \cosh(t)\cosh^2(c) + \cosh^2(t)\cosh(c) \\ &\quad - 4\cosh^2(t)\cosh^2(c) + 3\cosh^3(c), \\ G &= \sinh(t)\sinh(c)(-1 + 2\cosh(t)), \\ \Delta &= (\cosh(2c) - \cosh(t))\sqrt{(-2\cosh(t) + 3\cosh(c))(\cosh(t) + \cosh(c))}. \end{aligned}$$

The algorithm developed in [5] for obtaining the volume formula is rather universal. It can be also applied for other hyperbolic polyhedra with non-trivial symmetry.

The idea is the following. First, the polyhedron under consideration is modeled in Euclidean space. The coordinates of the vertices in $\mathbb{E}^3$ are calculated in some parameters according to the symmetry. Then the Euclidean polyhedron is placed into the projective Caley–Klein model of hyperbolic space. This gives rise to some additional conditions on the coordinates. Vector algebra in projective space is used to express hyperbolic edge lengths and dihedral angles in terms of coordinate parameters. Then symmetry is used again to exclude non-invariant parameters depending on the choice of coordinates. As a result we obtain a direct relation between lengths and angles of the hyperbolic polyhedron. These relations allow us to establish an existence criterion for such polyhedra in $\mathbb{H}^3$. Moreover, they allow us to find the solution of the Schläfli differential equation responsible for the volume. The latter provides an exact integral formula for the volume of the hyperbolic polyhedron.

Chapter 13

Contributions to non-Euclidean geometry I[*]

Eduard Study

The author's intention is to edit a series of articles under a common title concerning algebraic and differential geometry in non-Euclidean space, a subject that he has been investigating for many years although not yet arriving at any other than sketchy publications on the topic.

In the first of the present three contributions,[1] a seemingly new property of the straight line will be discussed. The second article is independent from the first. It is entitled "the notions of left and right,"[2] but it also treats other fundamental notions of non-Euclidean geometry. It is meant to be an introduction to further articles, and therefore it is kept elementary. It may perhaps also serve as an introduction to the methods that the author used in his book *Geometrie der Dynamen* (Leipzig, 1903). The third note contains a simple application to helical surfaces in non-Euclidean space of positive curvature that are considered as geodesics in a four-dimensional manifold.

I. Straight line and point as extrema

It seems not to have been noticed so far that the theorem of the straight line as the shortest path between two points has two analoga in hyperbolic geometry, where the *point* remarkably does not appear as the shortest but as the *longest path between two lines*.

If we extend the point continuum of *Lobatchevsky's* geometry to projective geometry by adding the infinitely far, or so-called ideal points in the well-known way, then one can also state this claim that obviously needs to be made more precise, in correlative form: *the straight line or rather a piece of the straight line appears as the longest path between two points.*

---

[*] "Beitrage zur Nicht-Euklidischen Geometrie. I.", *Amer. J. Math.* 29 (1907), no. 2, 101–116. Translated by Annette A'Campo-Neuen.

[1] [Editor's note] In the present volume, only the first contribution is translated, whose subtitle is *Gerade und Punkt als Extreme*, translated, as below, by *Straight line and point as extrema*.

[2] We plan to show elsewhere that a part of the concept of the notions of left and right does not need the notion of measurement but that it can be considered in the real projective geometry of space.

We first consider the plane geometry of constant curvature -1, associated to the absolute polar system

$$(xy) = x_1y_1 - x_2y_2 - x_3y_3 = 0. \tag{1}$$

Then we can uniquely define the distance (that is here always considered as *positive* ≥ 0) between two points in the interior $\{(xx) > 0, (yy) > 0\}$ of the absolute cone[3] by the formula

$$(x, y) = \operatorname{arccosh} \sqrt{\frac{(xy)^2}{(xx)(yy)}}, \tag{2}$$

where we choose the positive value for the square root and the function arccosh. The same formula provides a real "distance" for the points x, y, even in the case when they lie outside of the absolute cone such that the straight line joining them meets the absolute cone. Moreover, also in this case for three points y, x, z on a straight line, where the one in the middle x, separates the other two, the following equation holds:

$$(y, z) = (y, x) + (x, z). \tag{3}$$

Now consider a triangle x, y, z of distinct points in the exterior such that each of the lines joining two of the points meets the absolute cone. Hence

$$\begin{aligned} (yz)^2 - (yy)(zz) \geq 0, \quad (xx) < 0,\\ (zx)^2 - (zz)(xx) \geq 0, \quad (yy) < 0,\\ (xy)^2 - (xx)(yy) \geq 0, \quad (zz) < 0. \end{aligned} \tag{4}$$

Then one can distinguish two families of such triangles. If

$$(yz)(zx)(xy) < 0, \tag{5a}$$

then the longest side of the triangle x, y, z is always greater than the sum of the other two, or at least equal to their sum. And equality holds if and only if the three points are collinear.

If however

$$(yz)(zx)(xy) > 0, \tag{5b}$$

then the longest side may be greater or smaller than the sum of the other two, or it may be equal to their sum. But in this case the three points are never collinear.

---

[3] [Translator's note] The author uses the term "absoluter Kegelschnitt," i.e. absolute conic section, for the zero set of the bilinear form. Indeed the lines through zero on the cone form a conic section in the projective plane.

Let us now assume that

$$(y,z) \geq (y,x), \quad (y,z) \geq (x,z), \tag{6}$$

and ask under what assumptions we can conclude that

$$(y,z) \geq (y,x) + (x,z). \tag{7a}$$

Obviously, we can rewrite inequality (7a) in this form:

$$\cosh((y,z) - (y,x)) \geq \cosh(x,z).$$

After solving by using the addition theorem for the hyperbolic cosine on the left-hand side, the inequality takes the following form, assuming positive values wherever a square root is taken:

$$\sqrt{(yz)^2}\,\sqrt{(xy)^2} + (yy)\sqrt{(xz)^2} \geq \sqrt{(yz)^2 - (yy)(zz)}\,\sqrt{(xy)^2 - (xx)(yy)}.$$

Here, by the assumptions (4) and (6), both sides are positive. Hence the inequality is equivalent to the one that we obtain by taking squares:

$$(xx)(yy)(zz) - 2\sqrt{(yz)^2\,(zx)^2\,(xy)^2} - (xx)(yz)^2 - (yy)(zx)^2 - (zz)(xy)^2 \geq 0.$$

On the other hand,

$$(xx)(yy)(zz) + 2(yz)(zx)(xy) - (xx)(yz)^2 - (yy)(zx)^2 - (zz)(xy)^2 \geq 0,$$

since the left-hand side is equal to the square of the determinant (xyz). Therefore, if the inequality (5a) holds, then the last two inequalities coincide and (7a) holds. They are both equalities if $(xyz) = 0$. However, we cannot conclude that conversely (7a) implies (5a).

Now let us assume that (5b) holds. Then we claim that any of these relations are possible

$$(y,z) \gtreqless (y,x) + (x,z), \tag{7b}$$

or as above (assuming (6) *analogously*) the following may occur

$$(xyz)^2 - 4(yz)(zx)(xy) \gtreqless 0.$$

In fact, one can verify this easily by examples or by the argument given below. In this case (xyz) never vanishes because then in (7b) we would have equality. Therefore the product $(yz)(zx)(xy)$ would also vanish. But this is impossible by (4).

In order to obtain a clear idea of the corresponding triangular figures we want to assume that the points y, z are given. It is easy to see that then the set of all points x satisfying the inequalities (5a) or (5b) is represented by the shaded regions in Figure 1.

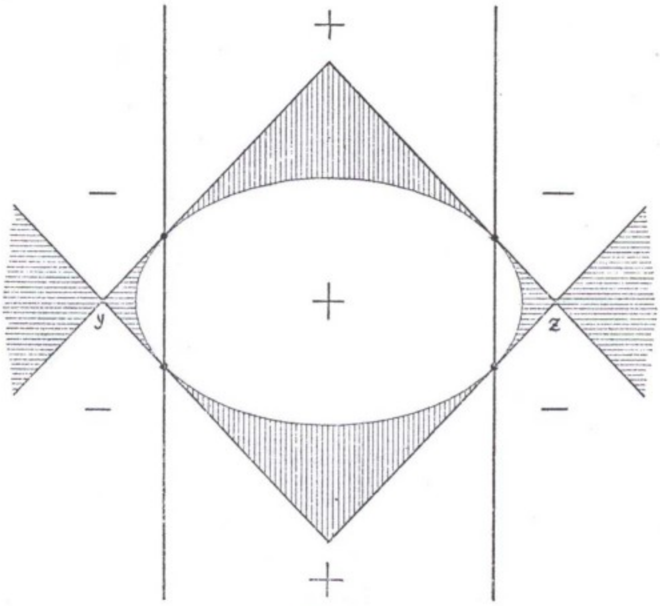

FIG. 1.

Vertical shading indicates that

$$(yz)(zx)(xy) > 0,$$

and horizontal shading indicates that

$$(yz)(zx)(xy) < 0.$$

Moreover, Figure 2 indicates with vertical and horizontal shading where

$$(y,z) - (y,x) - (x,z) \geq 0, \quad \text{or} \quad (y,z) - (y,x) - (x,z) \leq 0.$$

The figure also shows with fat lines the locus of all points x where

$$(y,z) - (y,x) - (x,z) = 0.$$

This locus consists of three completely separate curves. One of these curves is linear whereas the other two are parts of the curve of order 2

$$(yzx)^2 - 4(yz)(yx)(zx) = 0. \tag{8}$$

Firstly, this curve touches the polar lines of the points y, z, that is the lines $(yx) = 0$ and $(zx) = 0$, at their intersection points with $(yzx) = 0$. Now if we write down its equation in line coordinates using the notation

$$(ux) = x_1u_1 + u_2x_2 + u_3x_3, \quad (uv) = u_1v_1 - u_2v_2 - u_3v_3,$$

then after splitting off the non-vanishing factor $4(yz)\{(yz)^2 - (yy)(zz)\}$ from the quadratic covariant of the expression (8), one finds the equation

$$(yz)(uu) - (uy)(uz) = 0. \tag{9}$$

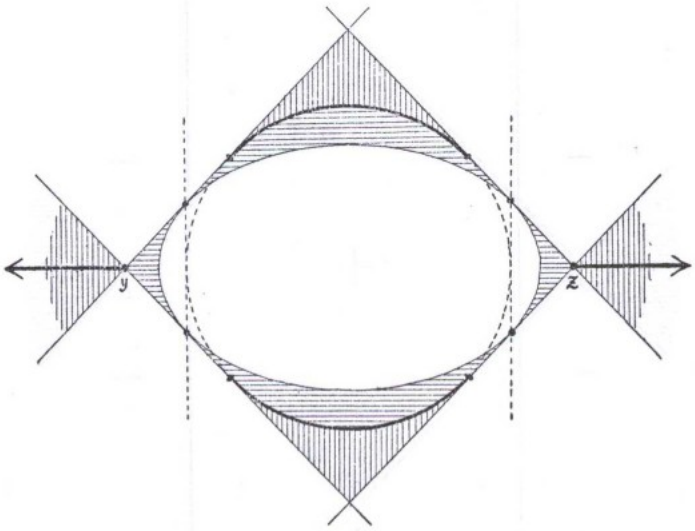

FIG. 2.

Hence one can see that the curve (8) touches the minimal lines through y, z, i.e. the tangents to the absolute cone going through y, z, of course in real points. Finally, through the two touching points of the curve (8) with the minimal lines through z there is the locus of $(y, x) = (y, z)$ which is not drawn in Figure 2, but could easily be added. The regions within the curves $(y, x) = (y, z)$ and $(z, x) = (y, z)$ belong to the inequalities $(y, z) < (y, x)$ and $(y, z) < (z, x)$, and are therefore horizontally shaded. The curve (8) however, separates the two kinds of shading wherever it lies *outside* of these regions. Now it is easy to see that the shadings are carried out correctly by letting x run through the boundary curves of the different regions.

For greater clarity, we add here a third figure—in collinear modification—showing for a given x, where the points y and z have to be if we require simultaneously

$$(yz)(zx)(xy) < 0 \quad \text{and} \quad (y, z) \geq (y, x) + (x, z). \tag{10}$$

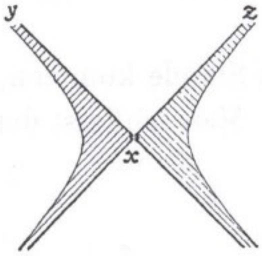

FIG. 3.

In this case, which will now be investigated further, we will say: "The point x separates the points y and z," or "The point x lies between y and z." If there is no minimal line among the lines joining the points x, y, z then the polar lines of the points x, y, z are in the relative position indicated in Figure 4a, whereas the triangles of the second family correspond to Figure 4b.

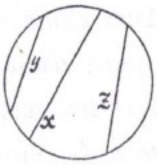

FIG. 4a.

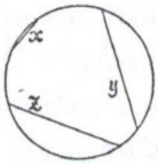

FIG. 4b.

In order to avoid lengthy arguments, for the following theorems we refer to intuition (see Figure 4a), or an obvious continuity consideration:

If the point x' lies between y and z, and the point x'' lies between (y and x' or) x' and z, then x'' also lies between y and z.

If two different points lie between y and z in such a way that the straight line joining them meets the absolute cone then all four points have a certain order y, x', x'', z or z, x'', x', y. More precisely, after suitable choice of notation, x' lies between y and x'', and x'' lies between x' and z, but not x'' between y and x', and not x' between x'' and z.

If, moreover, the point x lies between two such points x' and x'', then x also lies between y and z.[4]

---

[4] All this could be proved rigorously with purely algebraic means but as far as we can see the proof would not really be short. Unless it concerns fundamental theorems of deep theories, we may well permit ourselves to shorten the presentation if it is possible to fill the gaps easily if needed.

The two drawings in Figure 5, may sufficiently illustrate how those theorems are derived.

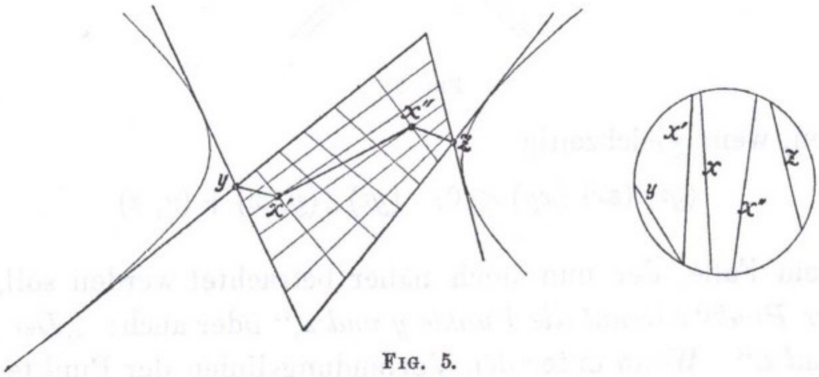

FIG. 5.

Now it is easy to conclude the following remarkable theorem:

Suppose that there is a given set of points outside of the absolute cone, forming a continuum, and such that each straight line joining any two different points of the set meets the absolute cone. Then every point of the set with at most two exceptions y_0, z_0, *has the following property: If this point* x *is removed from the set then the remaining points of the set form two again continuous subsets* (y) *and* (z) *such that* x *separates all the points* y *of the first set from all the points* z *of the second set.*

All the points of the set lying between two different points y, z *form together with* y, z *a closed, continuous curve whose points* x *can be assigned bijectively and continuously the values of a parameter* t *between* 0 *and* 1.

This curve has a well-determined length S *satisfying the inequalities*

$$0 \leq S \leq (y, z).$$

Moreover, if there are two exceptional points y_0, z_0 as mentioned above, then the entire set consists of these two points and a chain of curves joining them with a certain arc length and whose points different from y_0, z_0 all lie between y_0 and z_0. The points y, z referred to in the theorem always preserve the property of such limit points y_0, z_0 if one removes all those points of the set different from y, z that do *not* lie between y and z.

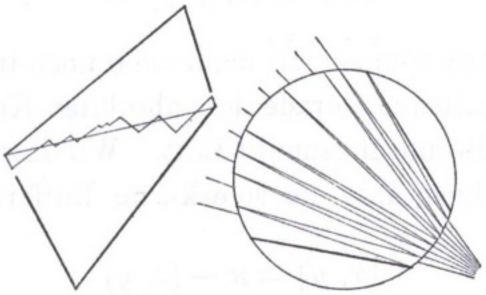

Fig. 6.

Such a chain of curves as described in the theorem will be called a *path* between y and z. Now we have the result announced in the beginning:

If y and z are two different points outside of the absolute cone, whose joining straight line meets the absolute cone, then the straight line is the longest among all paths between y and z.

Note these further useful remarks: *If the straight line joining the points y, z is a minimal line, i.e. if it touches the absolute cone, then this straight line is the unique path between y and z. In every other case, there are infinitely many paths between y and z, and arbitrarily close to any such path there are infinitely many other paths of length zero.*

Figure 6 illustrates how to construct a path that is arbitrarily close to the longest path, but itself is of length zero.

For the points of a straight line *not* intersecting the absolute cone, i.e. a line lying entirely in the ideal domain, we can define an elliptic measurement.[5] The distance of two points x, y on such a line will then only be determined up to sign and up to a multiple of a certain period, that we can assume to be π. Among the different values of this function, we choose the one with smallest absolute value, consider it as a positive value and denote it by (x, y). If moreover, we choose for all occurring roots their positive values, we obtain the equation

$$\cos(x, y) = \sqrt{\frac{(xy)^2}{(xx)(yy)}}, \tag{11}$$

and we always have

$$0 \leq \cos(x, y) \leq 1.$$

---

[5] [Translator's note] The author uses the term "Massbestimmung." It is not a metric however, since for the points in the exterior the triangle inequality does not always hold.

We can think of the same formula (11) as being true in the limiting case where the straight line containing x, y *touches* the absolute cone, but neither x nor y is the point of contact. We then set $(x, y) = 0$.

Now we want to show that the hereby defined distance (x, y) as well as its supplement

$$[x, y] = \pi - (x, y)$$

also has the property of being a *maximum* among all the lengths of certain "paths" between the two points, that still have to be defined.

Again we consider a triangle x, y, z of different ideal points but now such that the straight lines joining any two points shall *not meet or at most touch* the absolute cone:

$$\begin{aligned} (yz)^2 - (yy)(zz) &\leq 0, \quad (xx) < 0, \\ (zx)^2 - (zz)(xx) &\leq 0, \quad (yy) < 0, \\ (xy)^2 - (xx)(yy) &\leq 0, \quad (zz) < 0. \end{aligned} \tag{12}$$

Without loss of generality, we may assume that

$$\frac{\pi}{2} \geq (y, z) \geq (y, x) \geq (x, z) \geq 0. \tag{13}$$

The inequalities that we will have to assume consecutively

$$(y, z) \gtreqless (y, x) + (x, z) \tag{14}$$

may then be written in the following form:

$$\cos(x, z) - \cos(y, z)\cos(y, x) \gtreqless \sin(y, z) \cdot \sin(y, x).$$

Since here by assumption both sides are positive values, taking squares leads to equivalent inequalities

$$(xx)(yy)(zz) - 2\sqrt{(yz)^2(zx)^2(xy)^2} - (xx)(yz)^2 - (yy)(zx)^2 - (zz)(xy)^2 \gtreqless 0.$$

As before one can see that here only $>$ or equality is possible if

$$(yz)(zx)(xy) \leq 0, \tag{15}$$

whereas in the case

$$(yz)(zx)(xy) > 0 \tag{16}$$

one cannot draw a conclusion.

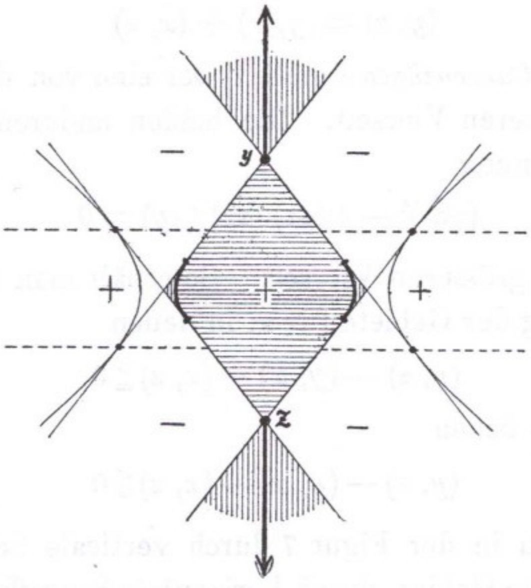

FIG. 7.

It will be sufficient if moreover we first exclude the easily treated limiting cases

$$(y, z) = \frac{\pi}{2} = [y, z] \quad \text{and} \quad (y, z) = 0, [y, z] = \pi$$

and hence assume that

$$0 < (y, z) < \frac{\pi}{2} < [y, z] < \pi.$$

Each of the two segments into which the straight line yz is decomposed by the two points y,z is now a diagonal of a simple quadrangle whose sides are pieces of minimal lines (compare Figure 7).

In the interior or on the boundary of these two quadrangles are all the points x satisfying the inequalities (12). Apart from that both quadrangles have different properties. By integrating the arc element along a straight line between y and z through the interior of one quadrangle one obtains the smaller value (y, z), and by integrating along a straight line through the other quadrangle one obtains the larger value $[y, z]$. The first “smaller" quadrangle as we call it for simplicity, is completely contained in the domain $(yz)(zx)(xy) < 0$. The other “larger" quadrangle is decomposed by the absolute polar lines of the points y, z into three parts, two outer parts where also $(yz)(zx)(xy) < 0$, and one inner part, where $(yz)(zx)(xy) > 0$. Moreover, analogously to above one finds *that the locus of all points x with*

$$(y, z) = (y, x) + (x, z) \tag{17}$$

consists of three separate curves. The first one of these is linear and lies entirely in the smaller quadrangle. The other two lie on the irreducible curve of degree 2

$$(yzx)^2 - 4(yz)(zx)(xy) = 0 \tag{18}$$

and are contained entirely in the larger quadrangle. Thus one finally obtains insight into the distribution of the regions of x where

$$(y, z) - (y, x) - (x, z) \geq 0$$

holds and the other ones with

$$(y, z) - (y, x) - (x, z) \leq 0.$$

In Figure 7, the first ones are indicated by vertical shading and the second ones or more precisely the *one* second domain is indicated by horizontal shading.

Now as above for the hyperbolic measurement, we obtain a notion of *path* between y and z lying in the smaller quadrangle, and we find the theorem that among all such paths the straight line is the longest. We further claim that in the larger quadrangle the same relations hold. That is, we claim that in the triangle x, y, z the length of the side yz is not less than the sum of the lengths of the other two sides if x is contained in the larger quadrangle and if all three lengths are defined via integration of the arc element along a straight line such that the path of integration does not leave the larger quadrangle.

One can see without difficulty that for the proof of this claim one has to distinguish three cases.

1) The point x lies in the middle part of the larger quadrangle (or on its boundary). Then $(yz)(yx)(zx) \geq 0$. The three lengths are $[y, z]$, (y, x) and (x, z). The claim is

$$[y, z] \geq (y, x) + (x, z).$$

2) and 3) The point x lies in one of the outer parts, e.g. in the part cut off by the polar line of the point y, or such that $(y, x) \geq (x, z)$. Then $(yz)(yx)(zx) \leq 0$, the three lengths are $[y, z]$, $[y, x]$, (x, z), and the claim is

$$[y, z] \geq [y, x] + (x, z) \quad \text{or} \quad (y, x) \geq (y, z) + (z, x).$$

In all these cases the proof can be carried out in the same manner as above.

Now we will state the result in a shorter form than previously and we will essentially only point out what is different from the previous theorem.

We call the used kind of measurement *pseudo-elliptic* since it coincides with a usual elliptic one in constant positive curvature $(+1)$, but differs substantially from it by the existence of paths of length zero. Using this terminology we can then say:

If y, z are two different points whose straight line joining them does not intersect the absolute cone, then there are two families of direct paths between y and z. Namely, there are two simple quadrangles bounded by minimal lines having y and z as opposite vertices. In the interior or on the boundary of each of these quadrangles there are the paths of the first or the second family respectively. Among all paths of the same family, using pseudo-elliptic measurement, the straight line appears as the longest.

Each direct path is a piece of a curve of a certain arc length whose secants either do not meet or at most touch the absolute cone. By any of its points x different from y and z, it is decomposed into two paths with the same property. If in the limiting case that we first excluded, y and z remain ideal points such that the straight line yz touches the cone then there is exactly *one* "proper" and *one* "improper" direct path between y and z. Both are linear. The first one lies entirely outside of the absolute cone; it has length zero. The length of the second path is not properly defined, but maybe set $= \pi$.

A piece of a curve can have the property that around each of its points one can draw a region where the piece of the curve is a direct path between any two of its points y', z', even though it may not have this property as a whole. For such pieces of curves, joining two given points y, z, the last theorem does not hold. On the contrary, one can obviously join two arbitrary ideal points—even those whose joining straight line intersects the absolute cone in separate points—by such curves whose length exceeds an arbitrary given number. The length of the direct path between the points y, z, if such a path exists, is hence in a much more restricted sense a maximum than the path length considered with respect to hyperbolic measurement.

Since the introduction of the so-called ideal points in Lobatchevsky's geometry is not really necessary, one might prefer a different formulation of the presented theorems avoiding that notion. Of course the translation from one language into the other can be carried out easily. For example the first result that we discussed can be rephrased as follows:

If among three straight lines y, x, z, that are pairwise either parallel or ultraparallel, the middle one separates the other two, then the length of the common normal between y and z is greater or equal to the sum of the lengths of the normals between y, x and between x, z.

Equality occurs if all three lines have a common perpendicular, or in the limiting case, if they are all parallel. If y, z are ultraparallel, the "length of the common normal between y and z" means the length of the *shortest* joining line between a point of y and a point of z, and in the limiting case of being parallel, length zero. Everything else follows immediately: The ideal point of intersection of two ultraparallel lines y, z, or its polar line, the common perpendicular of y, z, considered as the locus of the lines perpendicular to it, now appears as the *longest path* between these two lines.

Similarly, one can translate our second theorem with its corollaries. The fundamental fact in this case turns out not to be different from the well-known theorem on angles of a triangle, that can be expressed as follows:

In each ordinary triangle one of the outer angles is greater or equal to the sum of the two inner angles that occur at the side opposite to the outer angle. And equality holds if and only if the three sides go through one common point.

It is less intuitive to work with lines and their angles rather than with points and their distances. In the first case one does not have as in the second case a guiding principle in the analogous situation in Euclidean geometry. And that is the reason why up to now, one has not given this well-known result the turn on to which we focus here (if indeed the matter might be new). But if we present the straight line here as a however relative *maximum*, then this is certainly a fact that should not be missing in a complete system of non-Euclidean geometry. More generally, it may well be permitted to mention that as it seems to us, the development of non-Euclidean geometry is still very incomplete even in very elementary aspects. For example Lobatchevsky's trigonometry is certainly a very important part but always only a part: triangles with all or some ultraparallel sides, in particular the hexagons with only right angles corresponding to the first kind, have also to be considered in a system that claims some kind of completeness. The theory available at present still lacks finer perfection, the investigation of the corresponding groups, the connection to invariant theory etc., even though the tools for such investigations have long since been provided for.[6]

---

[6] The methods and formulae available in the literature are completely sufficient for those purposes. See S. W. Jacobsthal, article "Trigonometrie" in *Encyclopädie der elementaren Geometrie* (Leipzig, 1905), and E. Study, "Sphärische Trigonometrie" etc. (*Abh. d. Sächs.,* G. D. W. Leipzig, 1893), and E. Study, *Geometrie der Dynamen,* Leipzig 1903, pp. 209–212.

Now asking for an extension of the deduced results to arbitrary dimension, we find a remarkable difference among the sketched little theories.

Our first theorem on the straight line as longest path can be generalized to an arbitrary dimension, the second theorem only holds for the plane.

Namely, let the absolute polar system be given by

$$(xy) = x_1 y_1 - x_2 y_2 - \cdots - x_n y_n = 0.$$

Now first consider two points y, z outside of the absolute cone $(xx) = 0$ such that the straight line joining them meets the cone. In every plane through the line yz, we obtain the triangle figures that we have already investigated. So for hyperbolic measurement, instead of the quadrangle that we discussed above, we obtain a piece of the space of dimension $(n-1)$, bounded by pieces of two conoids emanating from y and z

$$(yx)^2 - (yy)(xx) = 0, \quad (zx)^2 - (zz)(xx) = 0.$$

Now "paths" in this piece of space have to be defined basically as before, but they do not have to lie in planes. The straight path is the longest among all such paths.

However, if the line yz does not meet the absolute cone then there are three different kinds of planar paths between y, z. Firstly, a plane through y, z might permeate the absolute cone in a real curve. For pseudo-elliptic measurement, (y, z) or $[y, z]$ appears as the maximum among all suitable piecewise linear paths. Secondly, the plane might touch the absolute cone. It is easy to see that in this case there are infinitely many equally long paths between both points. Finally, the plane may not intersect the absolute cone at all. In this case (y, z) is a minimum. *Hence the length of the straight linear path in this case is not extremal.*

But this obviously does not exclude the possibility that on a manifold of lower dimension with such a measurement, the problem of shortest (or longest) lines may get a clear content. For example in the eight-dimensional space, there is a four-dimensional manifold M_4 with the following strange property for suitably chosen pseudo-elliptic measurement:

The length of the shortest path measured on M_4 itself between two points y, z in M_4 equals the length of the straight linear path between these two points.[7]

We only want to sketch other generalizations of the matters discussed. Similar extremal properties as the ones considered here, can be found for geodesics belonging to an arc element whose square is defined by a quadratic differential form in the case that this form for line elements yields a hyperbolic measurement. Moreover, in some parts of our previous considerations, one can replace the cone by an arbitrary oval. Somewhat related to these ideas is for example the following easily proved but maybe still not completely uninteresting theorem:

---

[7] E. Study, "Kürzeste Wege im komplexen Gebiet," *Math. Ann.* 60 (1905), p. 361.

Consider a set of points in the finite part of the Euclidean plane forming a closed continuum and having the property that all secants between different points of the set have an angle φ *with a given straight line satisfying an inequality of the form*

$$|\tan(\varphi)| \leq M.$$

Then this point set is a rectifiable curve joining certain points y, z. *If* D *is the distance of the projection of the points* y, z *to the given line, then the arc length of this curve is at most equal to*

$$|D\sqrt{1+M^2}|.$$

1 Introduction

The aim of this chapter is to present the trigonometry of complex projective spaces. Section 2 is devoted to a congruence theorem for triangles in $\mathbb{C}P^2$ obtained by Brehm. We prove it here by another method which we presented in [3] and in [7]. It is shown that a triangle $([x],[y],[z])$ in $\mathbb{C}P^2$ with $\|x\| = \|y\| = \|z\| = 1$ is uniquely determined up to isometry by its side lengths $a = \arccos(|\langle y,z\rangle|)$, $b = \arccos(|\langle x,z\rangle|)$ and $c = \arccos(|\langle x,y\rangle|)$ and its *shape invariant*, the real part of the complex number

$$\langle x,y\rangle\,\langle y,z\rangle\,\langle z,x\rangle = \cos(a)\cos(b)\cos(c)e^{i\omega}.$$

Section 3 consists of Hermitian trigonometry. as it is developed in [4]. Precisely, we give the two laws of sines and the law of cosines of a triangle in $\mathbb{C}P^2$. In Section 4, we define the polar triangle associated to a given triangle and derive from it the second law of sines which does not appear in [2]. On the other hand, if we consider a triangle $([x],[y],[z])$ and its polar triangle $([X],[Y],[Z])$, and if we set

$$\langle X,Y\rangle\,\langle Y,Z\rangle\,\langle Z,X\rangle = \cos(p)\cos(q)\cos(r)e^{i\Omega},$$

we show that ω and Ω are linked. Indeed, consider the complex number

$$\langle u_2,u_1\rangle\,\langle v_1,v_2\rangle\,\langle w_1,w_2\rangle = |\langle u_2,u_1\rangle\,\langle v_1,v_2\rangle\,\langle w_1,w_2\rangle|\,e^{i\alpha},$$

where $u_1, u_2; v_1, v_2; w_1, w_2$ are pairs of unit tangent vectors at the vertex $[x]$, $[y]$, $[z]$ respectively. It is displayed that

$$\Omega = -\alpha - 2\omega + (2k+1)\pi, \quad k \in \mathbb{Z}.$$

This result is new in comparison with the results in the papers quoted. In addition, we relate Brehm's invariants to those of Hsiang [10] and those of Shirokov and Rozenfeld [14]. We close this paper by some remarks on trigonometry in general symmetric spaces.

2 Congruence theorem for triangles in $\mathbb{C}P^2$

In classical geometry, Euclidean, spherical, and hyperbolic spaces are commonly characterized by the same set of congruence axioms for geodesic intervals and triangles. In the language of Riemannian geometry, these axioms are stated as follows ([10]):

1. two geodesic intervals AB and $A'B'$ are congruent if they have the same length;
2. two geodesic triangles are congruent if they have two equal angles contained by a pair of equal sides.

Let ABC be a geodesic triangle in a symmetric space M of rank 1 and $\Delta(M)$ the moduli space of congruence classes of triangles in M. In the well-known classical spaces, a triangle has six basic invariants (side lengths and angles) which map $\Delta(M)$ into $\mathbb{R}^6$. The image set is of dimension 3 since the 6 invariants satisfy three basic functional relations, the laws of sines (which involve 2 equalities) and cosines (one equality). Riemannian symmetric spaces of rank 1 are precisely the two-point homogeneous spaces [18].

In 1994, in his Ph.D. thesis [7], the author gave new congruence criteria for finite subsets in both complex projective and complex hyperbolic spaces. The case of triangles is then easily derived. Using this point of view, he derived an easy congruence theorem for triangles. This leads directly to the laws of trigonometry in $\mathbb{C}P^2$ obtained by Brehm, from which one can easily derive those of the sphere.

We consider points in $\mathbb{C}P^n$, $n \geq 2$ as one-dimensional subspaces of the vector space $\mathbb{C}^{n+1}$. For $x \in \mathbb{C}^{n+1}$, $x \neq 0$, let $[x] := \mathbb{C} \cdot x$ denote the corresponding point in $\mathbb{C}P^n$. Let $\langle x, y\rangle = \sum_{i=1}^{n+1} \overline{x_i} y_i$ be the usual Hermitian product and let d be the Fubini–Study metric on $\mathbb{C}P^n$ defined by

$$d([x],[y]) = \arccos\Big(\frac{|\langle x, y\rangle|}{\|x\|\,\|y\|}\Big).$$

It is well known that $\Phi\colon \mathbb{C}P^n \to \mathbb{C}P^n$ is an isometry of $\mathbb{C}P^n$ if and only if there exists a unitary matrix U such that either $\Phi([x]) = [Ux]$ for all $x \in \mathbb{C}^{n+1}$ or $\Phi([x]) = [\overline{Ux}]$ for all $x \in \mathbb{C}^{n+1}$.

Let $[x]$, $[y]$, $[z] \in \mathbb{C}P^n$ with $\|x\| = \|y\| = \|z\| = 1$.

Definition 2.1. A *triangle* is a triple $([x], [y], [z])$ of three different points in $\mathbb{C}P^n$ such that the distance between any two of them is strictly smaller than $\frac{\pi}{2}$.

We imagine the vertices $[x]$, $[y]$, $[z]$ of a triangle being connected by the unique shortest paths between them, called sides. We set

$$a = \arccos(|\langle y, z\rangle|), \quad b = \arccos(|\langle x, z\rangle|), \quad c = \arccos(|\langle x, y\rangle|).$$

Consider the Hermitian matrix

$$H = \begin{pmatrix} 1 & \langle x, y\rangle & \langle x, z\rangle \\ \langle y, x\rangle & 1 & \langle y, z\rangle \\ \langle z, x\rangle & \langle z, y\rangle & 1 \end{pmatrix},$$

which is positive semidefinite with 1's on the diagonal. This matrix can be brought, by multiplication of columns by unimodular complex numbers and the corresponding rows by the conjugate of those complex numbers into the following form

$$\begin{pmatrix} 1 & \cos(c) & \cos(b) \\ \cos(c) & 1 & \cos(a)e^{i\omega} \\ \cos(b) & \cos(a)e^{-i\omega} & 1 \end{pmatrix}. \tag{1}$$

The complex number $e^{i\omega}$ is called the *direct shape invariant* in [3]. It was considered by Blaschke and Terheggen. Terheggen interpreted it in spherical geometry [15]. The real number $\cos\omega$ is called by Brehm the *shape invariant.* It was shown by Brehm [4] that a triangle in $\mathbb{C}P^n$ is determined, up to isometry, by its side lengths and its shape invariant. Brehm used the invariant $\sigma = \cos(a)\cos(b)\cos(c)\cos(\omega)$. The author showed in his Ph.D. thesis that two triangles in $\mathbb{C}P^n$ are directly congruent (if we do not allow conjugation) if and only if they have equivalent associated matrices. We already saw that the form (1) is determined up to equivalence by the real numbers a, b, c, and $\cos(\omega)$ (conjugation is allowed). Now let H be any Hermitian positive semidefinite 3-matrix with 1's on the diagonal. Clearly it can be decomposed as the product T^*T where T is an upper triangular matrix $(n+1, 3)$, $n \geq 2$ with diagonal positive real numbers and T^* is the transpose of its conjugate. The columns of T are the representing vectors of the desired triangle.

More general results on finite subsets in complex projective spaces can be found in [3].

A straightforward calculation gives the following vectors which are the columns of the upper triangular matrix T,

$$\begin{aligned} x &= (1, 0, 0, \dots, 0), \\ y &= (\cos(c), \sin(c), 0, \dots, 0), \\ z &= (\cos(b), z_2 + z_2' i, z_3, 0, \dots, 0), \end{aligned}$$

where

$$z_2 = \frac{\cos(a)\cos(\omega) - \cos(c)\cos(b)}{\sin(c)}, \tag{2}$$

$$z_2' = \frac{\cos(a)\sin(\omega)}{\sin(c)}, \tag{3}$$

$$z_3 = \frac{(1 - \cos^2(a) - \cos^2(b) - \cos^2(c) + 2\cos(a)\cos(b)\cos(c)\cos(\omega))^{1/2}}{\sin(c)}. \tag{4}$$

The triple $([x], [y], [z])$ is called in [4] the normal form of the congruence class of the triangle. We have then proved the following theorem due to Brehm. The proof presented here is slightly different from Brehm's one and was obtained in the author's Ph.D. thesis [7] and published in [3].

Theorem 2.2. 1. *A triangle in* $\mathbb{C}P^n$ *is determined uniquely up to isometry by its side lengths and its shape invariant.*

2. *Let* $0 < a, b, c < \frac{\pi}{2}$ *and* $\sigma \in \mathbb{R}$. *Then there exists a triangle in* $\mathbb{C}P^n$ *with side lengths* a, b, c *and shape invariant* σ *if and only if*

$$\frac{1}{2}(\cos^2(a) + \cos^2(b) + \cos^2(c) - 1) \leq \sigma \leq |\sigma| \leq \cos(a)\cos(b)\cos(c).$$

3 Complex projective trigonometry

Let $x \in \mathbb{C}^{n+1}$, $\|x\| = 1$. The tangent space of $\mathbb{C}P^n$ at $[x]$ can be canonically identified with $(\mathbb{C} \cdot x)^{\perp}$ in $\mathbb{C}^{n+1}$. The real part $\Re(\langle , \rangle)$ of the Hermitian product is the Riemannian metric of $\mathbb{C}P^n$. We represent as in [4] the tangent unit vector $u(x, [y])$ at $[x]$ of the shortest geodesic from $[x]$ to $[y]$ as

$$u(x, [y]) := \frac{y\,\langle y, x\rangle - x\,|\langle y, x\rangle|^2}{\|y\,\langle y, x\rangle - x\,|\langle y, x\rangle|^2\,\|}.$$

Consider the normal form given above and let us set $u_1 = u(x, [y])$ and $u_2 = u(x, [z])$. By a straightforward calculation one has

$$u_1 = (0, 1, 0, \dots, 0), \quad u_2 = (0, z_2 + z_2' i, z_3, 0, \dots, 0) \sin^{-1}(b).$$

The angular invariants of [4] are defined by

$$\begin{aligned}\Lambda(A) &:= \arccos(\Re(\langle u_1, u_2 \rangle)),\\ \Phi(A) &:= \arccos(|\langle u_1, u_2 \rangle|),\\ \Psi(A) &:= \arcsin(|\Im(\langle u_1, u_2 \rangle)|),\end{aligned}$$

where A, B, C correspond to the corners $[x]$, $[y]$, $[z]$ respectively. Geometrically, $\Lambda(A)$ is the angle between the geodesics, $\Phi(A)$ is the angle between the projective lines generated by u_1 and u_2 and $\Psi(A)$ is the smallest angle between the geodesic from $[x]$ to $[z]$ and a totally geodesic $\mathbb{R}P^2$ containing $[x]$ and $[y]$. However, the three angles are dependent, they satisfy $\sin^2 \Lambda(A) = \sin^2(\Phi(A)) + \sin^2(\Psi(A))$. Clearly the pair of angular invariants of one corner together with the lengths of its adjacent sides constitute a minimal set of congruence conditions. Thus, we have $\dim \Delta(\mathbb{C}P^n) = 4$. Therefore there exist five basic functional relations among the nine invariants of a triangle.

A short computation yields

$$\cos(\Lambda(A)) = \frac{z_2}{\sin(b)}, \tag{5}$$

$$\sin(\Psi(A)) = \frac{z_2'}{\sin(b)}, \tag{6}$$

$$\sin \Phi(A) = \frac{z_3}{\sin(b)}, \tag{7}$$

Theorem 3.1. *For any triangle ABC in $\mathbb{C}P^n$,*

$$\frac{\sin(\Phi(A))}{\sin(a)} = \frac{\sin(\Phi(B))}{\sin(b)} = \frac{\sin(\Phi(C))}{\sin(c)}, \tag{8}$$

$$\frac{\sin(\Psi(A))}{\sin(2a)} = \frac{\sin(\Psi(B))}{\sin(2b)} = \frac{\sin(\Psi(C))}{\sin(2c)}, \tag{9}$$

$$\begin{aligned}&\cos^2(a) - (\cos(b)\cos(c) + \sin(b)\sin(c)\cos(\Lambda(A)))^2\\ &\quad = \sin^2(\Psi(A))\sin^2(b)\sin^2(c).\end{aligned} \tag{10}$$

Proof. Equation (8) is obtained using (4) and (7). Equation (9) is obtained from (3) and (6). Now for the law of cosines we have from (2) and (5),

$$\begin{aligned}&\cos(a)\cos(b)\cos(c)\cos(\omega)\\&\quad=\cos(b)\cos(c)\sin(b)\sin(c)\cos(\Lambda(A))+\cos^2(b)\cos^2(c),\end{aligned}\tag{11}$$

and from (4) and (7),

$$\begin{aligned}&2\cos(a)\cos(b)\cos(c)\cos(\omega)\\&\quad=\sin^2(\Phi(A))\sin^2(c)\sin^2(b)-1+\cos^2(a)+\cos^2(b)+\cos^2(c).\end{aligned}\tag{12}$$

Combining (11), (12), and the relation between Λ, Φ and Ψ we arrive easily to the law of cosines (10). □

The law of cosines (10) does not appear in this form in Hsiang's and Brehm's articles. From (10) we find again the well-known law of cosines in elliptic and spherical spaces.

Brehm's law of cosines reads as follows:

$$\begin{aligned}&\cos(2b)\cos(2c)-\cos(2a)+\cos(\Lambda(A))\sin(2b)\sin(2c)\\&\quad=2\sin^2(\Phi(A))\sin^2(b)\sin^2(c).\end{aligned}\tag{13}$$

Remark 3.2. 1. If $\Phi(A)=0$ then (13) is exactly the classical cosine law for spherical triangles, noting that $\mathbb{C}P^1$ is isometric to the sphere of radius $\frac{1}{2}$.

2. If $\Psi(A)=0$ then (10) is exactly the classical cosine law for elliptic and thus spherical triangles.

3. The congruence theorem for geodesic triangles was stated for the first time by Blaschke and Terheggen [2]. They showed that the congruence class of a geodesic triangle in a complex projective plane is determined by its side lengths and a fourth invariant $\cos\phi$, satisfiying

$$\cos(\Phi(A))\sin(\phi)=\sin(\Psi(A)).$$

Later, Terheggen interpreted in [15] the invariant ϕ as an angle in spherical geometry. In addition, he showed that all spherical trigonometry in the sense of Study [16] is contained in the geometry of the complex projective line. Although Blaschke and Terheggen were unaware that we need five relations, they obtained three. By means of the notion of polar triangle in a complex projective plane, they obtained a sine and a cosine law. However, it is seen below that the second sine law can be easily derived from their investigation. Their sine law leads easily to the well-know spherical sine law obtained by Coolidge [5]. Another approach was put forward by Shirokov, in a paper published posthumously by Rozenfeld [14]. Shirokov took two angular invariants at each vertex: the Riemannian angle $\Lambda(A)$ between the two sides and the holomorphy inclination $\gamma(A)$. It is seen that

$$\sin(\Lambda(A))\cos(\gamma(A)) = \sin(\Psi(A)).$$

4 Blaschke and Terheggen laws

In $\mathbb{C}^3$, for any vectors x and y, Blaschke and Terheggen defined the product $x \times y$ which is a vector in $\mathbb{C}^3$ with coordinates

$$x_s y_t - x_t y_s, \quad (s,t) \in \{(1,2),(2,0),(0,1)\}$$

and which satisfies

1. $\langle x \times y, \bar{x}\rangle = 0$, $\langle x \times y, \bar{y}\rangle = 0$,
2. $\langle x \times y, u \times v\rangle = \langle x, u\rangle \langle y, v\rangle - \langle x, v\rangle \langle y, u\rangle$,
3. $(x \times y) \times (u \times v) = (xuv)y - (yuv)x$.

Item 2 is Bianchi's identity and (xuv) is the determinant of the three vectors. Now let $([x],[y],[z])$ be a triangle in $\mathbb{C}P^2$ with $\|x\| = \|y\| = \|z\| = 1$, $a = \arccos(|\langle y, z\rangle|)$, $b = \arccos(|\langle x, z\rangle|)$, and $c = \arccos(|\langle x, y\rangle|)$.

Definition 4.1. The triple $([X],[Y],[Z])$ with

$$X = \frac{\bar{y} \times \bar{z}}{\sin(a)}, \quad Y = \frac{\bar{z} \times \bar{x}}{\sin(b)}, \quad Z = \frac{\bar{x} \times \bar{y}}{\sin(c)}$$

is called the *polar triangle* of the triangle $([x],[y],[z])$.

Now set $|\langle X, Y\rangle| = \cos r$, $|\langle Y, Z\rangle| = \cos p$ and $|\langle Z, X\rangle| = \cos q$. Let us also set $v_1 = u(y,[x])$, $v_2 = u(y,[z])$, $w_1 = u(z,[y])$ and $w_2 = u(z,[x])$. Now consider the complex numbers ω, α and Ω:

$$\langle x, y\rangle \langle y, z\rangle \langle z, x\rangle = \cos(a)\cos(b)\cos(c)e^{i\omega},$$

$$\langle u_2, u_1\rangle \langle v_1, v_2\rangle \langle w_1, w_2\rangle = |\langle u_2, u_1\rangle \langle v_1, v_2\rangle \langle w_1, w_2\rangle| e^{i\alpha},$$

$$\langle X, Y\rangle \langle Y, Z\rangle \langle Z, X\rangle = \cos(p)\cos(q)\cos(r)e^{i\Omega}.$$

The invariants ω, Ω, and α are related as follows.

Theorem 4.2. *For any triangle ABC in $\mathbb{C}P^2$,*

1. $\Phi(A) = p$, $\Phi(B) = q$, $\Phi(C) = r$;
2. $\Omega = -\alpha - 2\omega + (2k+1)\pi$, $k \in \mathbb{Z}$.

Proof. A direct computation leads to the following formulae:

$$\langle u_1, u_2 \rangle = \frac{\cos(a)e^{i\omega} - \cos(b)\cos(c)}{\sin(b)\sin(c)}, \tag{14}$$

and

$$\langle Y, Z \rangle = -\frac{\cos(a)e^{-i\omega}\langle u_1, u_2 \rangle}{\langle z, y \rangle}. \tag{15}$$

By a cyclic permutation of a, b, c and x, y, z and X, Y, Z we obtain

$$\langle Z, X \rangle = -\frac{\cos(b)e^{-i\omega}\langle v_2, v_1 \rangle}{\langle x, z \rangle}, \tag{16}$$

$$\langle X, Y \rangle = -\frac{\cos(c)e^{-i\omega}\langle w_2, w_1 \rangle}{\langle y, x \rangle}. \tag{17}$$

Clearly from (15), (16), and (17) we arrive to $\cos\Phi(A) = \cos p$, $\cos\Phi(B) = \cos q$, $\cos\Phi(C) = \cos r$ and

$$\langle X, Y \rangle \langle Y, Z \rangle \langle Z, X \rangle = -e^{-2i\omega}\langle u_1, u_2 \rangle \langle v_2, v_1 \rangle \langle w_2, w_1 \rangle,$$

from which assertion 2 follows. ☐

All the trigonometric laws found by Blaschke and Terheggen, Rozenfeld, Shirokov, Hsiang and Brehm are the same. Of course, the second sine law was not found by Blashke and Terheggen although they knew that a triangle in $\mathbb{C}P^2$ depends on four invariants. The second sine law is self-contained in their investigation and it is derived as follows. With our notation the angles ϕ, χ and ψ of [2] are given by

$$\sin(\phi) = \frac{\cos(a)\sin(\omega)}{\cos(p)\sin(b)\sin(c)} = \frac{\sin(\Psi(A))}{\cos(p)}, \tag{18}$$

$$\sin(\chi) = \frac{\cos(b)\sin(\omega)}{\cos(q)\sin(c)\sin(a)} = \frac{\sin(\Psi(B))}{\cos(q)}, \tag{19}$$

$$\sin(\psi) = \frac{\cos(c)\sin(\omega)}{\cos(r)\sin(b)\sin(a)} = \frac{\sin(\Psi(C))}{\cos(r)}. \tag{20}$$

It follows from the equalitie of the left hand sides of (18), (19), and (20) that

$$\frac{\cos(p)\sin(\phi)}{\sin(2a)} = \frac{\cos(q)\sin(\chi)}{\sin(2b)} = \frac{\cos(r)\sin(\psi)}{\sin(2c)}. \tag{21}$$

Formula (21) is exactly the second sine law.

In [2] or from (14) we find the formula

$$\cos p = \left| \frac{\cos(b)\cos(c)e^{-i\omega} - \cos(a)}{\sin(b)\sin(c)} \right|.$$

By a direct computation, using $p = \Phi(A)$, (2) and (5) we arrive easily to the cosine law (10).

In [2] we find

$$\frac{\sin(p)}{\sin(a)} = \frac{\sin(q)}{\sin(b)} = \frac{\sin(r)}{\sin(c)}.$$

Clearly this is the sine law (8) since $p = \Phi(A)$, $q = \Phi(B)$ and $r = \Phi(C)$. We can then consider that all the laws were found by Blaschke and Terheggen. Item 1 of the above theorem is known in [15] in case of triangles degenerating in real projective planes. On the other hand, Terheggen showed that the work of Study on spherical trigonometry [17] is contained in the trigonometry of the complex projective line [15].
